

## **PROCEEDINGS OF THE INTERNATIONAL SOLVENT EXTRACTION CONFERENCE**

Edited by

**Kathryn C. Sole**  
Anglo American Research Laboratories

**Peter M. Cole**  
Hydrometallurgy Consultant

**John S. Preston**  
Mintek

**David J. Robinson**  
Anglo American Platinum Corporation

International conference held in Cape Town, South Africa, from 17 to 21 March 2002.  
Organised by the ISEC 2002 South African Organising Committee, and supported by  
the South African Chemical Institute, the South African Institution of Chemical Engineers,  
and the South African Institute of Mining and Metallurgy.

## TABLE OF CONTENTS

Foreword	xix
Preface	xxi
Acknowledgements	xxiii

### VOLUME 1

#### **Plenary Addresses**

Solvent extraction as an enabling technology in the nickel industry <i>Bacon G, Mihaylov I</i>	1
Developments in platinum group metals refining and the utilisation of solvent extraction technology <i>Charlesworth P</i>	14
Tailored solvents and colloids for green processing of chemicals and biochemicals <i>Hatton TA</i>	15
Achieving high performance low cost processes for the manufacture of organic chemicals using phase transfer catalysis <i>Halpern M</i>	24
Supercritical fluids: Clean solvents for extraction, reaction and crystallisation <i>O'Neil AS, Hamley PA, Poliakoff M</i>	34
Room temperature ionic liquids as alternatives to traditional organic solvents in solvent extraction <i>Visser AE, Holbrey JD, Rogers RD</i>	474

#### **Fundamentals: Coalescence and Interfacial Phenomena** 44

Electric fields in solvent extraction <i>Bart H-J</i>	45
Behaviour of interfacial tension at an oil-water interface in the presence of an applied electric field <i>Kuipa PK, Hughes MA</i>	53
Interfacial orientation of porphyrin at the liquid-liquid interface using UV-vis external reflection spectroscopy <i>Ogawa N, Moriya Y, Nakata S</i>	58
Mass spectrometry and laser microspectrometry for the study of interfacial reaction in solvent extraction systems <i>Watari H</i>	64
The drainage and rupture of the film between colliding drops in the presence of surfactant <i>Yeo LY, Matar OK, Perez de Ortiz ES, Hewitt GF</i>	70
Estimation of coalescence parameters for population balance models <i>Simon M, Bart H-J</i>	77
Flotation-assisted electrostatic coalescence <i>Bailes PJ, Edalat A</i>	83
Drop coalescence behaviour for extraction systems containing industrial extractants <i>Ban T, Kawaizumi F, Nii S, Takahashi K</i>	89
Non-invasive experimental study and modelling of toluene-in-water turbulently agitated liquid-liquid dispersions <i>Ribeiro MM, Baptista M, Texeira P, Soeiro JM, Ribeiro LM, Guimarães MML, Cruz-Pinto JJC</i>	95
AC fields in solvent extraction – influence on droplet formation and mass transfer <i>Gneist G, Bart H-J</i>	101

<b>Fundamentals: Advances in Solvent Extraction Theory</b>	<b>107</b>
Application of preferential solvation concept for interpretation of the mechanisms of solvent extraction: Part I: Acid solvent extraction by amines. Part II: Metal solvent extraction by acidic extractants <i>Kislik V</i>	108
Microemulsions and third phase formation <i>Osseo-Asare K</i>	118
Prediction of diffusivities in liquid associating systems <i>Bosse D, Bart H-J</i>	125
Study of the interaction of tributylphosphate, non-ionic surfactant and water by Fourier Transform infrared spectroscopy <i>Chang Z-D, Wei X-F, Wang J, Liu H-Z, Chen J-Y</i>	131
Analysis of amine-based extraction systems containing more than one organic phase: invariance and implications for extraction efficiency and selectivity <i>Eyal AM, Hazan B, Canari R, Vitner A, Reuveny T</i>	137
Computational time saving in the Monte Carlo simulation of liquid-liquid dispersions <i>El-Hassan Z, Perez de Ortiz ES</i>	143
An expression of equilibrium constants in synergistic extraction <i>Hasegawa Y, Matsubayashi I, Inagaki A</i>	149
Some fundamental aspects of the cloud point phenomenon and application to the extraction of phenol from aqueous streams <i>Materna K, Cote G, Szymanowski J</i>	155
Equilibria based on $g^E$ -models in a Co / Ni / phosphinic acid system <i>Manski R, Bart H-J, Görge A, Traving M, Strube J, Bäcker W</i>	161
Estimation of activities in the extraction of iron(III) with tri-n-butylphosphate and of cobalt(II) with Aliquat 336 from magnesium chloride media <i>Azimi A, Rice NM</i>	167
Aqueous two-phase equilibrium data for polyethylene glycol, potassium phosphate and bromelain <i>Moreira AS, Silva DN, Chiavone-Filho O</i>	174
Selectivity of metal extraction at the micellar mechanism <i>Sinegribova OA, Muravirova OV</i>	180
Micellar mechanism peculiarities of metal extraction by organophosphorus extractants in the presence of surfactants <i>Sinegribova OA, Muravirova OV</i>	186
Structure-reactivity studies of solvent extractants in metal extraction <i>Yuan C, Li S</i>	192
Colloid structures formed in extraction systems with organophosphorus extractants <i>Yurtov EV, Murashova NM</i>	197
A structure parameter characterising steric effect of organophosphorus acid extractants <i>Zhu T</i>	203
<b>Fundamentals: Kinetics and Mass Transfer</b>	<b>208</b>
Mass transfer coefficients of single liquid drops in extraction columns <i>Hashem MA, Saien J</i>	209
The development of mathematical correlations for mass transfer of film contacting of two aqueous phases <i>Jahim J, Slater MJ</i>	215

The effect of ionic surfactants on the mass transfer at the liquid-liquid interface for a toluene/water/ acetone system <i>Mendes-Tatsis MA, Pursell M, Tang S, San Miguel G</i>	221
Numerical approach to the motion and external mass transfer of a drop swarm by the cell model <i>Mao Z-S, Chen JY</i>	227
Mass transfer and microdrops at interfaces investigated on molecular level <i>Merzliak T, Schmäh M, Schott R, Pfennig A</i>	233
Study of salt effects on the kinetics of solute transfer and extraction at a free liquid-liquid interface <i>Simonin J-P, Hendrawan H</i>	238
Computer simulation of the mass transfer process between a single drop and an unbounded continuous phase <i>Uribe AR, Santamaría MP, Korchinsky WJ</i>	245
Influencing the rate of mass transfer in reactive extraction using high voltage <i>Wildberger A, Bart H-J</i>	251
A study on multi-component mass transfer coefficients of drop swarm <i>Wei H, Fei W</i>	257
Kinetic study of nickel(II) extraction from chloride solutions <i>Buch A, Pareau D, Stambouli M, Durand G</i>	262
Kinetics of rare earth extraction with sec-octylphenoxy acetic acid <i>Yue ST, Liao WP, Li DQ, Su Q</i>	268
Kinetics and mechanism of metal extraction onto a microcapsule containing organo-phosphorus extractant <i>Kamio E, Matsumoto M, Kondo K</i>	274
<b>Extractants</b>	<b>279</b>
New types of extractant to transport metal sulphates in base metal recovery processes <i>Gunn DM, Miller HA, Swart RM, Seward GW, Tasker PA, West LC, White DJ</i>	280
Physico-chemical properties of Cyanex® 301 <i>Cote G, Martin J-V, Bauer D, Mottot Y</i>	291
Towards recognition of the anion in the extraction of alkali metal salts by crown ethers and calixarenes <i>Moyer BA, Bonnesen PV, Delmau LH, Havelock TJ, Kavallieratos K, Levitskaia TG</i>	299
Extraction of gold from hydrochloric acid solutions by calixarenes <i>Belhamel K, Dzung NTK, Benamor M, Ludwig R</i>	307
Separation and concentration of Pd(II) with immobilised maleonitrile-dithiocrown ethers <i>Mickler W, Bukowsky H, Holdt H-J</i>	313
Separation of palladium from platinum <i>du Preez JGH, Hosten EC, Knoetze SE</i>	319
On the liquid-liquid extraction of Pt(IV/II) from hydrochloric acid by N-acyl(aryloyl)-N',N'dialkyl-thioureas: A multinuclear ( <sup>1</sup> H, <sup>13</sup> C, <sup>195</sup> Pt) NMR speciation study of the extracted complexes <i>Koch KR, Westra A</i>	327
Extraction of silver from concentrated chloride solutions: use of tri-n-butyl- and tri-n-octyl-phosphine sulphides <i>Capela RS, Paiva AP</i>	335
Extraction of base metals with binary extractants <i>Belova VV, Voshkin AA, Kholkin AI, Fleitlikh I Yu, Pashkov GL</i>	341

Diazopyrazolones as solvent extractants for copper from ammonia leach solutions <i>Campbell J, Cupertino D, Emeleus LC, Harris SG, Owens S, Parsons S, Swart RM, Tasker PA, Tinkler OS, White DJ</i>	347
Synergistic solvent extraction of Cu(II), Zn(II) and Ni(II) based on supramolecular assemblies <i>Gasperov V, Gloe K, Leong AJ, Lindoy LF, Mahinay MS, Stephan H, Tasker PA, Wichmann K</i>	353
Beta-diketone copper extractants: structure and stability <i>Kordosky G, Virnig M, Mattison P</i>	360
Solvent extraction of iron(III) from hydrochloric acid solutions by dihexyl sulphoxide <i>Sato T, Ishikawa I, Sato K, Noguchi Y</i>	366
Solvent extraction of iron(II) from hydrochloric acid solutions using N,N'-dimethyl-N,N'-diphenylmalonamide <i>Costa MC, Paiva AP</i>	371
Study of Sc and Zr extraction reactions by reactive materials containing acidic organo-phosphorus extractants <i>Cortina JL, Korovin V, Shestak Y</i>	377
Solvent extraction of tetravalent titanium, zirconium and tin from hydrochloric acid solutions by an $\alpha$ -hydroxyoxime <i>Sato T, Suzuki K, Sato K, Takahashi T</i>	384
Aggregation and metal ion extraction properties of novel, silicon-substituted alkylene-diphosphonic acids <i>McAlister DA, Dietz ML, Chiarizia R, Herlinger AW</i>	390
Separation of NaOH from salts by weak hydroxyl acids <i>Havelock TJ, Bonnesen PV, Brown GM, Chambliss CK, Levitskaia TG, Moyer BA</i>	396
Extraction of selected metal cations with the alkylaryl-phosphinic acid: 2,4,4-trimethylpentyl-phenylphosphinic acid <i>Nucciarone D, Jakovljevic B, Fir B, Hillhouse J, Depalo M</i>	402
Thermodynamics of the extraction of selected metal ions by di(2-ethylhexyl)alkylene-diphosphonic acids <i>Otu EO, Chiarizia R</i>	408
Comparison of solvent extraction method and ion-exchange method for the separation among alkaline earth metal ions in the presence of cryptands as the masking reagents <i>Tsurubou S, Umetani S, Komatsu Y</i>	414
Solvent extraction of metal ions with novel 4-acyl-5-pyrazolones having crown ether moiety as intramolecular synergist <i>Umetani S, Yamazaki S, Ogura K</i>	420
A novel synergism found in the extraction of In(III) ion with TTA and TOPO in carbon tetrachloride <i>Hokura A, Noro J, Kusakabe S, Sekine T</i>	425
Solvent extraction of indium(III) and iron(III) from sulphuric acid media by mixtures of D <sub>2</sub> EHPA and Cyanex 923 <i>Wang C, Liu D, Zhang J</i>	430
Extraction of rare earth ions by sec-nonaphenoxyacetic acid <i>Wang YG, Meng SL, Li DQ, Jin MJ, Li CZ</i>	436
Chemistry of solvent extraction of scandium(III) from sulfate solutions quaternary ammonia sulfates <i>Stepanov SI, Kharchev AE, Chekmarev AM</i>	441
Extraction of uranium(VI) from phosphate media in poly(ethyleneglycol) solutions <i>Safiulina AM, Sinegribova OA, Shkinev VM</i>	447

Development of environmentally benign new solvent extraction reagents from chitosan, a natural polysaccharide <i>Inoue K, Yoshizuka K, Ohto K</i>	453
<b>Novel Developments and Applications</b>	<b>458</b>
Novel electrochemical processing using conventional organic solvents <i>O'Keefe T, O'Keefe M, Fang R, Sun J, Dahlgren E</i>	459
Advanced liquid-liquid extraction system using photochemical reduction for metals <i>Nishihama S, Hirai T, Komasawa I</i>	467
Room temperature ionic liquids as alternatives to traditional organic solvents in solvent extraction <i>Visser AE, Holbrey JD, Rogers RD</i>	474
Toward "in silico" design of new potential extractants using chemical informatics methods <i>Varnek A, Wipff G, Solov'ev V</i>	481
Electrical tomography and other measurements in liquid-liquid systems <i>Korchinsky WJ, Bolton GT</i>	487
Solvent impregnated resins: Performance and environmental applications in metal extraction <i>Warshawsky A, Cortina JL</i>	493
Study of the sorption of Zn(II) with XAD-7 resin impregnated with Ionquest 801 <i>Benamor M, Draa MT</i>	500
Evaluation of alkylguanidine based solvent impregnated resins for gold cyanide extraction <i>Kautzmann RM, Sampaio CH, Korovin V, Shestak Y, Aguilar M, Cortina JL</i>	506
Sol-gel synthesized adsorbents for noble metal separations <i>Lee JS, Tavlarides LL</i>	512
Hydrophobic gel separation agents (X). Solvent extraction separation of copper(II) and lanthanide(III) in the presence or absence of hydrophobic silica gels <i>Komatsu Y, Kokusen H, Tsurubou S</i>	518
Coalescence extraction – from molecular dynamics to chemical engineering application <i>Schaadt A, Bart H-J</i>	524
Liquid-liquid extraction in aqueous biphasic systems: Partitioning behavior of silica and hematite in the dextran/triton X-100/water system <i>Zeng X, Osseo-Asare K</i>	530
The partitioning of some dyes and the effect of KSCN in polyethylene glycol/salts aqueous two-phase systems <i>Xu Y, Lu J, Li DQ</i>	537
Application of solvent extraction to the production of multicomponent composite powders <i>Shibata S, Yamamoto H</i>	543
<b>Analytical Applications</b>	
Determination of protonation constants of 2,2':6',2"-terpyridine by liquid-liquid distribution data <i>Andersson S, Ekberg C, Liljenzin J-O, Skarnemark G</i>	549
Separation of precious metals with crown ethers as their ion-pair complexes by means of solvent extraction <i>Honjo T, Hossain KZ, Camagong CT</i>	555
The binding constants of metal fulvate and humate complexes <i>Helal AA, Mourad Gh A, Khalifa SM</i>	558

Ion-pair extraction and one-drop flame atomic absorptiometric determination of silver with benzo-monothiacrown and bromothymol blue <i>Kojima I, Katsuzaki M, Yamada M, Yamaguchi M, Sakamoto H</i>	565
Extraction and spectrophotometric determination of copper(II) with isonitroso-5-methyl-2-hexanone and 5-methyl-2,3-hexanedione dioxime <i>Tandel SP, Jadhav SB, Malve SP</i>	570
Extraction behavior of soft metal ions with polythioether derivatives containing O or N donor atoms <i>Chayama K, Adachi K, Mori T, Tsuji H</i>	576
Application of Courier 30SX analyser to nickel laterite solvent extraction <i>Hughes DV, Kongas M, Saloheimo K</i>	581
<b>Biotechnology, Pharmaceutical and Nutriceutrical Applications</b>	<b>588</b>
Opportunities for extraction technology in chiral separations <i>De Haan AB, Kuipers NJM, Steensma M</i>	589
Mass transfer performance of two-phase electrophoresis with an emulsion solution as organic phase <i>Liu JG, Luo GS, Pan S, Zhai SL, Wang JD</i>	597
Study on the three-phase extraction of penicillin G with a single step method <i>Chen J, Liu H-Z, Wang B, An ZT, Liu QF</i>	602
Extraction of drug traces with liquid membrane systems <i>Grote M, Haciosmanoglu B, Nolte J</i>	607
Selectivity in the extraction of carboxylic acids by amine-based extractants <i>Eyal AM, Hazan B, Canari R, Vitner A, Reuveny T</i>	614
Optimisation of process conditions for industrial separation of amino acid enantiomers by fractional reactive extraction <i>Steensma M, Kuipers NJM, De Haan AB, Kwant G</i>	620
Extraction of borage seed oil by compressed carbon dioxide: Effect of process parameters <i>Gaspar F, Lu T, Santos R, Al-Duri B</i>	626
Liquid-liquid equilibrium data for the corn oil / oleic acid / aqueous ethanol system <i>Gonçalves CB, Meirelles AJ</i>	632
Liquid-liquid extraction for deacidification of vegetable oils <i>Batista E, Antoniassi R, Wolf Maciel MR, Meirelles AJA</i>	638
Influence of operating factors on the rhubarb extraction process <i>Lu YC, Luo GS, Dai YY</i>	644
Extraction of lysozyme with reverse micelles using a contactor agitated by automatic suction of liquid type stirrer <i>Zhang W, Liu H, Chen J</i>	650
Extraction of lysozyme by reversed micellar solution in a sieve-tray column <i>Nishii Y, Hara C, Kinugasa T, Nii S, Takahashi K</i>	656
Modeling of solubilities of essential oils in liquid carbon dioxide present in three odoriferous plants <i>Sousa EMBD, Silva DN, Chiavone-Filho O, Meireles MAA</i>	662
Evaluation of improved solvents for caprolactam extraction <i>Van Delden ML, Kuipers NJM, de Haan AB, Lerner O</i>	668
Extraction and enrichment of physiologically active lipids and nutrients from plant materials using supercritical fluid extraction <i>Westerman D, Al-Duri B, Santos R, Bosley J</i>	674

Forward and backward extraction of BSA using mixed reversed micellar system of CTAB and 4-methyl-2-pentanone <i>Zhang W, Lui H, Chen J</i>	680
<b>Membranes</b>	<b>686</b>
Optical sensor for chromium(VI) monitoring: optimisation of chromium(VI) transport through liquid membranes <i>Castillo E, Granados M, Cortina JL</i>	687
Application of novel extractants for actinide(III) / lanthanide(III) separation in hollow fibre modules <i>Geist A, Weigl M, Müllrich U, Gompper K</i>	693
Hollow fibre membrane-based non-dispersive extraction Ag(I) from alkaline cyanide media using LIX 79 <i>Kumar Pabby A, Melgosa A, Haddad R, Sastre AM</i>	699
Selective extraction of lithium ion with novel lipophilic phthalocyanine derivatives and its permeation through supported liquid membrane <i>Kondo K, Matsumoto M, Yoshida T, Kamio E</i>	706
Extraction of cadmium from phosphoric acid with an emulsion liquid membrane: water transport and membrane rupture <i>Gallego Lizon T, Perez de Ortiz ES</i>	712
Transfer properties of cadmium(II) and zinc(II) from hydrochloric acid with HEH/EHP using microporous hollow fibre membrane <i>Luo F, Jia Q, Li DQ, Wu YL</i>	718
A kinetic study of the extraction of zinc from hydrochloric acid solutions by a surfactant liquid membrane containing trioctylamine <i>Pérocheau S, Stambouli M, Pareau D, Durand G</i>	724
Extraction and separation of nickel and cobalt by electrostatic pseudo liquid membrane <i>Heckley PS, Ibana DC, McRae C</i>	730
Membrane selection in membrane-assisted metal extraction and stripping processes <i>Soldenhoff KH, McCulloch J</i>	736
Axial dispersion characteristics in hollow fibre modules for membrane extractions <i>Yujun W, Guangsheng L, Yan W, Youyuan D</i>	742
Swelling and stability of emulsions in liquid membrane extraction <i>Koroleva M Yu, Yurtov EV</i>	748
<b>Environmental Applications</b>	<b>754</b>
Commercial-scale recovery of hexavalent chromium for recycle water by anion liquid-liquid extraction <i>Monzyk B, Conkle HN, Rose JK, Chauhan SP</i>	755
Operation of a NDSX pilot plant for recovery of Cr(VI) from ground waters <i>Ortiz I, Galán B, Castenáda D, Irabien A</i>	762
Screening of reagents for recovery of zinc(II) from hydrochloric spent pickling solutions <i>Regel-Rosocka M, Miesi I, Sastre AM, Szymanowski J</i>	768
A continuous solvent extraction process for refining of pickling baths <i>Caron L, Pareau D, Stambouli M, Durand G</i>	774

Copper recovery from spent ammoniacal etching solutions <i>Ismael MRC, Carvalho JMR</i>	781
Recovery of nickel from spent electroless nickel plating baths by solvent extraction <i>Tanaka M, Kobayashi, M, Seki T</i>	787
Recovery of cobalt and nickel from spent catalysts using Cyanex 923 <i>Gupta B, Tandon SN, Deep A</i>	793
Cyanide recovery by solvent extraction <i>Dreisinger DB, Wassink B, Ship K, King JA, Hames M, Hackl RP</i>	798
Mercury recovery from dental amalgams using solvent extraction <i>Silva de Lima LA, Pereira de Souza C, Pereira Leite JY, Curbelo Garnica AI</i>	804
Supercritical fluid extraction-oxidation technology to remediate PCB contaminated soils / sediments <i>Zhou W, Anitescu G, Tavlarides LL</i>	809
Supercritical CO <sub>2</sub> extraction of halogenated flame retardants from polymer materials using different modifiers <i>Gamse T, Marr R</i>	816
Metal ion and dye extraction from textile wastewater by microemulsions <i>Cordeiro Beltrame LT, Barros Neto EL, Dantas Neto AA, Castro Dantas TN</i>	822
Recovery of polyphenols from olive mill waste-waters by precipitation and liquid-liquid extraction <i>Carvalho JMR, Santos C, Ismael R, Ferreira L</i>	828
Methyl tert-butyl ether – a new solvent for phenol and acetic acid extraction from waste water <i>Strătulă C, Oprea F, Panaiteescu C, Petre M, Boțoc, G</i>	834
Point source recovery of hydrocarbons from wastewaters by solvent extraction <i>Halevy M, Jones P</i>	840
Catalyst recovery from the wet peroxide oxidation process by means of non-dispersive solvent extraction <i>Urtiaga AM, Muela C, Ortiz I</i>	846
<b>Hydrometallurgical Applications</b>	<b>852</b>
Copper recovery using leach / solvent extraction / electrowinning technology: Forty years of innovation, 2.2 million tonnes of copper annually <i>Kordosky GA</i>	853
Solvent extraction in the primary and secondary processing of zinc <i>Cole PM, Sole KC</i>	863
Some design and operating problems encountered in solvent extraction plants <i>Ritcey GM</i>	871
The extraction of copper, zinc, cadmium and lead from waste streams in the lead-zinc industry <i>Cox M, Flett DS, Gotfryd L</i>	879
The extraction of arsenic(V) and sulphuric acid from acidic sulphate media by tri-n-butyl phosphate in Shellsol A or T: I - An equilibrium study <i>Demirkiran A, Rice NM, Wright AR</i>	884
The extraction of arsenic(V) and sulphuric acid from acidic sulphate media by tri-n-butyl phosphate in Shellsol A or T: II – Flowsheet development <i>Demirkiran A, Rice NM</i>	890

The solvent extraction properties of di-n-hexyl sulphoxide in relation to the refining of platinum-group metals <i>Du Preez AC, Preston JS</i>	896
Recovery of Ag and Au from aqueous thiourea solutions by liquid-liquid extraction <i>Dzul Erosa MS, Navarro Mendoza R, Saucedo Medina TI, Lapidus Lavine G, Avila-Rodriguez M</i>	902
Opportunities and challenges in developing a solvent extraction process for rhodium based on the use of stannous chloride <i>Demopoulos GP, Shang Y, Benguerel E, Riddle M</i>	908
Extraction of chlorocomplexes of platinum and palladium by diamines and their salts with organic acids <i>Belova VV, Jidkova TI, Kholkin AI, Brenno Yu Yu, Jidkov LL</i>	916
Commissioning of the new Harmony Gold Refinery <i>Feather A, Bouwer W, O'Connell R, Roux J</i>	922
Behaviour of Os(IV) aquachloro and aquochlorohydroxo complexes in solvent extraction from sulphuric acid media <i>Mayboroda A, Lang H, Troshkina ID, Chekmarev AM</i>	928
Solvent extraction and hydrochemical preparation of gold powders with dithiozone derivatives <i>Sánchez-Loredo MG, Grote M</i>	934
The application of solvent extraction to the refining of gold <i>Grant RA, Drake VA</i>	940
Pilot-plant solvent extraction of cobalt and nickel for Avmin's Nkomati project <i>Feather A, Bouwer W, Swarts A, Nagel V</i>	946
Separation of cobalt and nickel by solvent extraction from sulphate liquors obtained by the acid leaching of a product from the Caron process <i>García Liranza E, Moreno Daudinot A, Viera Martínez R, Rosales Bárzaga B</i>	952
Modelling methodology for the simulation of extraction processes – cobalt/nickel <i>Leistner J, Görge A, Bäcker W, Górká A, Strube J</i>	958
Cobalt-nickel separation by solvent extraction in Cuba <i>Moreno Daudinot AM, García Liranza E</i>	964
Bateman pulsed column pilot-plant campaign to extract cobalt from the nickel electrolyte stream at Anglo Platinum's Base Metal Refinery <i>Nagel V, Gilmore M, Scott S</i>	970
Extraction equilibria of Ni(II) and Zn(II) with LIX 984 <i>Draa MT, Benamor M</i>	976
The effect of organophosphoric extractant concentration and initial phase volume ratio on cobalt(II) and nickel(II) extraction <i>Maljković D, Lenhard Z</i>	982
Options of copper(II) and zinc(II) extraction from chloride media with bifunctional extractants <i>Borowiak-Resterna A, Kyuchoukov G, Szymanowski J</i>	988
Impurity removal from copper tankhouse liquors by solvent extraction <i>Cox M, Flett DS, Velea T, Vasiliu C</i>	995
Studies of copper extraction using the system saponified coconut oil / isoamyl alcohol / kerosene / copper sulphate solution <i>De Barros Neto EL, Dantas Neto AA, Castro Dantas TN, Duarte LJN, de Araújo ACM</i>	1001
Copper hydrometallurgy process evolution: Changing operating parameters and philosophies throughout the life of Giralambone Copper Company solvent extraction circuit <i>Dudley KA, Readett DJ, Crane PA, MacKenzie JMW</i>	1007

Application of two types of commercial extractants for copper in China <i>Jiaoyong Y</i>	1014
Pilot copper solvent-extraction testing using the Bateman Pulsed Column <i>Buchalter EM, Kleinberger R, Grinbaum B, Nielson C</i>	1021
Ammonia leach - solvent extraction – electrowinning process for treatment of high alkaline gangue-containing copper ores <i>Liu D, Jiang K, Wang C, Zhang P</i>	1027
Solvent extraction of copper from high concentration pressure acid leach liquors <i>Sole KC</i>	1033
Purification of copper electrolyte with Cyanex 923 <i>Wang C, Jiang K, Liu D, Wang H</i>	1039
Extending zinc production possibilities through solvent extraction <i>Martín D, Díaz G, García MA, Sánchez F</i>	1045
Effect of TBP as a modifier for extraction of zinc and cadmium with a mixture of DEHPA and MEHPA <i>Keshavarz Alamdari E, Darvishi D, Sadrnezhaad SK, Mos'hefi Shabestari Z, O'hadizadeh A, Akbari M</i>	1052
Zinc extraction and stripping with D2EHPA: Further consideration as a test system <i>Antonelli D, Vegliò F, Mansur MB, Biscaia Jnr. EC, Slater MJ</i>	1058
The integrated recovery of rare earths from apatite raw material in the Odda process of fertilizer production by solvent extraction. A plant experience <i>Al-Shawi AW, Engdal SE, Jenssen OB, Jørgensen TR, Røsæg M</i>	1064
Extraction of lanthanides and yttrium with PC-88A from aqueous phosphate media <i>Abdeltawab AA, Nii S, Kawaizumi F, Takahashi K</i>	1070
Extractive leaching in the technology of rare metal raw materials: Problems and perspectives <i>Chizhevskaya SV, Chekmarev AM, Cox M</i>	1076
Development of a solvent extraction process for the production of pure neodymium oxide from synthetic Mt Weld process liquor <i>Cheng CY, Soldenhoff K, Vaisey M</i>	1082
Separations and recoveries of uranium, thorium and lanthanides using CYANEX 923 <i>Gupta B, Malik P, Deep A</i>	1089
Solvent extraction pilot plant results for recovery of copper and nickel from an ammoniacal leach of deep-sea manganese nodules <i>Hubred GL</i>	1095
Possible application of offshore oil and gas phase separation technology to hydro-metallurgical solvent extraction <i>Stanbridge D, Sullivan J</i>	1102
<b>Nuclear Applications</b>	<b>1109</b>
Virtues and vices of reagents for actinide partitioning in the 21 <sup>st</sup> century <i>Nash KL</i>	1110
Update on the science and technology of tributyl phosphate <i>Navratil JD</i>	1118
Compounds of hexavalent uranium and dibutyl phosphate in nitric acid <i>Powell BA, Navratil JD, Thompson C</i>	1124
Effect of U(VI) concentration on equilibrium and kinetics in flow-extraction of U(VI) in HNO <sub>3</sub> /supercritical CO <sub>2</sub> and TBP system <i>Meguro Y, Iso S, Yoshida Z</i>	1131

New insights in third phase formation in the U(VI)HNO <sub>3</sub> -TBP-alkane system <i>Jensen MP, Chiarizia R, Ferraro JR, Borkowski M, Nash KL, Thiagarajan P, Littrell KC</i>	1137
Supercritical CO <sub>2</sub> fluid leaching (SFL) of uranium from solid wastes using HNO <sub>3</sub> -TBP complex as a reactant <i>Tomioka O, Meguro Y, Iso S, Yoshida Z, Enokida Y, Yamamoto I</i>	1143
Structural studies by NMR and molecular dynamic calculations of lanthanide complexes with ethoxy malonamides in solution <i>Berthon C, Guibard P, Bousquet M, Giminez C</i>	1148
Extraction of Ln(III) and Am(III) from nitrate media by malonamides and polydentate N-bearing ligands <i>Charbonnel MC, Flandin JL, Giroux S, Presson MT, Morel JP</i>	1154
Aggregation of complexes formed in the liquid-liquid extraction of nitric acid and/or metallic cations by malonamides <i>Martinet L, Berthon L, Peineau N, Madic C, Zemb T</i>	1161
Extraction of trivalent actinides and long-lived fission products by different classes of functionalized calixarenes <i>Dozol JF, Garcia-Carrera A, Lamare V, Rouquette H</i>	1168

## FOREWORD

We all have defining moments in life. Today one is defined for most of us by the question "What were you doing when you heard about the World Trade Center?"

One of my defining moments was travelling to Gatlinburg for the first real gathering of solvent extraction experts. About half an hour before we were due to land, we suddenly fell out of the sky. A few moments and several thousand metres later we were cruising down one of those Tennessee Valleys, banking on every bend, and breathing almost normally. The Captain said "On the next turn, look up, everyone. That's the US Air Force coming past!"

We did, and the sky was black with aeroplanes. The Bay of Pigs had just broken, and everything that could fly was heading south-east. The threat of a nuclear holocaust was very real. It was with a certain amount of unease and camaraderie that we gathered, uncomfortably near to Oak Ridge, a centre for nuclear development which would almost certainly be targeted if the holocaust burst forth.

Forty years on, we gather in Cape Town. The threats to our gathering are not as immediate as they were when we first met. The Organising Committee had some nervous moments when we wondered whether the Conference might go ahead, but in the end sense prevailed, and we are gathering to review the progress of our branch of science and technology.

Any reasonable review of papers from Gatlinburg and those presented here show that we have made immense progress on many fronts. Our speciality has developed in an orderly, almost stately way. It has become a mature technology, and has yielded solutions to difficult problems which have generally been as economically sound as they have been environmentally safe.

But I remain concerned that we lack a fundamental understanding of the liquid state. If you tell me the chemical composition of a gas mixture, I can do an excellent job of predicting its properties over a wide range of temperatures and pressures. I can even predict how and under what conditions its components are likely to react, and what the outcome of the reaction is likely to be, and my predictions will be within a few percent of what can be measured. But let the components condense, and I am lost.

If you tell me the composition and crystal structure of a solid, I can also predict its properties accurately. I may need to know something about its history, and I probably cannot predict its reactivity with any accuracy, but I can tell you when it should melt to a high degree of accuracy. Once it melts, however, I am again lost.

I cannot even predict from first principles the properties of a solution of a grain of common salt in a glass of water. Even empirical models break down if I add another salt to the solution. To be sure, we are making progress on these problems, but it is slow and we seek some insights to guide us to new directions.

If a single solution is intractable, how much more so is the world of solvent extraction. Take two separate solutions, carefully chosen to be essentially immiscible. Mix them to encourage them to react, and hope they have reached equilibrium. Separate them and see the results.

The description of this process is what concerns the majority of papers at this Conference. There is more on the theory of the mixing process than there is on the theory of species in solution. The body of empirical knowledge continues to grow, and in the midst of it we see some glimmers of patterns emerging, but they are glimmers, destroyed by slight changes in experimental conditions. I am always amused by the fact that we deal with subtle equilibria, and everyone knows that equilibria are affected by temperature, yet few bother to examine temperature as a controlled variable in their solvent extraction studies.

Difficult separations have been achieved because the experimenter saw fit to raise or lower the temperature at which he or she did the extractions, yet their findings have not found widespread application in solvent extraction technology. Similarly pressure is a controllable variable which few other than the supercritical extraction people worry about. Yet one subtle separation has been achieved because the developers realised that a solvent that had been abandoned because of its low boiling point could be used successfully under modest pressure.

This Conference provides an opportunity to exchange such ideas. Sadly, the exchanges cannot be captured in the Proceedings. The papers collected here represent the findings of, largely, individual workers from small groups. The collective wisdom of the workers is what is sustained by these Conferences, and it is for this reason that it is a privilege to host them.

Many people have been responsible for making this Conference possible. The Organising Committee has worked hard and well. The Mintek Secretariat has provided an underpinning of confidence and efficiency. The International Committee and the local professional institutions have been most supportive. The many Sponsors of the Conference are an indication of the value placed on the efforts of the researchers, and the hope that still more economically attractive processes will evolve from gatherings such as ours.

We are grateful to all who have submitted the papers collected here. Many of you will be present at the Conference, and I hope that you will not only have an intellectually stimulating meeting, but also will be able to find time to enjoy the natural wonders that make Cape Town one of the more beautiful cities in the world.

Philip Lloyd  
Chair: Organising Committee

## PREFACE

The ISEC 2002 gathering in Cape Town, South Africa, marks some important milestones in the field of solvent extraction. Although it is now the second time that this meeting has been held in the southern hemisphere (following ISEC '96 held in Melbourne, Australia), ISEC comes to the mineral-rich continent of Africa for the first time. Representing a maturing technology, these proceedings bear testimony to the many advances made in the understanding and application of solvent extraction during recent times.

At this first ISEC meeting of the new century, it is appropriate to reflect on our industry's achievements, as well as taking a look into the future. Solvent extraction (SX) started life as an analytical technique, developed in an era before sophisticated spectrometric instruments were able to detect trace quantities of elements in myriad hostile matrices. The purification of radioactive isotopes during the Manhattan project was the first application of SX for small-scale production. Two decades later, SX entered the hydrometallurgical arena, with the commissioning of the first copper SX plant in Arizona. Today, SX still has a strong and critical presence in both the hydrometallurgical and nuclear industries. As a glance at the contents pages of these volumes will show however, its applications now extend to industries as diverse as biotechnology, food technology, pharmaceuticals and petrochemicals. While many of these industries have traditionally been perceived to be associated with causes of pollution, it is encouraging to note the increasing use of SX dedicated to solving or remediating environmental problems.

Although the "solvent" part of solvent extraction raises concerns in many circles today over the safety, toxicity and environmental friendliness of this technology, the alternative description, "liquid-liquid extraction", has been side-lined for many years, despite being the nomenclature recommended by the International Union of Pure and Applied Chemistry (IUPAC). However, the time may have now come when the latter terminology more accurately represents many of the new advances in our field. Interesting developments are occurring with two-phase aqueous extraction systems, ionic liquids, magnetic fluid extraction and supercritical fluid extraction, amongst others. None of these techniques make use of traditional organic solvents. It may be that the first ISEC of the 21<sup>st</sup> century may also be the last! Should we be looking forward to ILLEC in Beijing in 2005?

While globalisation in many of our industries is now a reality, the need was never greater for technical innovation, for movement down the cost curve, and for more efficient recovery and use of our natural resources. However, in South Africa, as in many other parts of the western world, we see a declining interest in technical subjects at tertiary educational institutions. It is hoped that this conference will, in some way, help revitalise educational and research efforts.

The proceedings of ISEC 2002 comprise some 200 technical papers, representing contributions from 34 countries and almost 600 authors. For the first time, the ISEC proceedings are presented in CD-ROM format. This necessitated completely electronic organisation of the conference, with all papers being submitted, refereed, revised and edited via a series of e-mail iterations. This process was not without teething problems, but we hope that the final result will be both user-friendly and useful. Progress in this regard will, no doubt, proceed in leaps and bounds in years to come.

The editors gratefully acknowledge those efforts made by the many people involved in the compilation of these proceedings and those who have contributed to the success of the conference. The authors of the papers, many of whom are not English speaking, are thanked for their contributions. The critical inputs of some 100 referees from the global solvent-extraction community has ensured that a high technical standard has prevailed. Appreciation is also extended to the plenary speakers for their insightful and stimulating presentations, and to the session chairs and members of the International Committee for their contributions. Our corporate colleagues all provided generous sponsorship, and we urge delegates, in turn, to support these companies into the future.

Finally, we thank Yvonne Clayden and Jean Martins of the Mintek Conference Secretariat for their invaluable contributions (and their limitless patience with tiresome scientists!); Trevor Burt who assisted with the publication; Pam Oberholzer, Ken Brown and Steve Oberholzer of African Conferences and Incentives (our conference travel agents); Moonshine Advertising for all our graphics design and maintaining our website; Nigel Walker of Document Transformation Technologies for production of the CD-ROM; and our long-suffering publisher, Chris van Rensburg. The editors also extend personal thanks to our employers for their indulgence and support of the many hundreds of hours involved in the preparation of these proceedings, while we were getting paid to do "real" jobs!

It is our hope that you will enjoy both the technical and social aspects of the conference, and will find the ISEC 2002 proceedings a stimulating and valuable reference source for many years to come.

## **ISEC 2002 ORGANISING COMMITTEE**

Chair: Organising Committee : Prof Philip Lloyd, University of Cape Town  
Chair: Technical Programme : Dr Kathy Sole, Anglo American Research Laboratories (Pty) Ltd  
Treasurer : John Riordan, Bateman Engineering  
Technical Programme : Peter Cole, Hydrometallurgy Consultant  
: Angus Feather, Mintek  
: Dr Leon Krüger, De Beers  
: Dr John Preston, Mintek  
Technical Tours : Dr Dave Robinson, Anglo American Platinum Corporation  
Exhibition : Andrew Nisbett, Cognis Corporation  
Conference Secretariat : Yvonne Clayden, Mintek  
: Jean Martins, Mintek  
Conference Travel Agent : Ken Brown, African Conferences and Incentives  
: Pam Oberholzer, African Conferences and Incentives  
Sponsoring Institute : Dr Michael Booth, South African Chemical Institute  
Representatives : Wim Mandersloot, South African Institution of Chemical Engineers  
: Cathy McInnes, South African Institute of Mining and Metallurgy

## **ISEC 2002 SPONSORS**

Anglo American Platinum Corporation  
Anglo American Research Laboratories  
Cytec Industries, Inc.

Avecia	ExxonMobil
Bateman Advance Technologies	Impala Platinum
Bateman Engineering	Mintek
Bayer	Rhodia
Cognis	Sasol
CSIR BioChemtek	Schümann Sasol
Engen Chemicals	Shell Chemicals

## **INTERNATIONAL COMMITTEE ON SOLVENT EXTRACTION**

Prof Geoff W. Stevens, University of Melbourne, Australia (Secretary General)  
Prof Michael Cox, University of Hertfordshire, United Kingdom (Secretary)  
Dr Douglas S. Flett, St Barbara Consultancy, United Kingdom (Treasurer)  
Prof Hans-Jörg Bart, University of Kaiserslautern, Germany  
Prof Weiyang Fei, Tsinghua University, PR China  
Prof Stan Hartland, ETH-Zurich, Switzerland  
Dr Gary A. Kordosky, Cognis Corporation, USA  
Prof Philip J. Lloyd, University of Cape Town, South Africa

## SOLVENT EXTRACTION AS AN ENABLING TECHNOLOGY IN THE NICKEL INDUSTRY

Gord Bacon and Indje Mihaylov

Inco Technical Services Limited, Mississauga, Canada

The last decade had witnessed unprecedented growth in the development and implementation of solvent extraction technology in the extractive metallurgy of nickel and cobalt. Solvent extraction is proving to be a powerful tool, opening new opportunities for simpler, more cost efficient and environmentally sound metal refining processes. These advances, however, could not have been possible without the cooperative efforts between the nickel industry and the people and organizations involved with reagents, materials and equipment development and supply as well as solvent extraction research, aided by the accumulated knowledge and practical experience from the copper and uranium solvent extraction operations. This paper provides an overview of these developments and some of the challenges ahead.

### INTRODUCTION

Historically, the main source for primary nickel production has been the nickel-iron-copper sulphide ores (typically 1-3% Ni). The ability to upgrade these ores to a sulphide concentrate is essential as it ensures that the subsequent processing involves low volume high-grade nickel material. However, with a few notable exceptions, the known sulphide ore resources are located deep underground and their mining costs are high. As the more economical of these resources are gradually exhausted, the complexity of mining and processing inevitably increases.

The sulphide ores represent only about 30% of the world's land-based nickel resources. The remaining ~70% are represented by the nickeliferous lateritic ores (typically 1-2% Ni), which are also a major source for cobalt. The laterites are located close to surface and can be mined at significantly lower costs. Unfortunately, they are not readily amenable to upgrading thus resulting in higher processing costs than for the sulphides. For this reason, the use of these resources has been largely limited to the high-Ni saprolitic fraction leaving as generally uneconomical the much more abundant limonitic fraction.

Two hydrometallurgical technologies had played a key role in the development of commercially viable nickel recovery processes for these resources. One has been the pressure acid leaching of laterites using horizontal agitated autoclaves. Substantial advances in autoclave design and engineering were made over the last 10–12 years as part of the successful introduction of pressure leaching technology for treating refractory gold ores as well as zinc and nickel sulphide concentrates. Although the autoclaves used in these processes typically operate below 220°C, the accumulation of engineering know-how and operating experience spurred renewed interest in applying the technology to laterites.

The other hydrometallurgical technology has been the solvent extraction (SX) of base metals. Its acceptance by the nickel industry has been primarily influenced by the following factors:

- development and commercial availability of new solvent extraction reagents,
- demonstrated success in copper refining over a wide range of throughputs, and
- developments in solvent extraction equipment design and engineering.

Other factors, common to all base metals producers, such as declining ore grades and increasing ore complexity, decreasing (in real terms) prices and pressure to meet increasingly stringent environmental regulations, require continuous improvement, development and implementation of innovative techniques to address these issues.

Solvent extraction has a significant potential as a metal refining hydrometallurgical process—its operation is continuous, easily automated and requires little supervision. Unlike alternative separation/concentration techniques, no solids handling is routinely required (except for occasional crud and in some rare cases scale handling). These features contribute to low operating costs and high on-line availability of the typical solvent extraction circuit.

The first relatively large-scale SX application in hydrometallurgy—for uranium refining—dates back to the years around World War II. Solvent extraction is also well established in the refining of precious metals and rare earths. However, because in this case the amount of material to be processed is relatively small, the refining circuits are generally smaller in size, requiring less capital to build and to modify as needed in the future.

On the other hand, the business of base metals mining and refining is very capital intensive. For example, the capital cost of a nickel laterite plant is generally in the range of US\$8–12 per pound of Ni annual production. With few exceptions, the plants producing base metals as their primary product are by necessity large to maximize the economy-of-scale benefits and be economically viable. Hence, the acceptance of solvent extraction as a new technology in base metals refining is a fairly complex task. It requires not only a credible demonstration of the particular process at all levels of testing/piloting and in good integration with the upstream and downstream operations, but also a careful evaluation of the available engineering designs to support the technology and all potential risks associated with its implementation. It is thus not surprising that it usually takes years before the industry would embrace an otherwise technically and economically viable SX process. At the same time, the continuing pressure to develop more efficient and environmentally sensitive refining technologies inevitably dictates that the whole range of available process tools, and combinations thereof, are carefully evaluated in the quest to determine the optimum one for the specific feed material and the specific circumstances of the base metal producer.

One relevant example has been the development of the technology for the copper H<sub>2</sub>SO<sub>4</sub> leach-solvent extraction-electrowinning (L/SX/EW) operations. This particular experience had a substantial effect on the large scale solvent extraction application in the nickel industry and it is from that point of view that some of the major advances are reviewed below.

## COMING OF AGE IN COPPER SOLVENT EXTRACTION

The classical route for Cu recovery from sulphide ores involves concentration, smelting and electrorefining. It is well suited when the ore also contains appreciable amounts of precious metals. The route becomes uneconomical for low grade sulphides (and with minimal precious metals content) and for oxide ores. The preferred way to extract Cu from these types of ores is by mild H<sub>2</sub>SO<sub>4</sub> leach producing a dilute (~0.5–4.0 g/L Cu) CuSO<sub>4</sub> solution with a pH of ~1.4–2.0. The solution would then be treated to precipitate and concentrate the copper in one form or another—for example, by cementation using metallic iron or by precipitation using H<sub>2</sub>S. The concentrate would then be processed through smelting and electrorefining.

Solvent extraction provided a winning alternative to these routes. Building upon the class of known Cu-selective hydroxyoxime reagents used in analytical chemistry methods, the first commercial Cu extractants were developed in the mid-1960's. These extractants (LIX® 63, and particularly LIX® 64 and LIX® 65N) were able to selectively transfer copper from the dilute acidic leach solution with minimal Fe co-extraction (the main impurity) into a concentrated CuSO<sub>4</sub> solution (typically ~50 g/L Cu and 150–180 g/L H<sub>2</sub>SO<sub>4</sub>) from which copper could be electrowon. The acidic raffinate after extraction is used for leaching while the highly acidic lean copper electrolyte electrowinning is used for copper stripping from the loaded organic. In this elegant refining scheme, by separation and concentration, the SX process provides the link between leaching and electrowinning to produce high purity electrolytic copper.

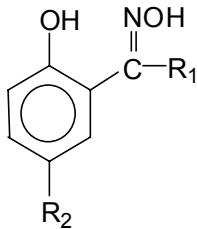

The use of solvent extraction resulted in significantly reduced operating costs (by some estimates, about 50% lower than for the cementation with Fe route). One of the newest Cu L/SX/EW plants, Codelco's Radomiro Tomic, is said to have cash production costs of about US\$ 0.38/lb of Cu. This lowering of costs allowed to include as copper resources feed materials previously considered uneconomical. Today, there are roughly about 50 such plants with a total production capacity of close to 2 million tonnes of Cu per year. The individual SX circuit capacity of these plants ranges from ~200 to ~3,000 m<sup>3</sup>/h of pregnant leach solution (PLS), proving that the technology can deliver a reliable and consistent performance over a wide range of throughputs. It is also quite telling that about 50% of these plants were commissioned during the last 10 years and another ~27% during the 1980s. This pattern of exponential growth is a testament to the success of the SX technology for this copper recovery route.

Perhaps the most important factor for the success of the solvent extraction in this case has been the development of solvent extractants and fine-tuning of their performance to meet the range of optimal process conditions both for the leaching and electrowinning side, as dictated by the individual plant's copper sources conditions. That meant having a copper-selective extractant, with fast extraction and stripping kinetics, able to maintain high Cu extractions over the pH range of the PLS and the product raffinate (*i.e.*, to pHs of as low as 1.2–1.4) while allowing at the same time to be readily stripped using lean copper electrolyte (typically ~30–35 g/L Cu and ~200 g/L H<sub>2</sub>SO<sub>4</sub>) to produce feed to electrowinning. One particular advantage of this Cu SX system is that no base addition is necessary during the extraction, resulting in base reagent cost saving and a simplified circuit operation since no pH control is necessary.

The constituents of the proprietary extractants, available from Avecia (formerly Zeneca) and Cognis (formerly Henkel), are nonyl (C9) and dodecyl (C12) hydroxyphenyl ketoximes and aldoximes (Table 1). The ketoximes are weaker extractants than the aldoximes but are more readily stripped at lower free H<sub>2</sub>SO<sub>4</sub> levels. Thus, the majority of the copper SX plants use specific formulations to balance the extraction and stripping properties required. These formulations include ketoxime/aldoxime mixtures (such as LIX® 984 and LIX® 973 from Cognis) or an aldoxime with the addition of various modifiers, such as nonylphenol (*e.g.*, Acorga® P5100 from Avecia), tridecanol (*e.g.*, LIX® 622), or proprietary esters (*e.g.*, Acorga® M5640). The last few years had also seen a gradual trend of phasing out the C12 in favour of the C9 aldoximes.

The Cu/Fe selectivity, phase-separation and crud formation, and to a certain degree the extractant stability, also affect the choice for a particular formulation of the SX plant organic. Crud formation has been and continues to be one of the biggest problems in the operation of these circuits; detailed studies on crud formation have identified a number of contributing factors (*e.g.*, colloidal silica, surfactants, solids, certain organic additives, *etc.*).

*Table 1. Chelating hydroxyoxime extractants for copper.*

	Type	R1	R2	Trade name
Ketoxime	C <sub>6</sub> H <sub>5</sub>	C <sub>12</sub> H <sub>25</sub>	LIX® 64	
Ketoxime	C <sub>6</sub> H <sub>5</sub>	C <sub>9</sub> H <sub>19</sub>	LIX® 65N	
Ketoxime	CH <sub>3</sub>	C <sub>9</sub> H <sub>19</sub>	LIX® 84	
Aldoxime	H	C <sub>9</sub> H <sub>19</sub>	Acorga® P50	
Aldoxime	H	C <sub>12</sub> H <sub>25</sub>	LIX® 860	

Improvements in mixer-settler design have also helped to minimize crud formation and phase entrainment (organic loss to raffinate and to copper electrolyte and transfer of leach solution with the loaded organic to copper stripping) and to maximize settler throughputs. Entrainment of leach solution with the loaded organic is particularly critical in those cases when the leach solution has high levels of Fe, Mn and Cl; in such circumstances, installation of a dedicated wash stage for the loaded organic is often required.

In addition to the standard box-type agitated mixer with gravity settler design, proprietary mixer-settlers are also in use. Krebs mixer-settlers were introduced in late 1980s at Phelps Dodge's Morenci and at WMC's Olympic Dam. By employing a conical pumper and superimposed launder for early phase-separation in the settler, the settler specific throughput is significantly (up to ~2x) increased, resulting in reduced capital costs and organic inventory needs. Their performance, however, has reportedly had a mixed success. Another proprietary mixer-settler introduced for Cu SX in the late 1990s is Outokumpu's Vertical Smooth Flow (VSF) unit. Examples of this technology in the Cu industry include two Chilean plants (at Zaldivar and Radomiro Tomic) and the latest SX plant at Phelps Dodge's Morenci operation. Key features of the VSF technology are the separation of the pumping and mixing functions allowing for a controlled and gentle mixing achieved with a helical Spirok impeller. This results in minimized overmixing and air entrapment leading to lower phase entrainment and crud formation.

Other developments include the implementation of methods for organic removal from raffinate and strip solution (e.g., coalescers, multimedia filters, Jameson cell) and for the clay treatment of the organic to remove organic-soluble contaminants (e.g., surfactants) which negatively effects plant performance (e.g., worsened phase separation, poorer extraction kinetics, etc.).

All SX plants represent a fire-hazard risk. This fact alone has historically been a major stumbling block for the adoption of otherwise technically and economically sound SX processes. The development and introduction of higher flash point diluents helped in reducing the fire hazards. The demonstrated effectiveness of fire prevention and fire fighting measures over time have increased the confidence in the ability of the technology to mitigate this risk. However, recent incidents (December 1999 and October 2001) at WMC Olympic Dam's Cu SX plant have shown that a lot more is needed in the areas of equipment design, layout and plant operating practices. Notwithstanding the success of the L/SX/EW process, it should be noted that the development of a similar chloride route has not been successful. Suitable copper extractants were developed (e.g., Acorga® CLX-50 for the Cuprex process), but difficulties in electrowinning high purity copper from chloride solutions are a major impediment. This example shows that as with any other tool, solvent extraction is not, and cannot be, a fit-for-all hydrometallurgical process.

The Cu L/SX/EW plant operations clearly showed that the solvent extraction technology does work over a wide range of scales. This engineering and operating experience, together with the already accumulated knowledge from existing nickel-cobalt solvent extraction operations, was particularly important for the acceptance of the technology for the large scale commercial hydrometallurgical processes for laterites, in development over the last several years.

## SOLVENT EXTRACTION IN NICKEL/COBALT REFINING

From solvent extraction's perspective, there are three principal types of solutions important in commercial Ni/Co refining, reflecting the range of lixivants used to solubilise Ni/Co values:

- chloride solutions—resulting from Cl<sub>2</sub> and/or HCl leaching of nickel matte, intermediates or secondary nickel sources (e.g., at Falconbridge's Kristiansand, SLN's Le Havre, SMM's Niihama, and Metallurgie Hoboken refineries);
- ammoniacal (ammonia–ammonium carbonate) solutions—resulting from leaching of reduction roasted laterites as part of the Caron process (e.g., QNI's Yabulu refinery, Tocantins in Brazil and Punta Gorda in Cuba) and of nickel-cobalt hydroxide precipitate (as practised by Cawse); and
- sulphate solutions—resulting from O<sub>2</sub> pressure leaching and/or H<sub>2</sub>SO<sub>4</sub> leaching of sulphide concentrates and precipitates, matte and lateritic ores.

### Chloride Solutions

In strong chloride solutions, the separation task is helped by the fact that cobalt forms anionic chloro-complexes (e.g., CoCl<sub>3</sub><sup>-</sup> and CoCl<sub>4</sub><sup>2-</sup>) while Ni does not. Hence, an anion-exchange extractant such as a tertiary alkyl amine in its salt form (R<sub>3</sub>NH<sup>+</sup>Cl<sup>-</sup>) is able to selectively extract Co away from the Ni-containing concentrated chloride (typically ≥ 5 N Cl) solution. Other metals, often present as impurities, such as Fe, Cu and Zn, also form strong chloro-complexes and can be selectively removed from the nickel solution as well. Impurities, such as Pb and Mn can also be extracted from the nickel solution, if required. Nickel is electrowon from the purified NiCl<sub>2</sub> solution and the generated Cl<sub>2</sub> is used in the upstream leaching operation. The cobalt is readily stripped from the loaded amine organic with any low in chlorides solution (such as water) producing a CoCl<sub>2</sub> solution with ≥60 g/L Co. This solution is typically low in acid and after additional purification, if required, becomes the starting point for producing a variety of Co products, such as Co metal (electrowinning), metal powders, salts, etc.

Not surprisingly, the first commercial SX applications in the Ni industry were based on this chemistry. Major developments in this area from late 1960s to mid-1970s resulted in the adoption of the selective Co extraction with tertiary amines such as tri-iso-octyl amine (TiOA) or tri-n-octyl amine (TnOA) from concentrated Ni/Co chloride solutions at several refineries at about the same time in early to mid-1970s, with most of the operations continuing to this day.

Because Ni is not chemically co-extracted, the Co/Ni ratios in the Co product can be very high, from at least ~3,000 to as high as 8,000–10,000. The main problem in reaching and maintaining these ratios has been the transfer of entrained Ni solution with the Co-loaded organic to stripping. For example, the Ni/Co feed to Co SX at Kristiansand contains about 220 g/L Ni (and ~11 g/L Co) and it would not take much physical entrainment of that solution into the loaded organic to substantially raise the nickel level in the cobalt strip product.

Various measures are in place to reduce the aqueous entrainment with the loaded organic. They include the use of one or more scrub stages in which the cobalt-loaded organic is contacted with an aqueous solution to remove entrained nickel; in most cases, this solution is a small portion of the cobalt strip product solution (subsequently reverted to extraction) in order to chemically displace less extractable metals, such as Mn, from the organic. Other measures include special design mixer-settlers to minimise entrainment or additional mechanically forced phase-separators (e.g., centrifugal separators).

Despite the very convenient Ni/Co separation chemistry, there are two particular process and engineering challenges. The first one is having to operate with highly corrosive Cl<sup>-</sup> solutions. Since the start-up of these refineries about a quarter century ago, the development of various acid-resistant composite materials and the accumulation of considerable expertise in materials selection have made the task of designing and building SX circuits for this type of solutions somewhat easier, yet it is still a challenge. The second one is the necessity to use all-aromatic diluents for the amine organic. There are several reasons for that, the primary one being the

need to keep the viscosity of the Co-loaded organic low and thus minimise the entrainment of Ni solution. The problem with these diluents is that they have lower flash points than the aliphatic diluents with low (e.g., ~20 vol%) or no aromatic content, are more volatile and more corrosive.

One such diluent initially used by some of these refineries was xylene, which has a flash point of only ~26°C and thus represents a major fire hazard. While it is not clear whether the choice of diluent was a factor in the May 1972 major fire at the new Ni/Co refinery at Kristiansand, this event did raise serious and long-lasting concerns about SX as a reliable hydrometallurgical process in the minds of many. On the positive side, there were subsequently significant developments in the areas of SX plant layout, piping design and construction, materials and instrumentation selection as well as fire fighting measures at Kristiansand and elsewhere to minimize the risk of this happening again.

Today's aromatic diluent formulations used by some of these refineries, such as Exxon's Aromatic® 100 and Shell's ShellSol® A100 have higher flash points of ~42–47°C and are thus safer alternatives. Using diluents with even higher flash-points, such as Exxon's Aromatic® 150 and Shell's ShellSol® A150 (flash points of ~63–64°C), would be preferable whenever possible.

### **Ammoniacal Solutions**

In early 1970s, a small Cu and Ni SX plant was commissioned and operated for some time by the SEC Corporation in El Paso, Texas. The plant treated a 70–90 g/L Cu, 30–40 g/L Ni liquor after the crystallization of CuSO<sub>4</sub> from Cu electrolytes of a close-by Phelps Dodge refinery. Following Cu extraction with LIX® 64N (LIX® 65N containing ~1 vol% LIX® 63; see Table 1), Ni was then extracted at pH 9–10, with LIX® 64N and using ammonia for pH control. The Ni-loaded organic was washed (pH~3–5) to remove entrained ammonia and then stripped with dilute H<sub>2</sub>SO<sub>4</sub> at pH~2 producing NiSO<sub>4</sub> electrolyte for Ni electrowinning. Although a very small scale (about 2 t of Cu and 0.5 t of Ni per day), this plant operation was significant in that it focussed the attention of a major extractant supplier on opportunities to use Cu extractants in Ni refining.

In 1975 Nippon Mining's Hitachi refinery began using LIX® 64N for Ni extraction in about the same way. Following sequential Zn and Co removal in separate SX steps, Ni was extracted from a sulphate solution (~30 g/L Ni) at pH~9–10 using ammonia for pH control; Ni was recovered to final product by electrowinning and spent electrolyte was used to strip the Ni from the organic. This operation (producing about 3,300 t of Ni and 1,300 t of Co per year in early 1980s) provided invaluable information and a working resolution for the problem of hydroxyoxime degradation. Further to the known almost irreversible Co extraction as Co(II) and accumulation in the hydroxyoxime organic as Co(III), it was discovered that LIX® 64N was losing its oxime group (C=NOH) by conversion to ketone (C=O) through Co-catalysed oxidation, hence losing its extractive capacity. Fortunately, it was found that the ketone could be re-oximated with high yields to the original oxime through contact with hydroxylamine salts in alkaline solutions. This regeneration process was further developed into a workable technology with the involvement of the extractants manufacturer. Without the re-oximation process, the commercial application of the ammoniacal SX process for Ni would not have been possible.

The QNI's Yabulu refinery uses the high cost and energy intensive Caron process, developed in the 1920s; at Yabulu, it involved ore drying and grinding, followed by reduction roast and ammonia-ammonium carbonate leaching of the reduced ore, Co removal by precipitation with H<sub>2</sub>S as mixed Ni/Co sulphide (Ni:Co~2) and shipment for refining elsewhere, Ni recovery by precipitation as NiCO<sub>3</sub> with subsequent calcination to NiO and partial reduction to 85–90% Ni in the final NiO product. By mid-1980s, the local (Greenvale) laterite feed was being exhausted and the plant had to switch to processing New Caledonian and Indonesian laterites with higher Co content. The change to imported laterite feed meant increased transportation costs; the higher Co content would have required a substantial expansion of the existing Ni/Co sulphide plant with increased costs for drying the sulphide and shipping it for refining overseas while reducing the proportion of the nickel available for on site NiO production. The net result would have been substantially higher operating costs, undermining the viability of the entire operation.

In the modified Yabulu refinery operation, the  $\text{NH}_3$  /  $(\text{NH}_4)_2\text{CO}_3$  leach liquor, containing ~10 g/L Ni, ~0.5 g/L Co, 80–90 g/L  $\text{NH}_3$  and ~60 g/L  $\text{CO}_2$ , is first pre-boiled to reduce the free ammonia from ~80 g/L to ~40 g/L (Ni extraction decreases with increasing ammonia concentration) and then the liquor is aerated to oxidize Co(II) to Co(III) to prevent co-extraction in the subsequent Ni ammoniacal SX (ASX) process. Nickel is extracted with LIX® 87QN, an extractant formulation prepared by Cognis for QNI containing LIX® 84 and undisclosed modifiers. The Ni extraction most likely proceeds through a cation-exchange reaction with  $\text{Ni}^{2+}$  replacing loaded  $\text{NH}_4^+$  from the extractant. Nickel stripping from the extractant requires contact with high-strength ammonia–ammonium carbonate solution (~280 g/L  $\text{NH}_3$  and ~230 g/L  $\text{CO}_2$ ) and produces strip liquor with ~80 g/L Ni. From this liquor, Ni is recovered to basic nickel carbonate and nickel oxide as before. The cobalt from the raffinate is removed by  $\text{H}_2\text{S}$  as sulphide, but the produced quantity is ~3 times less due to substantially lower nickel content (28% Ni and 14% Co before ASX, 2% Ni and 42% Co thereafter).

The development and implementation in late 1980s of the ASX process at Yabulu, in cooperation with the extractant supplier (Cognis), was crucial to the refinery's continuing operation. It also provided the additional confidence in the SX technology to proceed with the introduction in the late 1990s of a Co refining process, involving several SX steps, for on-site production of cobalt oxide hydroxide which also had the benefit of keeping all of the primary nickel for refining on site. The ASX process also enabled the refinery to expand the range of laterite feed materials it can process. At the present time, feasibility studies are in progress to expand the refinery (from the ASX process onwards) to almost double capacity to treat the mixed Ni/Co hydroxide from the Ravensthorpe pressure acid leach laterite project.

The ASX process does suffer from several disadvantages, although none are too critical: slow extraction and even slower (>5 min per stage required) stripping, a need to reductively strip accumulating cobalt from the organic and to operate the re-oximation process, relatively slow phase-separation. In addition, the small amounts of copper in the feed to extraction would accumulate in the organic due to high pH conditions in both extraction and stripping; copper removal would require separate  $\text{H}_2\text{SO}_4$  stripping. The transfer of ammonium with the organic between Ni extraction and stripping at Yabulu is inconsequential, as the solutions at both ends of the SX process are ammoniacal, but it is an issue in other refining schemes.

A similar SX process was adopted for the Cawse project. In this most technically successful operation (start-up early 1999) of all three Western Australian pressure acid leach laterite projects to date, an intermediate Ni/Co hydroxide precipitate is re-leached in  $\text{NH}_3$  /  $(\text{NH}_4)_2\text{CO}_3$  solution and then nickel is selectively extracted with LIX® 84 from the resulting solution (~12–15 g/L Ni and ~2–3 g/L Co). Unlike at Yabulu, the nickel-loaded organic is first scrubbed/washed to remove loaded ammonium, producing  $(\text{NH}_4)_2\text{SO}_4$  solution. This scrub/wash operation is also essential in minimizing the co-extraction of zinc, present in small quantities in the feed to extraction. The scrubbed/washed nickel-loaded organic is then stripped with  $\text{H}_2\text{SO}_4$  from the spent nickel electrolyte from electrowinning. Copper and cobalt removal from the organic as well as re-oximation is required.

With a nameplate capacity of only 9,000 t of Ni and 1,600 t of Co (in cobalt sulphide) per year Cawse is a relatively small operation but serves as a proving case for the technologies involved, including the solvent extraction.

### Sulphate Solutions

As a common solution matrix in Ni/Co hydrometallurgy, the Ni/Co SX from sulphate solutions had received considerable attention in the areas of extractants and applications development. The Ni/Co commercial SX processes to date involve the use of five extractants (Table 2).

Table 2. Development/commercial application of cobalt-nickel extractants for sulphate solutions.

Extractant	1960's	1970's	1980's	1990's	2000's
D2EHPA 					
Versatic® 10 					
PC-88A / Ionquest® 801 					
Cyanex® 272 					
Cyanex® 301 					

Three of these extractants are used for selective Co extraction from Ni/Co solutions. In chronological order of development to market, they are the di-2-ethylhexyl phosphoric acid, known as D2EHPA, the 2-ethylhexyl phosphonic acid mono 2-ethylhexyl ester, available as PC-88A (Daihachi Chemical Industries) and Ionquest® 801 (Albright&Wilson), and the bis (2,4,4-trimethylpentyl) phosphinic acid, available from Cytec Canada Inc. as Cyanex® 272.

The first SX process for Co separation from Ni was developed using D2EHPA in mid-1960s. The process developed for Eldorado Nuclear refinery in Canada was actually for ammoniacal leach solutions and prior to extraction the leach solution was aerated to oxidize Co(II) to Co(III). D2EHPA extracted Co as Co(III) pentamine in some preference to Ni; in the hydroxyoxime processes (QNI, Cawse), Co(II) is oxidized to Co(III) prior to SX so that it will *not* be extracted. Due to D2EHPA's relatively low Co/Ni selectivity, many extraction stages are required. This was perhaps a reason to choose sieve-plate pulsed column in the piloting. The loaded organic was scrubbed with high-cobalt amine solution. The D2EHPA process was further developed in the early 1970s at CANMET in Ottawa for sulphate leach solutions. The organic was pre-loaded with ammonia or sodium to avoid adding base for pH control (pH 5–6) during Co(II) extraction. The cobalt was stripped with H<sub>2</sub>SO<sub>4</sub> to produce electrolyte suitable for electrowinning.

At about the same time, a similar D2EHPA process was developed in the UK (Warren Springs laboratory) and later adopted at the Rustenburg base metals refinery, still in operation today. Cobalt is separated from the primary Ni feed to EW by precipitation of Co(OH)<sub>3</sub> with electrolytically produced Ni(OH)<sub>3</sub>. A reductive re-leach of the solids produces a Ni/Co sulphate solution, which is fed, after removal of impurities such as Fe, Cu, and Pb, to the Co D2EHPA SX circuit. The organic is pre-loaded with Na prior to extraction. A large number of extraction and scrubbing stages is needed to achieve the required Co/Ni ratio in the Co strip solution.

The development of the D2EHPA process was a major advance in Ni/Co refining from sulphate solutions which also focussed the attention of extractant developers on the organophosphine chemistry. Some of the disadvantages of using D2EHPA are the very strong Fe extraction, requiring a reductive or HCl stripping, low degree of Co/Ni selectivity, and preferential Ca, Mg and Mn extraction ahead of cobalt and nickel. In the Rustenburg operation, NaOH is used for iron removal thus the feed to Co SX contains only traces of Ca and Mg—both are co-extracted and occasional gypsum removal from the Co strip stages is necessary.

The D2EHPA separation process was introduced at Nippon Mining's Hitachi refinery in 1975. Several years later Daihachi introduced the organophosphonic acid extractant PC-88A. In many respects it was similar to D2EHPA. However, it was a poorer Ni extractant (same Ni extraction required a higher pH) and was thus more selective for cobalt over nickel. The testwork at Nippon Mining confirmed at least an order of magnitude better Co/Ni separation with PC-88A. On that basis, the new extractant was adopted at the refinery, despite being more expensive than D2EHPA. The rest of the SX operation remained essentially the same. The use of the PC-88A for cobalt continues to this day at least one major Ni/Co refinery.

In 1980 Cyanamid (now Cytec) Canada Inc. developed at their Welland, Ontario, plant a new extractant, Cyanex® CNX, which showed a significant promise as a selective reagent for Co over Ni. Inco's research laboratory in Mississauga, Ontario, was apparently the first facility outside Cyanamid to test the new reagent. It was not "perfect" (for example, it was in solid rather than in liquid form) but the internal Inco results were very encouraging and had a positive effect on the continuing efforts at Cyanamid. In early 1982, an improved version, Cyanex® 272, became available ("27" signified Co, "2"—the "second generation" reagent).

Keeping with the trend from D2EHPA and PC-88A/Ionquest® 801, Cyanex® 272 is an even poorer Ni extractant, while still extracting Co at about the same pH (i.e., pH 5–6), resulting in a substantially higher Co/Ni separation factor. With Cyanex® 272 it is much easier (less extraction and scrub stages) to achieve the required high Co/Ni ratios in the cobalt strip product, on par with what is achieved in the chloride system.

Due to its superior Co/Ni selectivity, Cyanex® 272 was relatively quickly adopted in Ni/Co refineries: the first plant to use this reagent was started in 1985 and by 1990 there were three more plants, including two major Co refineries in Europe. By 1995, the number of plants had doubled, with the latest addition being the newly upgraded and expanded Outokumpu's Harjavalta Ni/Co refinery, now part of the OM Group, Inc.

At Harjavalta, the Co SX process with Cyanex® 272 replaced Outokumpu's older process of Co removal from the  $\text{NiSO}_4$  electrolyte by precipitation as  $\text{Co(OH)}_3$  with  $\text{Ni(OH)}_3$ . Hence, the Ni:Co ratio in the feed to Co SX is >100 (typical feed (g/L): 130 Ni, 0.8–1.0 Co). Selective Co extraction from a solution with such a high Ni:Co ratio would not have been feasible with D2EHPA or PC-88A/Ionquest® 801. The Rustenburg base metals refinery uses that same Outokumpu process and its Co D2EHPA circuit is on the redissolved  $\text{Co(OH)}_3$  stream (Ni:Co ratio of only ~0.3); the Nippon Mining Co PC-88A circuit used to process Ni/Co feed with Ni:Co ratio of ~2–3 only.

The development of Cyanex® 272 in Canada expanded the range of possible SX applications in Co/Ni refining and enabled the replacement of more costly and/or environmentally and operator unfriendly technologies. According to Cytec's estimates, by the end of 1995, about 50% of the world Co production involved a Cyanex® 272 Co refining step. At the present time the total number of refineries (including Murrin-Murrin and Bulong) using the reagent has grown to about 10–12. Perhaps, the biggest disadvantage of Cyanex® 272 is its relatively high cost, hence its users are careful to limit entrainment and soluble losses to outgoing aqueous streams.

The fourth extractant used for Ni/Co refining in sulphate solutions is the Versatic® 10 carboxylic acid. Similarly to D2EHPA, it has been around for a long time, it is not particularly selective and its price is one of its most attractive features. Unlike D2EHPA, Versatic® 10 is selective for Ni and Co over Ca and Mg. Unlike all three organophosphorus reagents, Versatic® 10 is selective for Ni over Co; the selectivity is minimal, however, and cannot be used in reality. There have been considerable efforts to increase the extractant's affinity for Ni by introduction of various modifiers and improve its selectivity for Ni over Co. Although not particularly successful to date, the approach is worth pursuing, given the low cost of the extractant. Versatic® 10 is also a weaker extractant, requiring pH of ~7 for efficient Ni extraction, which exacerbates its biggest problem, namely, the high aqueous solubility (3–5 g/L) and relatively poor phase separation.

For ~20 years SMM' Niijhama refinery used Versatic® 10 to transfer Ni and Co from sulphate into a concentrated chloride solution. Similarly to the Rustenburg refinery operation, the feed to Versatic® 10 SX was the Ni/Co product solution from the reductive re-leach of  $\text{Co}(\text{OH})_3$  precipitate after the removal of impurities such as Fe, Mn and Cu. Ammonia was used for pH control and the raffinate was contacted with  $\text{H}_2\text{SO}_4$  to recover some of the solubilised organic. Nickel and Co were stripped with HCl, producing ~200 g/L Ni+Co strip solution. Cobalt was then selectively extracted with a tertiary amine; both Co and Ni were recovered by electrowinning.

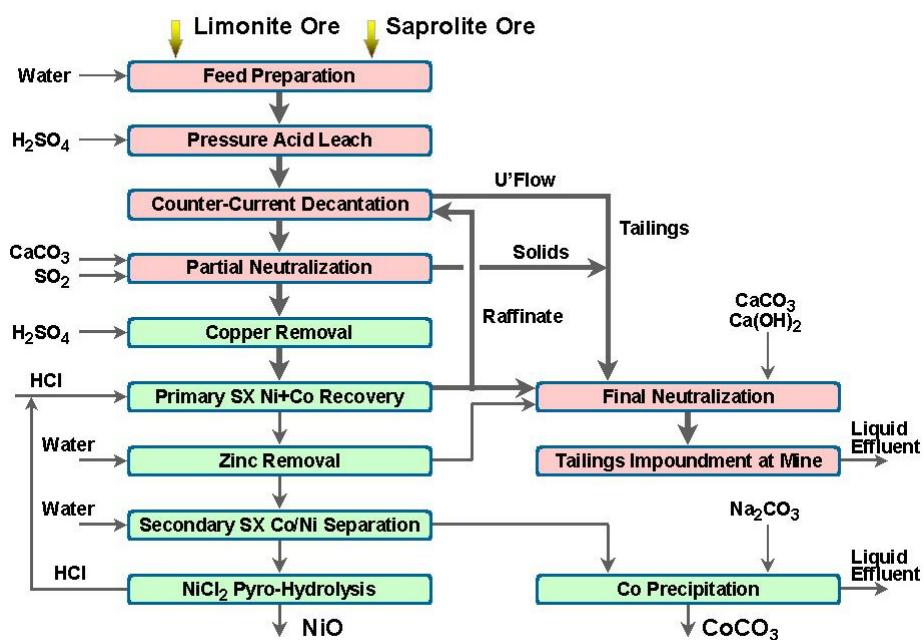

Recent interest in Versatic® 10 results largely from its application at the Bulong laterite plant for Ni SX. This plant (design capacity of ~9,000 t of Ni and ~1,000 t of Co per year) is the only one of the three new Western Australian laterite projects to use SX directly on the partially neutralized Ni/Co leach solution. At Bulong, there are two SX circuits on the entire volume of the dilute Ni/Co leach solution after partial neutralization with limestone ((g/L): 3.5 Ni, 0.3 Co, 1.0 Mn, 15 Mg, 0.5 Ca). Cyanex® 272 is first used for Co and ammonia is added for pH control. Cyanex® 272 extracts Mn preferentially to Co while the selectivity for Co over Mg is relatively small at the unfavourable Co:Mg ratio in the feed. Hence, the loaded organic is largely carrying Mn and Mg, with Co representing at most ~10% of the total metal load. Because the feed to extraction is also Ca-saturated some Ca would be extracted in one extraction stage and displaced in another, resulting in likely gypsum formation; aqueous phase dilution in extraction due to the water from the ammonia for pH control will help to minimise the formation of gypsum.

The raffinate from the Cyanex® 272 circuit is processed through the Versatic® 10 circuit. Here Ni is separated from the Ca and Mg; any Co not extracted in the Cyanex® 272 circuit will follow the Ni and report into the electrowon Ni metal; ammonia is used for pH control and Ni electrolyte bleed is needed to balance the transfer of co-extracted ammonia to nickel stripping. One main problem at the circuit has been the cross-contamination with Cyanex® 272, resulting in higher Ca extraction and displacement within the extraction stages, leading to gypsum precipitation.

The fifth, and the newest, reagent used for Ni/Co refining in sulphate solutions is Cyanex® 301, developed by Cytec in late 1980s as a selective extractant for Zn over Ca and Mg. Although similar in many respects to Cyanex® 272 (both extractants also are manufactured at the same Welland plant), the replacement of both oxygens with sulphur (Table 2) results in a reagent with a very different extractive strength and selectivity for base metals.

The Ni/Co extraction with Cyanex® 301 is a key feature of the Inco-Goro hydrometallurgical process for laterites (Figure 1). The Goro Nickel plant, presently at detailed engineering stage, is expected to have an annual capacity of 54,000 tonnes of Ni and 5,400 tonnes of Co.

The use of Cyanex® 301 allows Ni and Co to be removed quickly (fast extraction kinetics) and efficiently (>99.9% extraction) from the large flow of relatively dilute partially neutralised leach solution (~4.5 g/L Ni) without the co-extraction of any of the major impurities (Mn, Ca, Mg), without the need for pH control and having to add expensive base reagents. Any traces of Cu in solution after partial neutralization are removed by ion-exchange ahead of SX, to prevent practically irreversible Cu extraction. Due to strong Ni and Co extraction, the strip kinetics is relatively slow and contact with strong acid is required. The use of HCl produces a concentrated Ni/Co strip solution (~80–100 g/L Ni) with about 20 times reduction in volume, significantly reducing the size of the downstream refining circuits. Zinc is completely co-extracted with Ni and Co but is selectively removed by ion-exchange from the chloride solution. Cobalt separation from Ni is done using a tertiary amine extractant. Nickel is recovered by pyrohydrolysis as the desired NiO product, while the HCl is regenerated and recycled back to Cyanex® 301 stripping.

*Figure 1. The Goro process.*

Compared with the other four extractants, Cyanex® 301 has the lowest aqueous solubility which is even lower under the acidic conditions of the raffinate ( $pH \leq 1.5$ ). The phase separation in both extraction and stripping is fast, thus contributing to very low soluble and entrainment losses.

Extensive testing of the Cyanex® 301 process was required as there were no commercial operations using this new reagent. It was carried out at the Inco's laboratory, mini-plant and pilot plant scale operations in Canada and at the fully integrated pilot plant operation at Goro. In close collaboration with Cytec's Phosphine Technical Centre, the stability of the extractant was thoroughly investigated. The product of Cyanex® 301 ( $R_2P(S)SH$ ) degradation was identified (a disulphide,  $R_2P(S)S-S(S)PR_2$ ) and several processes to convert it back into  $R_2P(S)SH$  were developed. The Cyanex® 301 degradation was caused by metal-catalysed (e.g., Fe) oxidation by air. By operating under an  $O_2$ -excluded atmosphere, the degradation rate was demonstrated to be essentially nil. In the Goro pilot plant operations (processing 12 t (dry basis) of ore per day) to date, the Cyanex® 301 circuit have performed very much as expected, and in fact with much less troubles than anticipated.

In many respects, Cyanex® 301 may be regarded as a sulphide, performing a similar function to  $H_2S$  in selectively recovering Ni and Co from the laterite acid leach solution as practised at Moa Bay and more recently at Murrin-Murrin. One major difference, and advantage of using Cyanex® 301, is that this selective Ni/Co recovery is achieved without the safety concerns associated with the use of  $H_2S$  and without the need for solids handlings and subsequent re-dissolution of the sulphide precipitate. The Cyanex® 301 development by Cytec and the development of the technology for Ni/Co refining by Inco is yet another demonstration of the potential of SX to streamline and improve refining operations in the nickel industry.

### Equipment and Materials

At the present time, all SX operations in Ni/Co refining use mixer-settlers contacting equipment. Proprietary technologies, such as the Krebs mixer-settler and Outokumpu's Vertical Smooth Flow (VSF) mixer-settler were first developed in mid-1970s to early 1980s and introduced at Ni refineries in France and Finland, respectively. Both technologies are used to this day and are continuously evolving.

In the last ~5 years, there has been a renewed interest in using columns in Ni/Co SX circuits. This has been due in part to the considerable efforts of Bateman Projects Engineering in Israel of promoting their pulsed column technology for Ni/Co refining. However, it also reflects nickel industry's increased confidence in SX technology and the ever present need for further operational and capital cost savings. Columns have been used for decades as contacting equipment for many processes in the chemical industry, including liquid extraction, but except for a few cases of uranium refining (e.g., in France), there have been no hydrometallurgical applications.

This all changed with the successful introduction of the Bateman disc and doughnut pulsed columns in late 1990s for uranium extraction at WMC's Olympic Dam operation, which served as a powerful stimulus for a number of metal refineries to consider possible adoption in their operations. Pilot tests were carried out in the last 2–3 years at many Ni/Co refineries; examples include Impala's base metals refinery and QNI's Yabulu refinery.

The use of columns instead of mixer-settlers is advantageous in processes where many extraction or stripping stages are required, where extractants are costly, flammable, volatile, where processes require special atmosphere and/or well sealed environment, and where processes are particularly sensitive to moving parts and materials of construction. Columns are often easier to operate than mixer-settlers. Columns with axial energy input provide much more uniform size distribution of droplets, thus leading to reduced organic entrainment in outgoing aqueous streams.

With significantly reduced organic vapours, acid and other emissions, due to their fully sealed environment, and with their more uniform mixing thus leading to lower organic entrainment in the outgoing aqueous streams, the pulsed columns are a particularly attractive option for minimizing the impact of the solvent extraction operations on the environment.

As part of the testwork and piloting of the Inco-Goro process for laterites, the Bateman pulsed columns technology was also evaluated. The use of pulsed columns for both SX circuits is attractive for a number of reasons, including the ability to seal the equipment, to maintain the required atmosphere and to limit fugitive organic and acid emissions, lack of internal moving parts, reduced fire risks, simpler operation and minimum organic entrainment losses.

The increased interest in columns application in Ni/Co refining had also attracted the attention of other developers/suppliers of columns equipment. One example is Koch-Otto York who have many years of experience in various types of columns technology for the chemical industry.

These increased activities in the area of contacting equipment are expected to result not only in improvements in known technologies but also in novel, more efficient and safer ways of carrying the process of solvent extraction in the hydrometallurgical refineries.

As the scope of solvent extraction systems and range of applications increases, so does the challenge of finding and proving the right materials for the equipment. Despite significant advances in that area, there are still concerns particularly when the materials have to withstand *combinations* of various corrosive reagents, such as organic extractants, diluents and modifiers, in contact with corrosive acids, gases, etc., sometimes at elevated temperatures. These concerns, of course, are not limited to solvent extraction processes only. In addition, the science of detection and removal of any products of such interactions needs further development to better address this types of issues in refining operations.

## **CONCLUSIONS**

The use of solvent extraction for nickel/cobalt refining in the nickel industry have substantially progressed since its earliest applications in the 1970s. The successful development of new extractants and the advances in contacting equipment technology (mixer-settlers and columns) have significantly expanded the scope of technologically and economically sound nickel-cobalt refining options. All these are very much needed as the industry is faced with having to process feed materials of increasing complexity and often decreasing grades while meeting at the same time the challenges of stricter limits on the environment impact of its operations.

## DEVELOPMENTS IN PLATINUM-GROUP METALS REFINING AND THE UTILIZATION OF SOLVENT EXTRACTION TECHNOLOGIES

Peter Charlesworth

Anglo American Platinum Corporation Limited, Anglo Platinum Research Centre,  
Johannesburg, South Africa

The discovery of the platinum-bearing ore bodies of the Bushveld Igneous Complex (primarily in the Merensky and UG2 reefs) in South Africa in 1923 sparked the growth of a significant industry which today contributes some 4 % of the South African GDP. The production of platinum-group metals has developed steadily from exploration through mining and overseas toll treatment to the current situation whereby South Africa leads the world in the production of high-purity platinum-group metals for a variety of demands and applications. Over the last few years, South Africa has been responsible for the production of 70 to 80 % of the world's platinum, with Anglo Platinum being responsible for approximately one half of this production. The variety of demands for platinum, from jewellery through to industrial and automotive catalysts and the future fuel cells, has established platinum as the true "metal of the millennium". Ongoing forecasts for significant growth in demand place South Africa and this industry in a good position.

The early refining routes used in South Africa were largely based upon the classical gravimetric analytical methods by which the metals had been separated on a small scale over many decades. While these were reliable, they were expensive to operate, often required skilled operators, were time-consuming, and were often both capital- and inventory-intensive. The development of ion exchange and, more recently, solvent extraction separation technologies for a range of metals from the base metals through to the lanthanides and actinides presented an opportunity for improved processing routes which were eagerly engaged by Anglo Platinum. The current Anglo Platinum Precious Metals Refinery is the most modern, efficient and productive platinum-producing refinery in the world. The core separation processes are based largely on the selective solvent extraction (using some commercially available reagents and other proprietary reagents) of either individual elements or groups of elements producing individual platinum-group metal feed streams for final purification.

## TAILORED SOLVENTS AND COLLOIDS FOR GREEN PROCESSING OF CHEMICALS AND BIOCHEMICALS

T. Alan Hatton

Massachusetts Institute of Technology, Cambridge, USA

Alternative solvents and extraction concepts can be developed to minimise the deleterious effect of solvent losses to the environment. Two new concepts are discussed here. First, the tailoring of solvents can minimise the extent to which they may be lost to the environment, and can minimise the number of unit operations required in a chemical process; this approach is demonstrated to be effective in a sequence of reactions required in the synthesis of an HIV protease inhibitor. Secondly, the use of bulk solvents can be avoided by covalently attaching solvent-like polymers to the surfaces of colloidally dispersed magnetic nanoparticles, that can be recovered directly using high gradient magnetic separations.

### INTRODUCTION

Solvents are used ubiquitously in chemical synthesis and separation operations. Solvent extraction, in particular, has evolved to be the workhorse of many processes as it provides a versatile and selective class of unit operations for the recovery or removal of a wide range of materials from both aqueous and organic solutions. A continuing challenge facing the chemical and biochemical industries is how to enhance the selectivity and capacity of these processes, and how to adapt them for new separations problems, such as in the biotechnology arena, where the interest has progressed from proteins through to larger materials such as nucleic acids and viral particles, and even cells. In recent years, there has also been a growing interest in micro-scale separations for the purification of products from micro-reactors used in, e.g., combinatorial chemistry, and for the pre-treatment of compounds to be analysed in micro-scale total analysis systems. At the same time, increasing attention has had to be paid to alleviating potential impacts of solvent usage on the environment caused by solvent losses through entrainment or dissolution in aqueous discharge streams, and through air emissions.

In this paper we discuss recent developments in our laboratory to develop alternative solvents and extraction concepts for the separation and production of chemicals and biochemicals. We show that in some cases conventional solvents can be tailored to modify their physical properties while retaining their chemical functionalities, and that this can lead to dramatic advances in pollution reduction through elimination of many energy-intensive unit operations required in some pharmaceutical processing. We also show that some advantages can accrue by avoiding the use of bulk organic solvents altogether by relying on the use of non-volatile colloidal aggregates and coated nanoparticles dispersed within aqueous feed phases that are able to capture targeted solutes rapidly and efficiently, and that can be recovered by means other than settling or centrifugation.

## TAILORED SOLVENTS

The implementation of various pollution prevention regulations has resulted in an increased awareness of organic solvent use in chemical processing, and has reinforced the need to develop new technologies for the minimisation or elimination of solvent wastes. In many instances, the attributes that make a solvent ideal for a particular application, such as in chemical synthesis operations, can hamper subsequent processing steps in which the products or byproducts must be recovered in a second phase in which the solvent is significantly soluble in its own right, tetrahydrofuran (THF) in water being one such example. For these synthetic applications, significant processing advantages may be gained by using alternative solvents for existing processes or by developing new chemical routes to desired products that can exploit more benign solvent systems. Rational design and implementation of these solvents can lead to significant decreases in the environmental burden associated with solvent losses and in energy usage through the simplification of process flowsheets.

As one example of a "green" replacement for traditional solvents used in fine chemical processing, we have modified the solvent tetrahydrofuran (THF) to reduce its volatility and water solubility significantly while retaining its chemical characteristics. The structures of THF and nOTE (*n*-octyl tetrahydrofurfuryl ether), and some of their physical properties are shown in Figure 1. The addition of the alkyl tail to the THF ring through the ether linkage essentially eliminates solvent losses through vapor emissions and aqueous discharge streams, and allows for simplified processing options in reaction sequences.

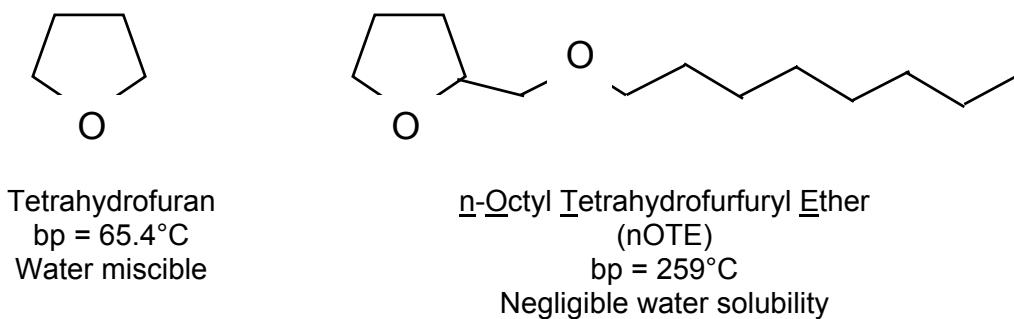

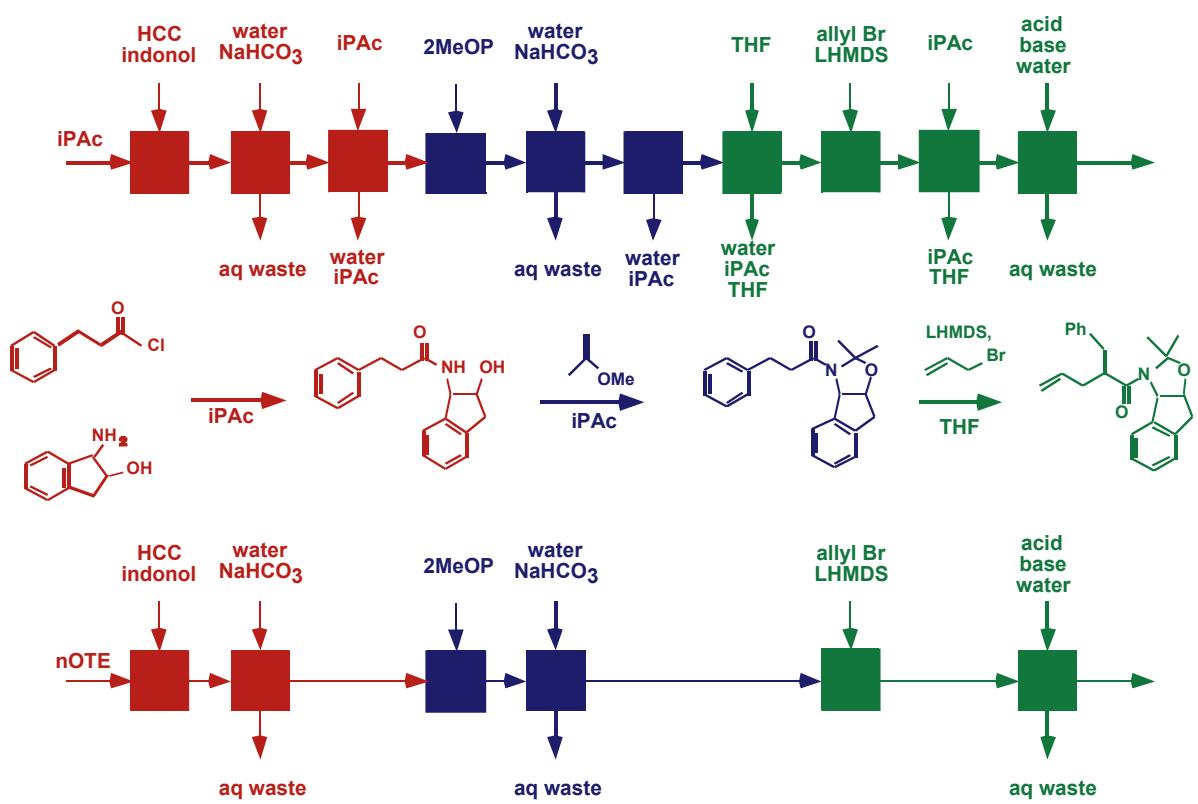

Figure 1. Tetrahydrofuran and its tailored analog, nOTE.

Figure 2 shows the energy-intensive separations and solvent exchanges that can be avoided using this new class of solvents (most notably or nOTE) in a series of reactions in the synthesis of the Merck HIV protease inhibitor, Crixivan. The traditional process uses iPAC in some of the reactions, but in others it is necessary to switch over to THF. This poses a problem as the reaction cannot be quenched with water and washed when it is carried out in THF because THF and water are completely miscible. It is therefore necessary to conduct another solvent switch, this time back to iPAC. In all cases, the aqueous waste streams leaving the different units must be treated offline, usually requiring either energy-intensive distillation or incineration. The new solvent, nOTE, can be used during the entire reaction sequence, so the solvent switches can be avoided, along with their attendant waste generation and need for offline separations, and the loss of the solvent to the aqueous wash streams is negligible owing to nOTE's very low solubility in water. Moreover, as the water uptake by nOTE is low, the need for drying is also obviated, or drastically reduced relative to that with iPAC, which has a fairly high capacity for water. Thus, it is clear that the solvent replacement strategy in this case can lead to rather significant reductions in the number of unit operations required, as well as in the off-line separations needed to regenerate the solvents, or to prepare the streams for discharge.

*Figure 2. Comparison of the published process for a series of reactions in the synthesis of intermediates for the HIV protease inhibitor Crixivan with the proposed process.*

## COLLOIDAL STRUCTURES IN TWO-PHASE SYSTEMS

Often co-solvents or solubilising agents are added to solvents to enhance their selectivity and/or capacity for targeted solutes, and sometimes these form micelles to provide a more positive interaction with the solute than that afforded by the pure solvent on its own. The separation of proteins using reversed micellar phases provides one example, in which the proteins are encapsulated within the cores of surfactant-stabilized water-in-oil microemulsion drops in equilibrium with a bulk aqueous phase. The selectivity of such operations can be enhanced dramatically by the addition of cosurfactants with specificity for the targeted protein. In the hydrometallurgical field, micelles have also been implicated in the selective extraction of metals from aqueous liquors. A drawback of these systems is that organic solvents are still used, which may have undesirable environmental consequences. Thus, there is interest in avoiding the use of bulk organic solvents altogether, one means being the use of biphasic aqueous systems, in which colloidal interactions can lead to the formation of two immiscible phases, each of which is composed primarily of water. For instance, the two polymers poly(ethylene glycol) and dextran, each of which is very soluble in water, are nonetheless themselves incompatible when mixed together in an aqueous solution, and cause a phase separation, such that one phase is rich in the PEG and the other in dextran. It has been shown that proteins, viruses, nucleic acids and even cells can partition between the two phases. It has also been shown that certain metal ions in solution can partition favourably to one phase over the other, pointing the way to an organic-solvent-free extraction operation, which could have many environmental benefits.

Biphasic aqueous systems can also be generated using micellar solutions that tend to phase separate as the temperature is increased, owing to increased micelle-micelle interactions, leading to a micelle-rich and a micelle-poor phase. Proteins and viruses can be separated through volume exclusion effects, and organics through solubilisation in the micelle-rich phase. Again, the avoidance of a bulk organic phase could provide a route to greener processing of process streams.

## COLLOIDAL EXTRACTANTS

In the examples cited above, the colloidal material is an integral part of the phase itself, and it is the bulk partitioning of materials between the two macroscopic phases, as mediated by the presence of the colloid, that is exploited in the separation process. Traditionally, interfacial transport between the two immiscible macroscopic liquids is enhanced by distributing one of these phases as a coarse dispersion in the other to provide the surface areas required for effective mass transfer operations. These operations can be beset by difficulties associated with poor contacting between the phases through flow maldistributions, while entrainment in the disengagement zones poses environmental discharge concerns. It is possible to avoid the use of macroscopically biphase systems by exploiting the solubilising powers of the colloids directly as colloidally dispersed extractants distributed spontaneously within the feed phase. We describe here two different systems, one based on the self-assembly of surfactant molecules to form micelles, and the other on the use of tailored nanoparticles coated with polymers or surfactants to provide the solvation of the targeted solutes.

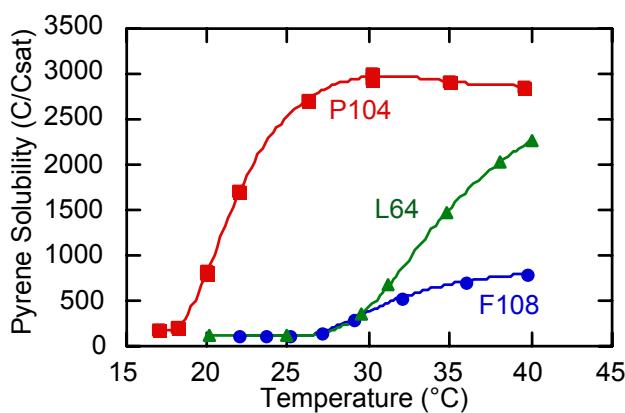

### Micellar Systems

Surfactant molecules self-assemble to form micelles with oily interiors that can solubilise hydrophobic compounds, surrounded by hydrophilic coronae that stabilise the colloidal dispersion against macroscopic phase separation. Surfactant micelles formed within the feed stream effectively remove organic solutes from the surrounding aqueous phase, and hence can be treated as solvents in their own right. The process is single-phased, with intimate contact between the feed and the colloidal extractant, which disperses spontaneously and does not require strong agitation to maintain the dispersion. Difficulties associated with flow maldistributions and channeling are by-passed, but the traditional use of countercurrent-type operations is no longer possible because of the thermodynamic stability of the dispersion, and the difficulty in getting the micelles to move independently of the surrounding fluid. Also, phase disengagement cannot be accomplished through normal gravitational or centrifugal settling operations, unless a phase separation can be induced through changes in the environmental conditions, such as temperature, pressure or ionic strength to form two immiscible phases, one rich in the loaded micellar solutions (the coacervate) and the other consisting primarily of the treated water phase. The loaded micelles can be separated from the feed mixture by ultrafiltration, however, where the membrane retains the loaded surfactant micelles and the solvent phase (usually water) is recovered as a clear permeate; this process is known as micellar-enhanced ultrafiltration (MEUF).

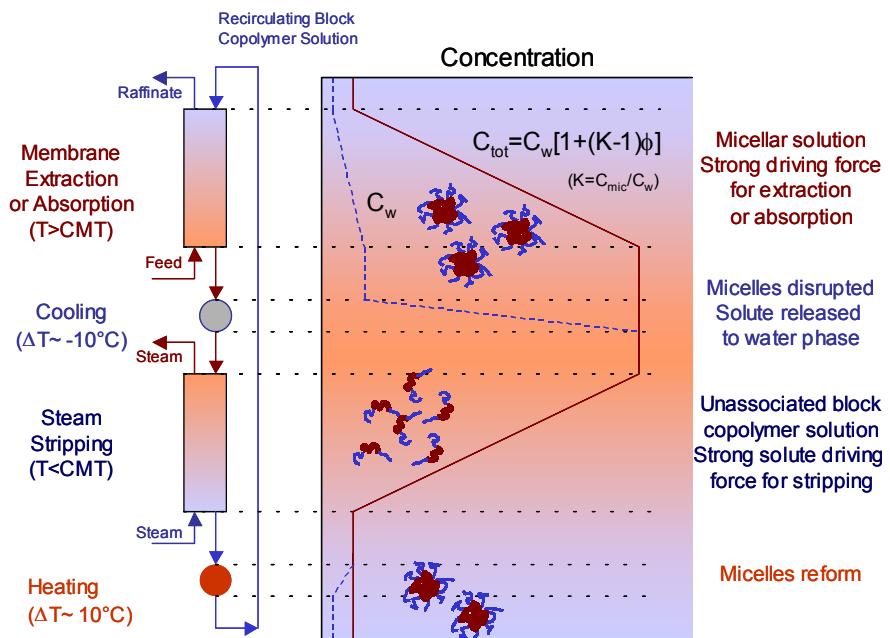

The effective loading of the micelles in MEUF is limited by the single-stage nature of the system, although in principle the membrane modules can be staged. An alternative approach which utilises the full capacity of the micellar systems in a true countercurrent process in a mechanically-simple process is to pass the micellar solution through the lumens of a hollow fibre bundle, with the feed phase introduced to the shell side of the membrane module. The micellar suspension can be treated as an aqueous-based solvent phase immiscible with the aqueous feed because of the intervening membrane since although water can pass through the membrane, the micelles cannot. The solute itself diffuses across the membrane and is picked up by the micelles. The large capacity of the micelles for the solute provides a strong

driving force for this trans-membrane diffusion, while the large membrane area available in hollow fibre membrane modules offsets the diffusional resistances offered by the membrane such that this process has potentially a greater volumetric efficiency than conventional two-phase solvent extraction processes. The recovery of the solute from the loaded micelles and regeneration of the micellar solution after the contacting step must be accomplished efficiently if this process is to find technological acceptance. Steam stripping, carbon adsorption, and solvent extraction are among the approaches that have been used successfully to perform the task. The efficiency of these approaches can be enhanced if the micelles are disrupted prior to the recovery stage so that they release their loads; in some cases the released solutes reporting to the aqueous phase may be at concentrations well above their aqueous solubilities and they form a separate phase, either solid or liquid, which can be removed by filtration, centrifugation or decantation. Temperature is one method that can be used to alter the micellar structures.

Figure 3 illustrates these concepts with a thermally-reversible block co-polymer micellar solubilisation process. The solubilisation of naphthalene in solutions of triblock Pluronic® poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide) (PEO-PPO-PEO) copolymers is seen to be a strong function of temperature; at low temperatures the polymers are readily soluble in water and do not form hydrophobic domains for the solubilization of the solute. As the temperature is increased, the PPO block is dehydrated and the micelles begin to form, providing the hydrophobic environment required for solubilisation. Thus, the capacity of the aqueous phase is greatly enhanced by the presence of the micelles. These observations can be exploited in the development of strategies for the removal of trace contaminants from aqueous streams as shown in Figure 4. In the micellar phase, the aqueous phase concentration (or activity) is low, even for high overall concentrations in the micellar solution, and the driving force for extraction or absorption of the solute in a countercurrent membrane process (the concentration difference across the membrane between the water phases) is kept high during the process. Upon cooling, the micelles fall apart and release the solubilised solute to the water phase. The dramatically increased aqueous phase concentration (or activity) provides a large driving force for either phase separation of the solute as a solid (e.g., naphthalene) or liquid (e.g., toluene), or, as shown here, for a stripping operation. The stripped polymer solution is then heated to form micelles again, and the solution is recirculated to the beginning of the process. Only small temperature changes would be required to change the capacity of the micellar solutions dramatically.

*Figure 3. The solubility enhancement of pyrene in Pluronic® PEO-PPO-PEO block copolymer solutions relative to the saturation solubility in water depends on the polymer molecular weight and composition. Significant solubilization occurs only at temperatures above which micelles begin to form.*

*Figure 4. Implementation of the block copolymer micelle solubilization scheme for removal of trace organics from contaminated waste streams showing the importance of small temperature swings for micelle regeneration.*

Rosslee and Abbott have recently reported another example in which the reversible assembly and issolution of micelles can be used to good advantage in separations. Redox-active surfactants such as (11-ferrocenylundecyl)trimethylammonium bromide form micelles which can solubilize hydrophobic compounds selectively when in the reduced state. On oxidation of the ferrocenyl moiety, however, these micelles break up into the monomers, releasing the solubilized materials. When a mixture of two hydrophobic compounds deposited on a substrate surface is challenged with the micellar solution, they are solubilized within the micellar cores, potentially with some selectivity for one component over the other such that the micelles are enriched in that component relative to the feed mixture. The solubilizate-laden micelles can now be transported to the cathode where the surfactants are oxidised, the micelles fall apart, and the released solutes deposit on the cathode surface. The surfactant monomers are returned to the anode, reduced to amphiphilic form and self-assemble to form new micelles ready to solubilize the solutes. While the selectivity in any given step is small, the separation effectiveness can be enhanced dramatically by redissolving the deposited material now enriched slightly in one of the compounds, and going through the micelle dissolution process once again to deposit an even richer mixture on the electrode surface. In one set of experiments in which this cycle was repeated five times an initial equimolar mixture of the two compounds was resolved to 97% purity.

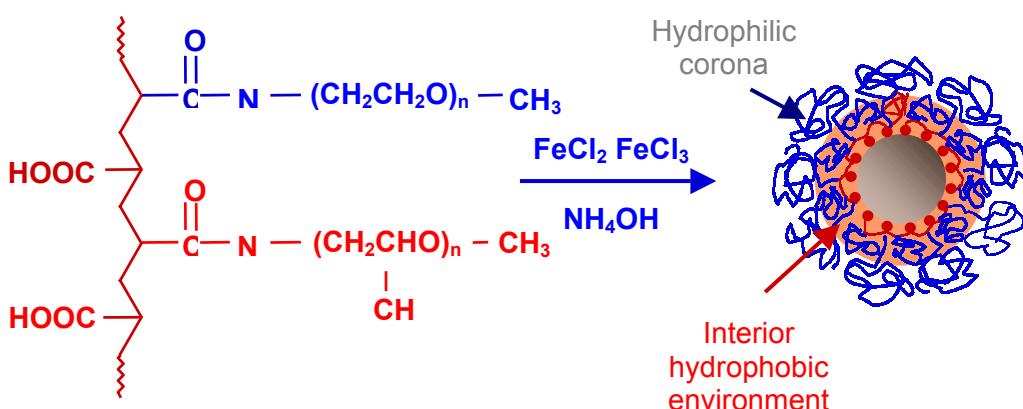

The two examples given here rely on changes in the temperature and the oxidation state of the surfactant, respectively, for the disruption of the micelles and release of the solubilizates. Other stimuli can also be used for this purpose, as there are many other physical driving forces that can be used to alter the state of the surfactant, including pH, ionic strength, pressure and, in the case of photoresponsive surfactants, light. The challenge in some cases would be to scale these processes up from small-scale operations ideally suited for microchemical and low volume/high value-added operations to large-scale production

operations. Nonetheless, they offer intriguing opportunities for the green processing of chemicals and biochemicals by colloidal solvent extraction in which the use of bulk organic solvents can be bypassed in favour of the higher molecular weight and non-volatile surfactant and polymer self-assembled colloidal extractants.

### Coated Nanoparticles as Extractants

Possible disadvantages of self-assembled surfactant micellar systems include the necessary presence of monomeric surfactants at the critical micelle concentration, which cannot be ultrafiltered and can end up either in the recovered product phase or as counter-contaminants of the feed stream being treated. This problem can be overcome to a large extent using specially prepared nanoparticles coated with various self-assembled layers of surfactants and polymers to provide an environment for effective recovery and/or separation of materials from dilute solutions. With coatings covalently attached to the particle surface, these particles behave as micellar systems but without some of the disadvantages of monomer loss and micelle dissolution upon dilution or change in solution conditions. The particles must be captured and regenerated for subsequent reuse, and the solute must be recovered. This capture can be done through ultrafiltration, or the particles can be induced to agglomerate to form large flocs that can be microfiltered. Alternatively, deep-bed filtration of the particles can be attempted. These techniques can be confounded if there are other nano- or microscopic materials present, such as particulates or cell debris, and it would be advantageous to use another handle to latch onto the particles. One approach is to use magnetic nanoparticles, which can then be recovered by high gradient magnetic field separation techniques.

One class of particles that we have synthesized is shown on Figure 5, where the stabilizing comb-like polymer is amphiphilic in character; along the polyacrylic acid backbone are attached both PEO and PPO polymers, the PEO providing the stabilization of the particles in suspension, and the PPO collapsing to provide a strongly hydrophobic shell surrounding the particle. The solutes of interest can be either solubilized directly within the layer, or can adsorb through specific interactions with the external moieties on the coating surface. These particles have high surface areas per unit volume, and minimal transport resistances owing to the small diffusional distances between particles. They can also be used in systems with high solids content, such as cell suspensions or in the extraction of natural products.

*Figure 5. Synthesis and structure of an amphiphilic magnetic nanoparticle. The PPO domains can solubilise organic solutes, while the PEO chains stabilise the particle dispersion in water.*

We compare the partitioning of a range of solutes between water and the PPO shell with the results reported by a number of workers on Pluronic® copolymer micelles. Clearly, the good agreement between the two sets of data shown in Figure 6 indicates that the environment afforded by the chemisorbed polymers on the particle surfaces is similar to that in the Pluronic® micelle cores, and that high solute loadings (~0.1-0.5 g/g PPO) can be attained. The particles themselves can be filtered from the aqueous solution using high gradient magnetic separation, in which the particle-laden stream is passed through a bed of stainless steel mesh inserted between the poles of an electromagnet that can generate fields of up to 2 Tesla; the wires in the mesh dehomogenise the magnetic field, creating very high gradients near the wire surfaces that are sufficient to hold even the small (10 nm) particles at the wire surface, effectively removing them from the suspension. The particles are collected by turning the magnets off and flushing the mesh with a clean aqueous stream. They can be regenerated either by steam-stripping of the particles while trapped in the bed, or the solute can be removed by extraction with a small amount of solvent and recovered by distillation. The partitioning of weak acids or bases to the coated nanoparticles can be controlled by pH, which can be selected relative to the  $pK_a$  of the material to either drive the solubilisation of the stripping operation.

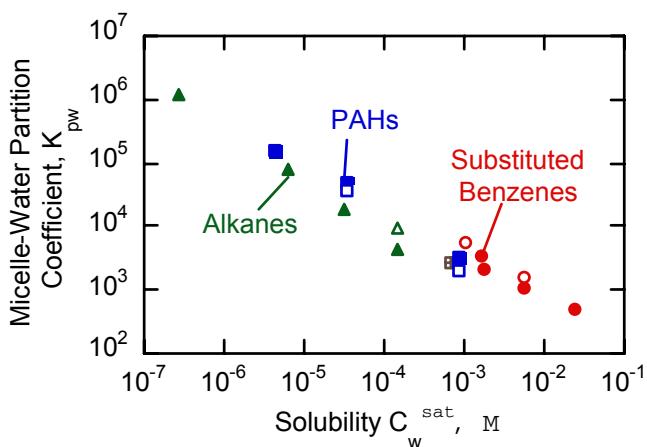

Figure 6 . Partitioning of organic solutes to PPO domains in Pluronic(r) micelles (solid symbols) and magnetic nanoparticle shells (open symbols).

In these systems the solvent phase is tethered to the nanoparticles, which themselves can be readily recovered through the application of an external magnetic field, and this can provide some unique benefits from the standpoint of green processing applications.

## CONCLUSIONS

The need for alternative approaches for using solvents in chemical and biochemical separation processes is dictated by the increasing awareness that their impact on the environment must be minimised. We have shown that by simple modification of a conventional solvent (THF) through the attachment of an alkyl tail, we can change its physical properties significantly to minimize both its water solubility and its potential to be lost to the environment through vapour emissions, and yet can retain its chemical functionality. The utility of such a solvent was demonstrated in the industrially-relevant process for the synthesis of an HIV protease inhibitor, where it was noted that we can eliminate many of the unit operations used in the published process

We have also discussed a few methods for the avoidance of a bulk organic solvent altogether through the use of colloidal extractants dispersed within the aqueous feed phase, either in the form of micelles, or as amphiphilic polymers attached to magnetic nanoparticles. Advantages associated with these systems include the wide range of polymeric species that can be envisaged, and that can be tailored to the specific needs in any particular chemical separations process. This is a rich area that has significant potential in a range of process industries, and provides many challenging and rewarding avenues for research and development.

#### **ACKNOWLEDGEMENTS**

I wish to acknowledge the contributions of the current and former students to the research results reported here. Linda Molnar, Bain Chin, Laura Cermenati and Professor Steve Buchwald participated in the tailored solvents work, supported by the DOE, EPA and NSF. Patricia Hurter and Paschalis Alexadridis conducted the thermodynamics and solubilisation studies on Pluronic® copolymer systems. Geoff Moeser, undergraduate student Kaitie Roach and Professors Paul E. Laibinis and William H. Green were responsible for the work on the polymer-stabilised magnetic fluids, which was supported by the NSF. Geoff Moeser has also received support in the form of a Fellowship from Kodak.

# ACHIEVING HIGH-PERFORMANCE LOW-COST PROCESSES FOR THE MANUFACTURE OF ORGANIC CHEMICALS USING PHASE TRANSFER CATALYSIS<sup>[1]</sup>

Marc Halpern

PTC Organics, Inc., Mt. Laurel, New Jersey, USA

Phase Transfer Catalysis, PTC, is widely used in the commercial manufacture of specialty and commodity organic chemicals. PTC can be described as catalytic one-step extraction and reaction of anions. PTC can also be used to simultaneously extract and react anions (or easily ionized organic compounds) from waste streams and convert them into value added products. Such waste streams can include cyanide from mining, mercaptans from petrochemicals and phenol from chemical processes. PTC processes provide many cost and performance benefits, including high yield, short cycle time, flexible choice of solvent, reduced solvent usage, lower excess of reactants, use of alternate less expensive raw materials and a variety of safety and environmental benefits.

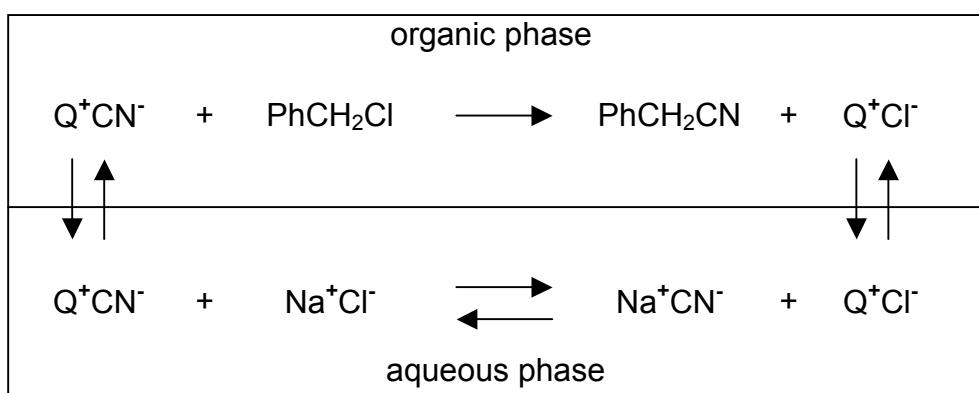

## INTRODUCTION

Phase transfer catalysis (PTC) is used in hundreds of commercial processes to manufacture organic chemicals including agricultural chemicals, monomers, polymers, pharmaceuticals, additives, dyes and colors, photographic chemicals, flavors and fragrances, explosives, rubber chemicals and a wide variety of specialty and fine organic chemicals [2, 3]. PTC can also be used to remove certain anions from waste streams and convert them into value added products. This paper will describe the mechanism of PTC, selected applications of PTC, the benefits of PTC and how PTC may be used to convert byproduct streams (such as cyanide from mining operations, mercaptans from petrochemicals and phenol from chemical processes) into value added products.

## MECHANISM

Since this paper is being presented at a Solvent Extraction conference, phase transfer catalysis may be described as a catalytic one-step process for EXTRACTION and REACTION of anions. The goal of most PTC systems is to convert anions into value added products. Figure 1 illustrates the mechanism of PTC [4] by example, for the extraction and reaction of cyanide to produce the agricultural chemical and pharmaceutical intermediate benzyl cyanide. The catalyst is a quaternary ammonium cation, Aliquat® 336 (trademark of Cognis Corporation; methyltricaprylyl ammonium), represented by Q<sup>+</sup>. Starting at the left side of Figure 1, the ion pair Q<sup>+</sup>CN<sup>-</sup> distributes between the aqueous phase and the organic phase. For the case of the highly lipophilic Aliquat 336 shown here, this distribution happens to be > 99% in the organic phase. Once the cyanide has been transferred to the organic phase, it can react with benzyl chloride to produce the benzyl cyanide product and liberate

chloride as the leaving group byproduct. When the irreversible organic phase reaction liberates the chloride leaving group, it pairs with  $\text{Q}^+$  to form  $\text{Q}^+\text{Cl}^-$  which also equilibrates between the two phases. The  $\text{Q}^+$  cation can then pick up another cyanide anion from the aqueous phase and the cycle restarts. The cyanide anion reacts with greatly enhanced reactivity due to three reasons: (1) the cyanide anion is actually solubilized in the organic phase by  $\text{Q}^+$  and therefore the reaction with the benzyl chloride is homogeneous (not interfacial), (2) the cyanide anion is stripped of most of its hydration shell once transferred into the non-polar organic phase and is thereby greatly activated and (3) the bulky  $\text{Q}^+$  cation forms a loose ion pair with the cyanide anion, rendering the cyanide ion much more reactive than if it were associated with a small  $\text{Na}^+$ , for example. In all, the mechanism includes two “extraction” steps, one ion exchange step and one actual chemical reaction in which bonds are formed or broken. Only the chemical reaction is irreversible (the other three steps are equilibrium steps) and that is what drives the catalytic system forward to completion. On balance, the phase transfer catalyst  $\text{Q}^+$ , transfers cyanide to the organic reaction phase and transfers the chloride leaving group to the aqueous phase while benzyl chloride is converted into benzyl cyanide.

*Figure 1. Phase transfer catalysis mechanism (illustrated by CN/Cl reaction example).*

### SCOPE OF APPLICATION

There are literally hundreds of anions which can be successfully transferred and reacted under PTC conditions. As a result there are 10,000 publications and 2,000 patents which describe applications in 40 broad reaction categories. Table 1 shows examples (partial list) of anions which have been reacted under PTC conditions. Note that the list includes neutral molecules such as phenol, mercaptans and carboxylic acids which can easily be ionized to anions at high pH. Table 2 shows the reaction categories in which PTC excels.

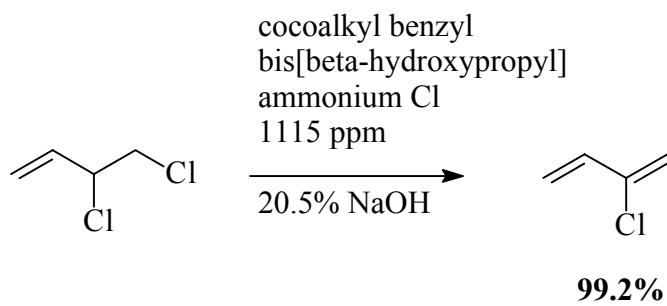

*Table 1. Examples of anions successfully reacted under PTC conditions.*

Bases	hydroxide, carbonate
Inorganic Nucleophiles	cyanide, azide, fluoride, bromide, iodide, thiocyanate, cyanate
Organic Nucleophiles	phenol, alcohols, carboxylic acids, mercaptans, heterocycles, Most organic compounds containing an O-H, C-H, N-H or S-H group with a pKa of under 23
Oxidizing Agents	permanganate, hypochlorite (bleach), dichromate, peroxide
Reducing agents	bороhydride, formate, dithionite, nitrite

*Table 2. Selected reaction categories in which PTC excels.*

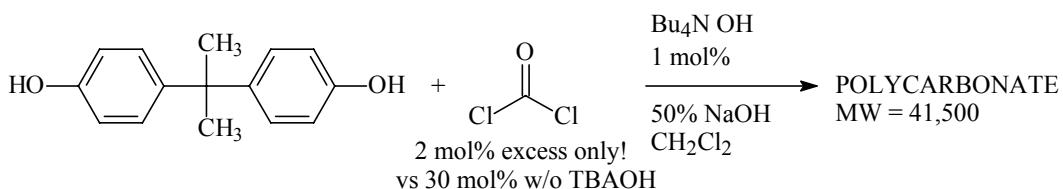

Etherification (O-Alkylation)
Esterification (carboxylic acids with alkyl halides)
Transesterification
N-Alkylation
Thioetherification (S-Alkylation)
C-Alkylation (nucleophilic)
Cyanation
Fluorination
Iodination
Azidation
Hydrolysis (Saponification)
A variety of nucleophilic aliphatic substitutions
A variety of nucleophilic aromatic substitutions
Reactions of N-H, O-H, and S-H groups with highly water-sensitive compounds including acyl halides, sulfonyl halides, phosphorous halides, esters, phosgene, others
Dehydrohalogenation
Carbene Reactions
Oxidation
Epoxidation
Reduction
Hydrogenation
Carbonylation
Michael Addition
Aldol Condensation
Darzens Condensation
Wittig
Condensation Polymerization
Radical Polymerization
Transition Metal Co-Catalyzed Reactions
HCl/HBr Reactions
Any reaction above for polymer modification

As will be shown in the next section, there are many benefits in using PTC in industrial applications, most of which focus on cost savings and/or pollution prevention. Following are some examples of industrial applications and highlights of their key benefits:

*Figure 2. Continuous dehydrohalogenation to produce a large scale monomer [5].*

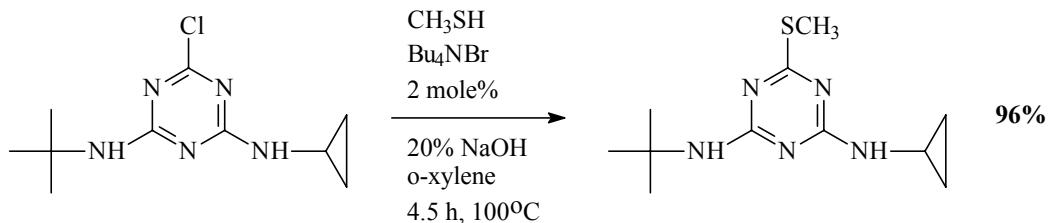

Achieved:  
Productivity: 16 tons/hr, 99.2% yield and NaOH usage of only 0.8 mole % excess!

*Figure 3. Outstanding reduction of excess hazardous high volume raw material [6].*

Achieved:

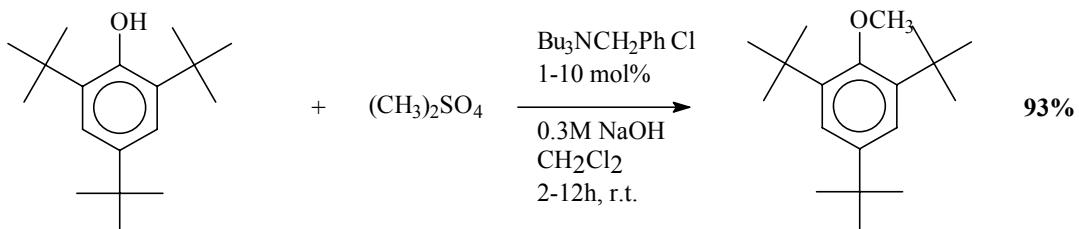

Great improvement in safety and environmental by reducing phosgene excess by 94%!  
PTC provides 200X less hydrolysis of phosgene/chloroformate according to GE patent.

*Figure 4. Thiolation [7] (using methyl mercaptan).*

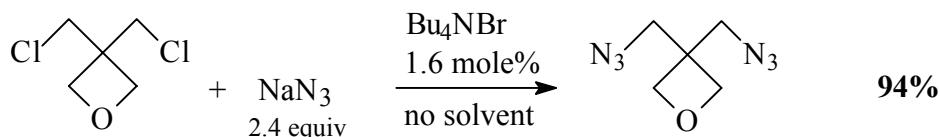

Achieved:

High yield for > 40 triazines, reduced cycle time by eliminating unit operations;  
no isolation of intermediates; achieved single solvent for 3 steps with low emissions.

*Figure 5. Etherification [8] (O-alkylation).*

- PTC usually best Williamson ether synthesis
- high yield etherification
- no need for excess pre-formed alkoxide
- usually short cycle time and easy workup
- non-dry mild reaction conditions
- aliphatic and phenolic O-alkylation many commercial bis-phenol A processes

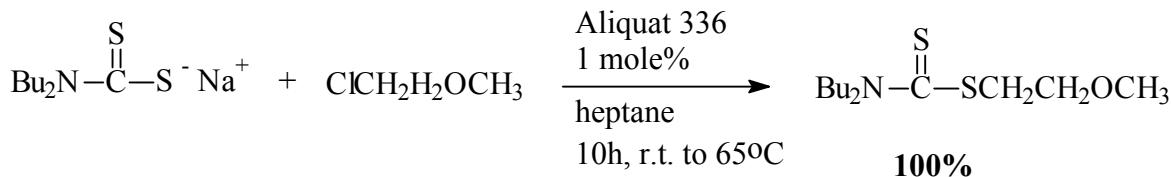

*Figure 6. High yield solvent-free hazardous nucleophilic displacement [9].*

Achieved:

High yield, with no solvent; reduced excess of explosive reactant; scaled up to 200 L.

### Sulfur Removal from Diesel Fuel [10]

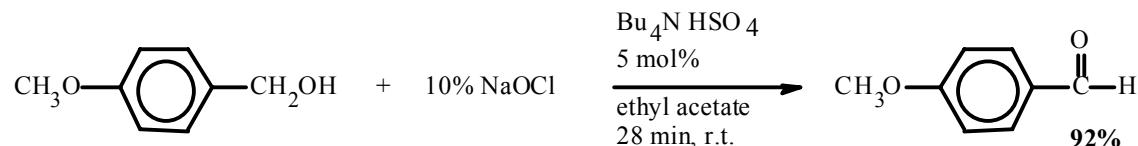

Legislation in the US and Europe reduced the permitted sulfur levels in diesel fuels by 84% during the past few years. PTC/H<sub>2</sub>O<sub>2</sub> was used as part of a process to achieve excellent desulfurization of diesel oil. A key sulfur component of diesel oil is dibenzothiophene and was quantitatively oxidized using 0.5 wt% Aliquat 336, 0.3 wt% phosphotungstic acid and 11% aq. H<sub>2</sub>O<sub>2</sub> (6.4 wt% on a 100% basis) at 60°C. Since H<sub>2</sub>O<sub>2</sub> is expensive, the PTC oxidative desulfurization (ODS) is preceded by hydrodesulfurization (HDS). HDS of gas oils to < 0.5 wt% sulfur is difficult. Thus, sequential HDS followed by PTC ODS was used to achieve 0.005 wt% sulfur, which is an order of magnitude lower than US and European requirements.

*Figure 7. Thioesterification for lubricant [11].*

### Carbonylation

Phase-transfer catalysis offers a variety of conceptual and practical advantages when performing carbonylations as described in [2] (Chapter 13). Among the advantages unique to PTC is the ability to transfer the anionic forms of metal carbonyls to the organic phase, in which CO is about 10 times more soluble than in water, which further leads to less hydrolysis of CO to formate and esters to acids. For example, malonic esters can be made by PTC carbonylation of ethyl chloroacetate at 1 atm CO at 25°C in the presence of cobalt carbonyl [12]. Ni(CN)<sub>2</sub> was used for the PTC double carbonylation of alkynols, using PEG-400 as the phase-transfer catalyst, LaCl<sub>3</sub> as an additional co-catalyst, toluene as the solvent, and 5.0 N NaOH as the optimum base concentration [13]. Yields of ene-dicarboxylic acids were up to 97%. PTC carbonylation has also been used to convert alkyl halides to acids and esters, and aryl halides to aryl carboxylic acids.

*Figure 8. Oxidation [14] (hypochlorite).*

Achieved:

High yield in short reaction time at room temperature;  
inexpensive oxidizing agent/no transition metal with high selectivity (vs. over-oxidation).

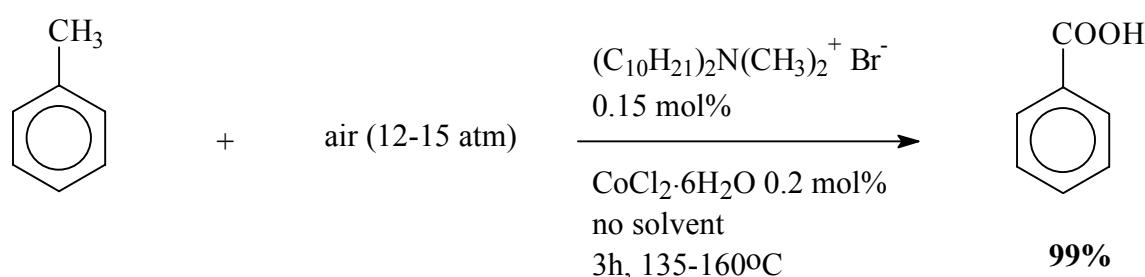

Figure 9. Oxidation [15] (air).

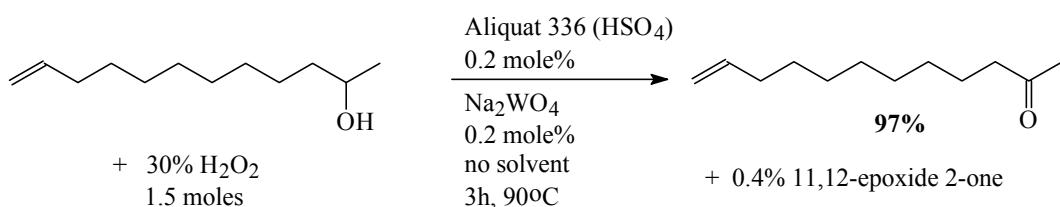

Figure 10. Oxidation [16] (hydrogen peroxide).

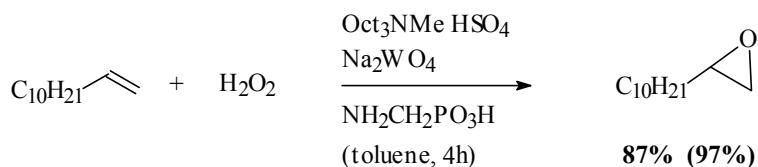

Figure 11. Epoxidation [17].

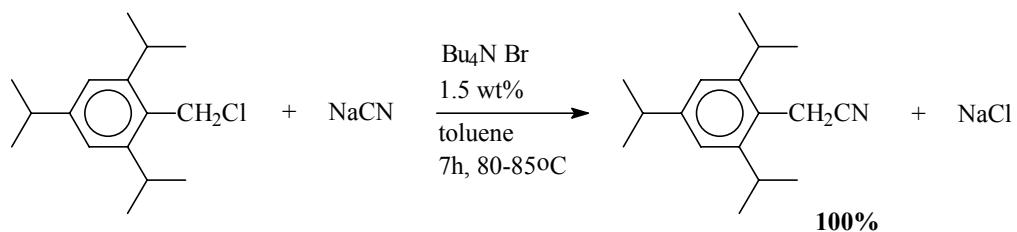

Figure 12. Cyanation [18].

Achieved:

Yield increase of 19% vs previous DMSO process. 100% recycle of toluene solvent vs no recycle of DMSO with 40% less solvent taking up reactor space. 95% (!) less cyanide excess, 85% (!) less aqueous waste, 3 less workup unit operations and better controlled exotherm through agitation vs. stepwise cyanide addition.

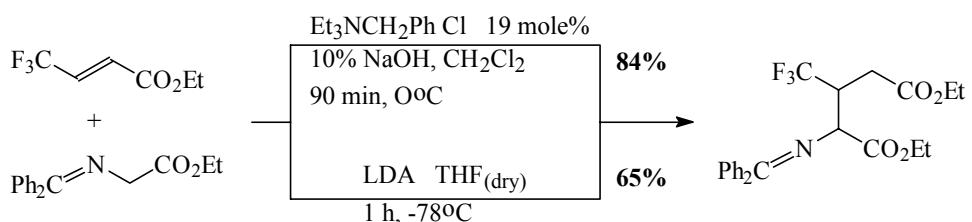

Figure 13. Michael Addition [19].

Achieved:

Eliminated very expensive hazardous organic strong base (LDA) at very expensive very low temperature with 19% yield increase!  
Multiple Michael addition to acrylates used for lubricants also reported [20].

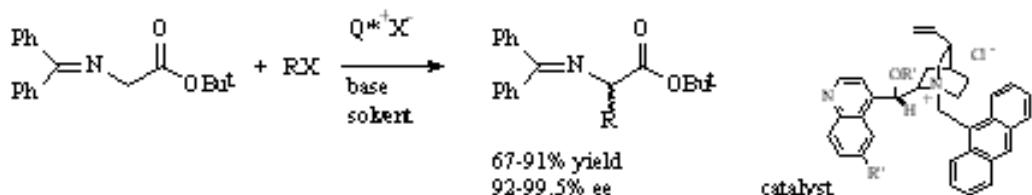

Figure 14. Chiral alkylation [21].

## BENEFITS OF PHASE TRANSFER CATALYSIS

Table 3 shows the primary benefits provided by PTC systems. There are several fundamental underlying reasons for the ability of PTC to provide these benefits and they are mostly related to the two phase nature of PTC systems and the ability to carefully regulate the transfer of species between the phases. As noted in the Mechanism section above, high reaction rates are achieved due to the co-location of the reactants in a single phase, the reduced hydration of the anion and the looseness of the ion pair. This results in advantageously reduced cycle time. The lower energy of activation achieved in PTC systems can also be exploited to perform the reaction at lower temperatures. Reduced temperature may sometimes be important not only to reduce energy costs but also to reduce the heat history of the reactants and products, thereby increasing the purity or assay of the product which in turn may lead to lower separation costs. PTC systems often achieve higher yield than non-PTC systems, because byproducts can be minimized and equilibrium reactions can be replaced by irreversible reactions (e.g., performing esterification by the reaction of an alkyl halide with a carboxylic acid salt instead of an alcohol with a carboxylic acid). One surprising advantage of PTC systems is the ability to work with highly water sensitive compounds such as acyl halides, phosgene, sulfonyl halides, phosphoryl halides, esters and anhydrides. This ability is due to the ability to “protect” the water sensitive compound from hydrolysis by either working under anhydrous solid-liquid PTC conditions, or if a water phase is used, by using the catalyst to transfer the anion to the organic phase with very low agitation thereby minimizing interfacial hydrolysis. When hydrolysis is minimized, yield increases. The ability to minimize hydrolysis also results in significant cost savings by reducing the amount of excess reactant used to several mole%. As shown in the applications section above, this has been achieved to reduce excess phosgene from 30 mole% to 2 mole%, excess cyanide from 70 mole% to 5 mole% and excess expensive borohydride from 30 mole % to 4 mole%.

Another great advantage of PTC is the flexibility in choosing solvent. The proper choice of phase transfer catalyst can allow almost any anion to be transferred into almost organic liquid. Therefore, any reactant or product which is a liquid can be used as the solvent and so-called "solvent-free PTC" is achieved. If a solvent is absolutely necessary, it can be chosen based on cost, recovery, toxicity, environmental considerations, recrystallization procedures in later or earlier steps or almost any other reason. The choice of solvent in PTC is rarely dependent on the ability of that solvent to dissolve salts. Therefore, one can very often replace DMSO, DMF, NMP, DMA and other polar aprotic solvents with solvents which are easy to recover such as toluene and MIBK.

One of the greatest cost advantages in using PTC is the ability to substitute expensive hazardous strong bases with inexpensive inorganic bases. Often, the combination of PTC with sodium hydroxide can replace sodium methoxide, ethoxide, t-butoxide, sodium amide, sodium hydride, sodium metal and sometimes even LDA. Savings achieved are usually in the range of \$1,250 to \$18,000 per ton of strong base purchased [22].

### **PTC APPLICATION TO BYPRODUCTS FROM MINES AND CHEMICAL PROCESSING**

This ISEC 2002 conference is attended by a significant number of professionals from the mining and heavy chemicals industries who may not be likely to be interested in the manufacture of fine organic chemicals. However, we may be able to offer those individuals the opportunity to substitute some of their waste treatment costs with profit!

For example, mining and electroplating companies generate large aqueous waste streams containing cyanide. PTC can be used to catalytically extract cyanide from an aqueous phase and react it with an alkylating agent, such as benzyl chloride (list price ~ \$1.5/kg) to produce a value added product such as benzyl cyanide (list price ~ \$5/kg). This represents a significant opportunity for cyanide stream generators since it currently costs money to treat cyanide streams and with PTC it may be possible to generate profit from these streams. The economic feasibility would have to be evaluated on a stream-by-stream basis and depends on many factors, including the concentration of the cyanide in the stream. This reaction is illustrated in the Mechanism section above.

Organic compounds which are easily ionizable to anions at pH of 12 and under can also be catalytically extracted and reacted in one step from aqueous streams to produce value added products. An excellent example includes extracting phenol (or phenol derivatives such as bisphenol A, resorcinol and others) from a dilute aqueous stream at pH 11 and react it with any of a variety of alkylating agents to form phenyl ethers. In one report, 99.9% removal of phenol from a 5000 ppm aqueous stream was achieved using PTC and benzoyl chloride to produce an ester in 15 minutes at room temperature in either a batch or continuous process [23].

Mercaptans can likewise be catalytically extracted and reacted in one step from aqueous, gaseous or organic streams to produce thioethers (organic sulfides). It is noteworthy that mercaptans can be converted into thioethers without the need to pre-form the sodium mercaptide salt. The mercaptide salt can be formed *in situ* by passing the mercaptan over the base (e.g., NaOH) in the presence of the phase transfer catalyst and alkylating agent to efficiently produce the thioether.

## SUMMARY

Phase transfer catalysis provides great economic benefit and high performance in the manufacture of a very wide range of organic chemicals. Although significant expertise is required to develop and commercialize PTC opportunities, companies could improve profit and process performance by partnering with a process development company with dedicated and highly specialized expertise in industrial PTC (such as PTC Organics, www.ptcorganics.com) to identify, develop and commercialize opportunities. In addition, companies which generate waste streams with certain anions (such as cyanide from mining) may be able to convert their waste treatment cost centers to profit generators by applying the fundamentals and practical aspects of phase transfer catalysis.

*Table 3. Benefits of phase transfer catalysis.*

- **Increase Productivity**
  - ⇒ increase yield
  - ⇒ reduce cycle time
  - ⇒ increase reactor volume efficiency
- **Improve Environmental Performance**
  - ⇒ eliminate, reduce or replace solvent for lower emissions and/or easier workup
- **Increase Quality**
  - ⇒ improve selectivity
  - ⇒ reduce variability
- **Enhance Safety**
  - ⇒ control exotherms
  - ⇒ use less hazardous raw materials
- **Reduce Other Manufacturing Costs**
  - ⇒ eliminate workup unit operations
  - ⇒ use alternate less expensive or easier to handle raw materials such as replacing NaOMe/OEt, t-butoxide, NaH, NaNH<sub>2</sub>, Na metal or LDA
  - ⇒ reduce excess reactants
  - ⇒ reduce temperature

## SUPERCRITICAL FLUIDS: CLEAN SOLVENTS FOR EXTRACTION, REACTION AND CRYSTALLISATION

Adam S. O'Neil, Paul A. Hamley and Martyn Poliakoff

School of Chemistry, University of Nottingham, Nottingham, England

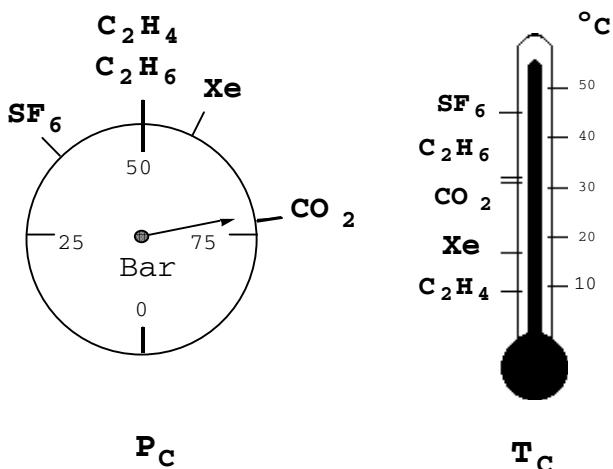

Supercritical fluids are becoming increasingly attractive as an environmentally acceptable replacement for organic solvents in chemical reactions and material processing. This paper highlights the properties of supercritical fluids, especially supercritical CO<sub>2</sub>, which offer particular advantages for extraction. The paper includes references to a number of reviews, which together provide a brief introduction to the State of the Art.

### INTRODUCTION

Supercritical fluids have excited the interest of physical chemists for the past 150 years. Indeed, a gas which displays some of the properties of a liquid remains fascinating even today [1]. However it is only recently that the fluids have aroused substantial technological interest. The primary reason for this is their solvent power which can often approach, and occasionally exceed, those of organic solvents but without the environmental complications associated with the use of those solvents.

In the early 1980s, there was significant research into possible applications of supercritical fluids but, sadly, the proponents of these fluids oversold their wares. The result was considerable disillusionment about the real value of supercritical solvents. Now, with the Montreal Protocol and a generally heightened environmental awareness, supercritical fluids are beginning to show their true value. However, it is not just the spectre of environmental regulation which is driving this comeback. The renewed interest is based on a broad foundation of recent academic research which has shown that supercritical fluids can provide an additional degree of control and performance in reaction chemistry and materials processing, which would be difficult to achieve with conventional solvents.

Supercritical fluids are gases compressed until their densities approach those of liquids. Such compression can only occur above the so-called 'critical temperature' of the fluid; at lower temperatures, the fluid will simply liquefy on compression. Several materials have critical temperatures close to room temperature (Figure 1). Of these CO<sub>2</sub> is currently the most commonly used due to its easy availability and relative cheapness.

*Figure 1. Schematic representation of the critical temperatures ( $T_c$ ) and critical pressure ( $P_c$ ) of selected pure materials with critical points near room temperature.*

This paper draws attention to some recent developments and concentrates on the particular properties of supercritical fluids which differentiate them from more conventional solvents. Apart from the excellent books by McHugh and Krukonis [2] and Jessop and Leitner [3], there have been recent reviews in the area of extraction and reaction chemistry [4], extraction, materials processing [5, 6], and new industrial applications [7].

## SUPERCritical SOLVENTS

The solvent properties of supercritical fluids have been known since the 19th century. Broadly, the solubility of non-polar materials in sc $CO_2$  is similar to that in light hydrocarbons, such as hexane. However, unlike solubility in hexane, the solubility in sc $CO_2$  can be “tuned”; the higher the applied pressure and hence the higher density of the fluid, the greater the solubility in the fluid. Furthermore, heating sc $CO_2$  under constant pressure causes a reduction in density which, in turn, can lead to a drop in solubility. Thus, one has the interesting possibility of depositing dissolved material onto a *heated surface* directly from the supercritical solution. Such deposition would be extremely difficult in an ordinary solvent. The solvent power of  $CO_2$  can be enhanced by adding so-called “modifiers”. The most common modifier is MeOH but it has a tendency to self-associate, thus limiting its effect at high concentrations. Work in our laboratory suggested that HCFC compounds, e.g.,  $CH_2FCF_3$  (R134a), etc., might be quite effective modifiers for sc $CO_2$  [8] and this has now been confirmed by Abbott and coworkers [9]. The critical points of mixtures are more complicated than for pure substances and the relevant phase behaviour is described in References [2, 3]. Although phase behaviour can appear discouragingly complex to those starting in the field, it cannot be ignored. Fortunately, once the basics have been mastered, the behaviour of a particular system is often quite easy to understand.

In the context of this Conference, it is important to stress that sc $CO_2$  differs from conventional hydrocarbon solvents in its affinity for fluorinated compounds, many of which are more soluble in sc $CO_2$  than they are in alkane solvents under similar conditions. The origins of this increased affinity are beyond the scope of this paper but, somewhat simplistically, it can be considered to be the result of the inherent volatility of the fluorinated compounds and also to thermodynamically favorable interactions between the fluorinated materials and  $CO_2$ . Whatever the origins of the effect, it has generated interest in the use of

fluorinated materials to aid the extraction of metal [10, 11] and in the use of fluorinated surfactants to create aqueous inverse micelles [12-16] and to emulsify polymers [10]. Indeed, DeSimone has coined the phrase “CO<sub>2</sub>-philic” to describe the behaviour of these fluorinated materials.

### RAPID EXPANSION

The dependence of solubility on fluid density has led to the development of a whole technology of powder and particle formation, based on the Rapid Expansion of Supercritical Solution (RESS) [17]. The technique is almost self-explanatory. It involves pumping a supercritical solution through an expansion nozzle or valve, see Figure 2(a).

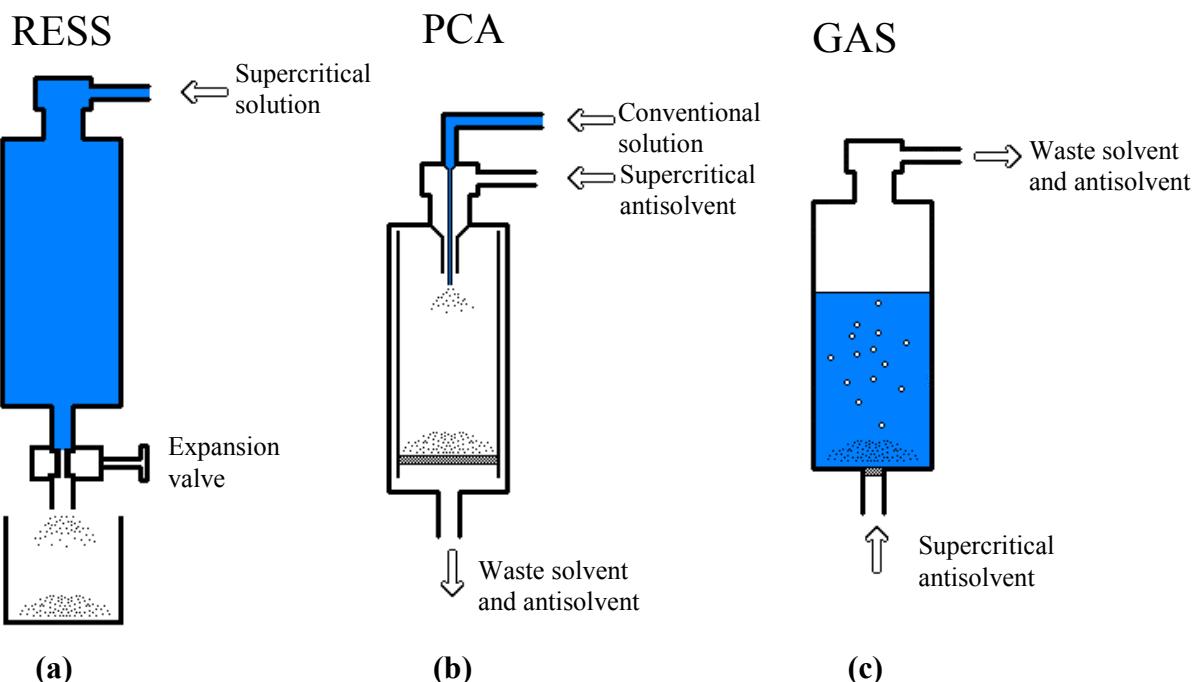

Figure 2. Principles of (a) the RESS, (b) PCA and (c) GAS processes for precipitating powdered materials using supercritical fluids. For further details, see references [17-33].

The solute is precipitated as a very uniform powder. The particle size and other properties of the powder can be controlled by varying the expansion conditions and by the careful design of the nozzle. Originally developed by Smith and coworkers [17], the technique has been heavily investigated by Debenedetti and coworkers [18, 19]. RESS has the disadvantage that it requires a relatively large amount of supercritical solvent, but this should be less of a hindrance in the deposition of coatings than it would be in the preparation of bulk materials.

RESS expansion is used for the recovery of extracts in the majority of analytical scale supercritical extractions. Although analytical techniques are largely outside the scope of this lecture, it should be noted that supercritical fluid extraction has widespread applications for detection of residual monomers or oligomers in polymeric materials, and more generally for the characterisation of thermally labile high molecular weight compounds such as polymer additives and stabilisers [34].

## SUPERCritical ANTISOLVENTS

A more recent development has been the use of supercritical fluids to precipitate materials which are insoluble in the supercritical solvents. The technique is similar to that used by synthetic chemists when they add one solvent to another to induce precipitation. There have been a number of different variations of the supercritical technique, the most important of which are the GAS (Gas Anti-Solvent, Figure 2(c)) and the PCA (Precipitation by Compressed Antisolvent, Figure 2(b)) [21-25] approaches. In the GAS process scCO<sub>2</sub> is pumped into a solution of a material dissolved in an organic solvent [2, 20, 33]; GAS precipitation has been used for materials as diverse as hormones and explosives. During PCA a solution is injected into a flow of antisolvent, for example a polymer in tetrahydrofuran (thf) is pumped into a vessel containing scCO<sub>2</sub>, the thf is stripped off, and the polymer is precipitated.

The advantage of both the GAS and PCA techniques is that the particle size of precipitated material can be controlled very precisely to generate a highly uniform product. Variations have already attracted interest in the pharmaceutical industry [35-39] where the morphology of a material can have a profound effect on its therapeutic value. The technique can also be combined with coating technology so that the material can be both precipitated and coated with a surfactant material in a single process.

Precipitation can also provide a method of synthesis. C<sub>60</sub>(gas) inclusion compounds have previously only been produced by using very high temperatures and pressures to force gas into the solid lattice [40]. Supercritical fluid antisolvent has been shown to provide a much simpler route to these compounds [26]. With CO<sub>2</sub> as an antisolvent, C<sub>60</sub> was precipitated as a solid around the CO<sub>2</sub> molecules, creating C<sub>60</sub>(CO<sub>2</sub>). We have extended this work to preparation [41] of hydrocarbon intercalates which cannot be prepared by the traditional forcing methods. These intercalates include C<sub>60</sub>(C<sub>2</sub>H<sub>4</sub>), C<sub>60</sub>(C<sub>2</sub>H<sub>6</sub>), C<sub>60</sub>(C<sub>3</sub>H<sub>6</sub>) and C<sub>60</sub>(C<sub>3</sub>H<sub>8</sub>). Our specific antisolvent techniques used included a new method, strongly analogous to conventional antisolvent precipitation. This method involves simple layering of a pressurised gas (ca. 10 MPa) over a C<sub>60</sub> solution. Slow diffusion of this gas into the solution creates a gradual reduction in solvating power and hence reduction in its ability to hold the C<sub>60</sub> in solution. This process was observed to progress over 2-3 days and to produce crystals of material that were measurable on a mm scale. Some of the crystals were of sufficient quality to allow characterisation by single crystal X-ray diffraction. This has proved successful for compounds which previously have been found to be extremely difficult to crystallise, virtually all other work in this area relies on powders as the only means of diffraction analysis [40].

## SUPERCRITICAL EXTRACTION

The use of SCFs for extraction is well established technique [2]. In the words [42] of Chien Wai, supercritical extraction is “over the hump”. For the extraction of metals, much of the current research is focused on finding the optimal ligands for sequestering and solubilizing the target ions [43]. This search is now beginning to lead to an understanding of the factors affecting solubility of such complexes [11]. When fully developed, this understanding will have a significant influence on the design of ligands for selective SCF extraction and for reaction chemistry [4]. There are several attractive aspects of scCO<sub>2</sub> for extraction. Firstly, it can eliminate the need for using volatile organic compounds. Secondly, the extractant can be recovered totally free of solvent merely by reduction in pressure. Thirdly, and most significantly, pressure can be used to tune the solvent power of scCO<sub>2</sub> and hence to alter the selectivity of the extraction. One of the interesting recent developments is the use of scCO<sub>2</sub> for reactive extraction. Recently, Wai and coworkers reported a striking example [44] of this, the reactive extraction of uranium oxide, UO<sub>2</sub>, into scCO<sub>2</sub> using the CO<sub>2</sub>-soluble complex TBP-HNO<sub>3</sub> (TBP = tri-*n*-butyl-phosphate) to convert the oxide to the nitrate, which had previously been shown to be soluble in scCO<sub>2</sub> modified with TBP [43].

## IMPREGNATION OF POLYMERS

As explained above, supercritical CO<sub>2</sub> is widely used for extraction on an industrial scale [2]. The appeal of scCO<sub>2</sub> is the absence of toxic residues and a relatively low temperature needed for the extraction process. Precisely the same properties make scCO<sub>2</sub> a useful solvent for the *impregnation* of materials into polymers and porous solids. Our research group at Nottingham has used this approach for a number of chemical reactions [45, 46], and the technique is being used for impregnating dyes into polymeric materials [47-49].

Dyeing is traditionally carried out in water, which generates very substantial clean-up problems before the wastewater can be discharged from the dye works [50-53]. The problem is exacerbated by the intense colour of the dyestuffs. Supercritical dyeing totally eliminates the need for water but there are still problems in achieving the uniformity of dyeing needed for the clothing industry. The technique has the interesting ability to dye several types of synthetic material simultaneously, for example, both the teeth and the backing material of zip fasteners.

At Nottingham, we have developed spectroscopic techniques for monitoring the impregnation of metal complexes into polymers [54]. We have found that impregnation is relatively uniform over small distances (centimetres) [55]. Once impregnated into the polymers, the metal compounds can be induced to react with the polymers photochemically [56] or even to modify the polymer either by isomerization of olefinic bonds or hydrogenation [46].

## REACTIONS IN SUPERCRITICAL FLUIDS

A number of chemical processes are traditionally run under conditions which are supercritical. Probably the best known example is the high-pressure polymerisation of ethylene which has been carried out for nearly 50 years [2]. Supercritical fluids (SCFs) offer a wide range of opportunities as solvents for chemical reactions and supercritical CO<sub>2</sub> is becoming increasingly important as a benign replacement for more toxic media [4, 57-60]. High pressure reactions, however, are more capital intensive than conventional low pressure processes. Therefore, supercritical fluids will only gain widespread acceptance in those areas where the fluids give real chemical advantages as well as environmental benefits.

Our research group initially became involved with SCFs via inorganic and organometallic chemistry, a field which we comprehensively reviewed recently [4]. We were among the first to recognise that the miscibility of H<sub>2</sub> with SCFs could be exploited for new chemistry and we generated a number of previously unknown organometallic dihydrogen complexes [61]. More recently we developed the use of miniature flow reactors to isolate new, highly labile alkene and dihydrogen complexes from SCF solution [62, 63]. At the same time, other groups were working on enhanced homogeneously catalysed reduction of CO<sub>2</sub> [59, 64, 65] and increasing the efficiency of catalytic hydrogenation of fats [66], our work on H<sub>2</sub>-complexes and flow reactors lead us to the supercritical hydrogenation of organic compounds. This initiated a fruitful collaboration between the University of Nottingham and Thomas Swan & Co. Ltd. The attraction of scCO<sub>2</sub> is that it offers new possibilities in chemical processing as well as being cleaner. Many of the limitations in current catalytic hydrogenation stem from the inherently low solubility of H<sub>2</sub> in conventional solvents. Above the critical temperature of CO<sub>2</sub>, 31.6 °C, H<sub>2</sub> is completely miscible with CO<sub>2</sub>. It also offers the possibility of converting from batch to continuous processes, with the advantages of smaller reactors, lower inventories of chemicals and increased safety. Several groups have reported the use of continuous reactors for hydrogenation[66-74]. Our own work has focused on the hydrogenation of compounds of interest to the fine chemicals industry. We have shown that scCO<sub>2</sub> and supercritical propane can be used as solvents for the continuous supercritical hydrogenation of a wide range of organic functionalities [68, 69].

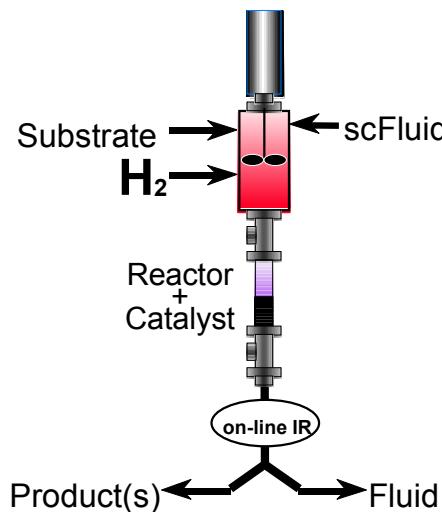

Figure 3. Schematic diagram of a supercritical flow reactor.

The organic substrate, H<sub>2</sub> and scCO<sub>2</sub> are mixed by the stirrer, and are then passed over a heterogeneous catalyst bed, such as Pd/Deloxan (a polyamino-siloxane support from Degussa), Figure 3. Depressurization of the system downstream gives phase separation of the CO<sub>2</sub> and organic products. Conditions can be optimised to give very high selectivity and efficiency in such a reactor. We have shown how this concept can be extended to other organic reactions, for example Friedel Crafts alkylation [75], etherification [76] using a solid acid catalyst and hydroformylation [77]. In each reaction, scCO<sub>2</sub> appears to offer significant advantages, as well as process intensification. Thus, supercritical hydrogenation of isophorone gives 99.6% selectivity for dihydro-isophorone [69], better than is achieved in most commercial hydrogenation processes for this compound. In the Friedel-Crafts reaction, there is high selectivity for mono-alkylation and long catalyst lifetime [75]. In hydroformylation, there is a very good selectivity and catalyst lifetime [77]. In all of the reactions, the products are recovered free from any liquid solvent, which greatly simplifies the subsequent work-up.

Near critical (ncH<sub>2</sub>O) and supercritical water (scH<sub>2</sub>O) have attracted much attention in the synthesis of metal oxides [4, 78, 79]. Most of the published work has been done in batch reactors, with limited control of the process. In contrast, flow reactors allow a better control of the experimental conditions. We have previously reported the synthesis of a large range of different nano-particulate single metal oxides in a flow reactor [80]. The materials, as fresh prepared, are crystalline, have very small particle sizes and a narrow size distribution. Flow reactors seem especially suitable for the synthesis of heterometallic compounds [78]. A solution containing a mixture of the metal salts at room temperature was mixed with a stream of water heated up to 400 °C by a pre-heater. After the mixing point, the mixture was cooled down immediately by a water cooler. Reaction temperatures at the mixing point were between 260 and 370 °C depending on the experiments. The pressure was kept constant and equal to 25 MPa by a back-pressure regulator (BPR). The high self-dissociation constant of water at near critical conditions allowed hydrolysis of the metal salts without addition of any base. The lower dielectric constant induced super-saturation and precipitation of small hydroxides, which underwent fast dehydration. The products were passed through a filter (to remove large aggregates) upstream of the BPR and were collected as suspensions. The solids were decanted and dried at 100°C. Examples include Ce<sub>1-x</sub>Zr<sub>x</sub>O<sub>2</sub> [80] and La<sub>2</sub>CuO<sub>4</sub> [81].

## EXPERIMENTAL TECHNIQUES

The prospects of carrying out experiments at high-pressure are often very discouraging to new workers in the field. Our group at Nottingham has developed a range of techniques to enable supercritical fluid experiments to be carried out on a small scale so that new ideas can be tested effectively, rapidly and, above all, safely. We have developed a range of miniature cells and components which together form a modular system. Even quite complicated apparatus can be assembled very easily from the basic modules [4, 82]. The high compressibility of supercritical fluids adds a whole new dimension to chemistry by allowing the solvent to be tuned. Unfortunately, it also adds an extra parameter which has to be optimised. The key to our work has been the use of spectroscopy, particularly infrared and Raman, to monitor processes in supercritical fluids [83, 84]. Reaction conditions can then be monitored in real time and conditions can be optimised much more effectively. In this way, quite wide areas of chemistry can be explored rapidly and the most useful applications of supercritical fluids can be identified.

## CONCLUSIONS

Working at high-pressure always introduces additional complications to any procedure. Therefore, the use of supercritical fluids in a particular process must be based on sound scientific reasons to justify the extra complexity. Fortunately, supercritical fluids offer a whole range of new opportunities to chemists. These opportunities are far more profound than merely complying with environmental legislation. The value of supercritical fluids lies in control. They allow materials and reactions to be manipulated more precisely, more effectively, and more efficiently than in conventional solutions. Supercritical science is inherently interdisciplinary. Scientists who are interested in applying supercritical fluids to their particular problem will find that workers in the field are willing to collaborate and are especially receptive to new ideas.

## ACKNOWLEDGEMENTS

We are grateful for the support of EPSRC Clean Technology Unit, the Royal Society, ICI, and the Royal Academy of Engineering for supporting work at Nottingham. We thank our colleagues, collaborators and coworkers for their help and advice and Mr. M. Guyler and Mr. K. Stanley for their technical assistance.

## ELECTRIC FIELDS IN SOLVENT EXTRACTION

Hans-Jörg Bart

Institute of Thermal Process Engineering, University of Kaiserslautern,  
Kaiserslautern, Germany

Electric fields influence mass transfer and hydrodynamics in solvent extraction. The transfer of ionic species may be affected by external electrical fields or an ionic Helmholtz double layer near the interface. The latter one is induced by adsorbed ionic surfactants and its influence can be quantified and related to  $\xi$  potential measurements. This will be shown in detail with the extraction of organic acids, where negative layers repulse and positive ones attract the solute anion and thus change the mass transfer velocity. The aspects of electric migration due to external fields on basis of the Nernst-Planck equation will be discussed too. Hydrodynamic effects like formation, coalescence and break-up of the droplets are also affected by electrical fields, which are again related to a change in mass transfer behaviour as is expressed with several examples.

### INTRODUCTION

The driving forces in separation processes are usually based on chemical potentials. Additional forces like centrifugal, gravity, pressure forces and electrical gradients can promote and intensify a certain task. The latter ones are important for mass transport and diffusion of electrolytes and also influence coalescence and formation of droplets [1-6]. In contrast to this, in wide industrial use are only electrostatic coalescers in the oil industry to separate fine dispersed aqueous droplets from crude oil [7].

In the following, aspects of droplet hydrodynamics and mass transfer in an electrical field will be discussed in detail. A special focus is on ionic surfactants which adsorb at the liquid-liquid interface. Their influence on mass transfer may then be via a different mechanism. A blocking effect of adsorption layers in a diffusional transport regime is well known and results in a reduction of mass transfer [8-11] and even Marangoni instabilities [12,13] are found. However, in the kinetic mass transfer regime, both an enhancement and retardation of mass transfer [13] is with Gibbs surfactant layers. When extracting ionic species, ionic surfactants will induce an electrostatic double layer, which can be related to the  $\xi$ -potential. As a result, in addition to the chemical potentials, an electrostatic potential difference exists. In order to quantify these effects, a combination of electrostatic and chemical potential differences as driving force has to be considered [14]. In an alternative manner, electrostatic fields can be used to induce migration of ions to the interface, even in the kinetically controlled transfer regime [15]. Furthermore, electrohydrodynamics with single droplets or droplet swarms will predominately change the mean Sauter diameters compared to the interfacial area and thus the mass transfer characteristics [16].

## REACTIVE MASS TRANSFER WITH ELECTRIC FIELDS

### Equilibria

As a prerequisite to understand chemical kinetics, one should know beforehand the reactive phase equilibria. The dissociation and complexation behaviour of the aqueous and organic species have to be taken into account for a proper hydrodynamic description. Recent  $g^E$ -models [17, 18] based on the Pitzer model [19] are capable of describing the non-ideal behaviour of strong and weak electrolyte mixtures. As an example, the extraction of acetic acid (HAc) with tri-octylamine (TOA) in toluene compared to isododecane in the presence of sodium chloride will be discussed. In this system the following reactions will occur:

The following extractive reaction stoichiometry will be seen, where a and b are derived from independent spectrometric data [20] (bar indicates organic species) :

$$K_{ab} = \frac{\overline{\text{TOA}_b \cdot \text{HX}_a}}{(\text{HX})^a \cdot (\text{TOA})^b} \times \frac{\gamma_{\overline{\text{TOA}_b \cdot \text{HX}_a}}}{\gamma_{\text{HX}}^a \cdot \gamma_{\text{TOA}}^b} \quad (5)$$

The Hildebrand-Scott-parameters which account for the non-idealities of the organic complexes and the physically extracted compounds HAc,  $(\text{HAc})_2$  are shown in Table 1 and the Pitzer parameters can be found elsewhere [21]. On the basis of binary data, it is possible to predict the behaviour of the quaternary systems  $\text{H}^+$ ,  $\text{Na}^+$ ,  $\text{Ac}^-$ , TOA resp.  $\text{H}^+$ ,  $\text{Na}^+$ ,  $\text{Cl}^-$ , TOA. For the quaternary system  $\text{H}^+$ ,  $\text{Na}^+$ ,  $\text{Ac}^-$ ,  $\text{Cl}^-$ , TOA, a new compound  $\text{TOA}\cdot\text{HCl}\cdot(\text{HAc})_2$  has to be introduced to correlate the experimental data. Figure 1 depicts the distribution coefficient of the anions ( $P_{\text{anion}}$ ) as a function of the aqueous acetic acid molality. As could be shown experimentally, in accordance with theory that there is no influence of electric fields on the phase equilibria of ionic solutes in aqueous/organic systems [15, 22].

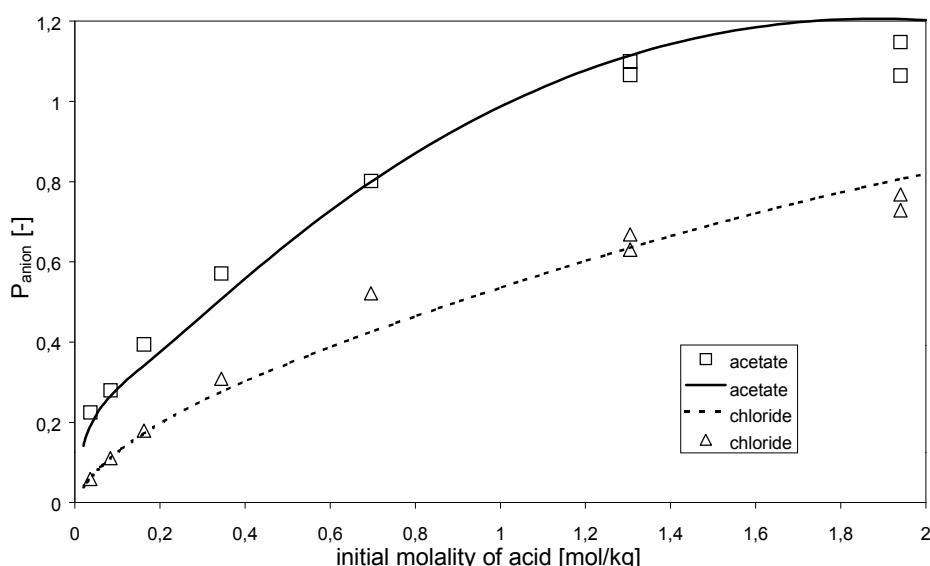

Figure 1. Distribution coefficient  $P$  of different anions as a function of the acetic acid concentration.

Table 1. Equilibrium constants and Hildebrand-Scott solubility parameters  $\delta$ .

System a:b	Toluene		Isododecane	
	$\ln K_{a:b}$ [-]	$\delta$ [cal $^{1/2}$ cm $^{-3/2}$ ]	$\ln K_{a:b}$ [-]	$\delta$ [cal $^{1/2}$ cm $^{-3/2}$ ]
toluene	-	8.9	-	-
isododecane	-	-	-	7.0
TOA	-	8.5	-	8.5
HA	2.726	10.1	1.883	10.1
(HA) $_2$	7.469	10.1	6.633	10.1
TOA·HA	4.778	9.567	3.768	9.567
TOA·(HA) $_2$	-	-	7.845	9.593
TOA·(HA) $_3$	14.953	9.610	-	-
TOA·(HA) $_4$	-	-	16.750	9.881

### Mass Transfer

In systems with liquid ion exchangers, the following transfer regimes may exist:

- chemical reaction regime,
- diffusion controlled regime and
- mixed regime, with both diffusional and kinetic resistances.

A discrimination can be made in a Lewis-cell type cell with a constant interfacial area. As is known, with increasing power input, diffusional resistances diminish as the diffusional boundary layer is reduced. The chemical reaction regime occurs when a plateau is reached when plotting initial mass transfer rates versus power input (rpm or vibrational rate), as is discussed in detail in literature [23, 24].

In order to model the chemical rate determined regime, the equilibrium equation with the 1:1 complex in a dilute system

can be split into the following molecular steps according to Danesi [25]:

The subscript "ad" represents those species which are adsorbed at the interface. Therefore, the first reaction step depicts protonation at the interface of an adsorbed TOA molecule. The first step is in quasi stationary equilibrium, which is in contrast to the two following rate determining steps:

This reaction represents the formation of an ion-pair molecule which is adsorbed at the interface. This molecule is then replaced by a fresh TOA molecule from the organic bulk phase in the third and last reaction step:

The interfacially adsorbed anion exchanger species are balanced according to Gibbs' law:

$$[\text{TOA}_{\text{ad}}] + [\text{TOAH}^+_{\text{ad}}] + [\text{TOAHA}_{\text{ad}}] = \frac{\alpha_m \cdot [\text{TOA}]}{\gamma_m + [\text{TOA}]} \quad (10)$$

$\alpha_m$  and  $\gamma_m$  are the adsorption constants which have been determined by interfacial tension measurements to be  $1.489 \times 10^{-3}$  for  $\alpha_m$  and  $8.156 \times 10^{-2}$  mol/kg for  $\gamma_m$  in isododecane [22]. To guarantee that the model is able to describe the equilibrium state ( $t = \infty$ ), the activities of the species are used instead of their concentrations. Combining the rate determining steps (Eqns. 7-9) and Eqn. (10) yields the kinetic rate equation,  $R'$ :

$$R' = \frac{(a_{\text{H}^+} \cdot a_{\text{A}^-} \cdot a_{\text{TOA}} - 1/K_{\text{EX}} \cdot a_{\text{TOAHA}}) \cdot (\alpha_m \cdot a_{\text{TOA}} / (\gamma_m + a_{\text{TOA}}))}{C_1 + C_2 \cdot a_{\text{H}^+} + C_3 \cdot a_{\text{H}^+} \cdot a_{\text{A}^-} + C_4 \cdot a_{\text{H}^+} \cdot a_{\text{TOA}} + C_5 \cdot a_{\text{TOA}} + C_6 \cdot a_{\text{TOAHA}}} \quad (11)$$

The constants  $C_1$  to  $C_6$  are functions of the kinetic parameters, where  $k_{-3}$  is calculated from  $K_{\text{EX}}$  ( $K_1 = 3.015$  [kg/mol],  $k_{-2} = 0.0108$  [ $\text{s}^{-1}$ ],  $k_2 = 83.07$ ,  $k_3 = 1814$ ,  $k_{-3} = 7192$  all in [kg/(mol s)]):

$$C_1 = \frac{k_{-2}}{k_2 \cdot k_3 \cdot K_1}, C_2 = \frac{k_{-2}}{k_2 \cdot k_3}, C_3 = \frac{1}{k_3}, C_4 = \frac{1}{k_2}, C_5 = \frac{1}{k_2 \cdot K_1}, C_6 = \frac{1}{k_{-2} \cdot K_{\text{EX}}} \quad (12)$$

At an equal interfacial covering of surfactants, the mass transfer of acetate is enhanced by cationic surfactants (DTACl, dodecyl trimethylammonium chloride), unaffected by nonionic surfactants (TX100 octylpolyethylene glycolether)<sub>10</sub>), and slowed down by anionic surfactants (NaLS, sodium lauryl sulfate; NaDdS, sodium dodecyl sulfate). This can be quantified when calculating the true interfacial concentrations,  $m_{\text{PG},i}$ , in the electrochemical double layer with the Boltzmann equation:

$$m_{\text{PG},i} = m_{\text{B},i} \cdot \exp \left( -\frac{z \cdot e \cdot \Psi_0}{k \cdot T} \right) \quad (13)$$

where  $m_{\text{B},i}$  is the bulk concentration,  $z$  is the valence,  $e$  is the elemental charge,  $k$  is the Boltzmann-constant and  $T$  represents the absolute temperature. The interfacial potential  $\Psi_0$  is calculated in accordance with the electric double layer theory after Stern [27], with the approximation of  $\Psi$  is about the zeta potential,  $\xi$  [28]:

$$\tanh \left( \frac{z \cdot e \cdot \Psi}{4 \cdot k \cdot T} \right) = \tanh \left( \frac{z \cdot e \cdot \Psi_0}{4 \cdot k \cdot T} \right) \cdot \exp (-\kappa \cdot x) \quad (14)$$

Here  $\kappa$  is the Debye-Hückel constant and  $x$  the distance to the interface which is estimated to be 3 nm [26] in the discussed system. There is a difference between bulk and interfacial concentrations in magnitudes, e.g., bulk pH = 3 and the interfacial pH = 1.0 after 60 min. at 298 K with  $7.5 \times 10^{-7}$  mol/m<sup>2</sup> NaDdS (or pH = 6.7 with DTACl) in a system of 1 % acetic acid, 10 % tri-n-octylamine in isododecane. This is similar for all ionic species involved according to the attraction/repulsion forces.

The model simulations in the kinetic regime are given in Figure 2. The nonionic surfactant TX100 has no influence; the cationic surfactant (DTACl) shows enhanced kinetics and the anionic surfactants (NaDdS, NaLS) a slowed down kinetics in a model derived in a surfactant-free environment. However, this interfacial polarization effect will dampen with higher ionic strengths and under system conditions where molecular or eddy diffusion dominate the mass transfer process in relation to the interfacial chemical reaction rate resistance.

The influence of the interfacial charge of the anionic surfactant NaDdS and the cationic surfactant DTACl on the transfer rate is shown in Figure 3. The upper limit in these experiments is given by the critical micelle concentration (cmc) of the components. In the range of lower interfacial charge, the systems behave as in Figure 2, an increase of the surfactant concentrations leads in the same way to a decrease of the initial flux for NaDdS as to an increase for DTACl. But at higher concentrations the mass transfer for the cationic surfactant increases non-proportionally with the interfacial charge and in a similar manner is even an increase instead of a stronger decrease in the anionic case. This can be explained by the constitution of the surfactant film at the interface, because an increase of the surfactant concentration leads to a transformation of the gas-analogous film into a condensed and strictly ordered surfactant film, which makes penetration and mass transfer easier. This is in accordance as with the other systems, e.g., water/acetone/toluene in the presence of NaDdS [29].

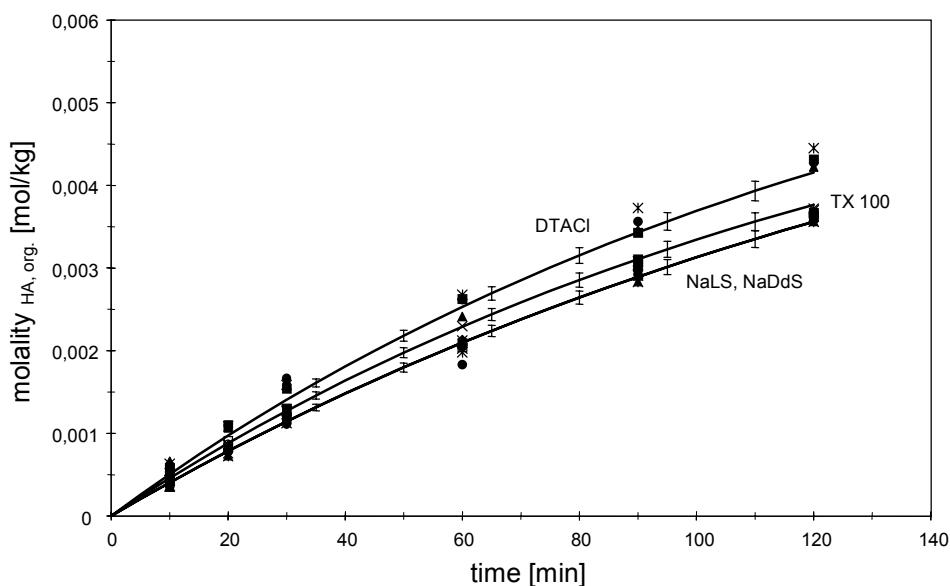

Figure 2. Model comparison at an equal amphiphile interfacial covering of  $7.5 \times 10^{-7} \text{ mol/m}^2$  (1 % acetic acid, 10 % tri-n-octylamine in isododecane, 298 K).

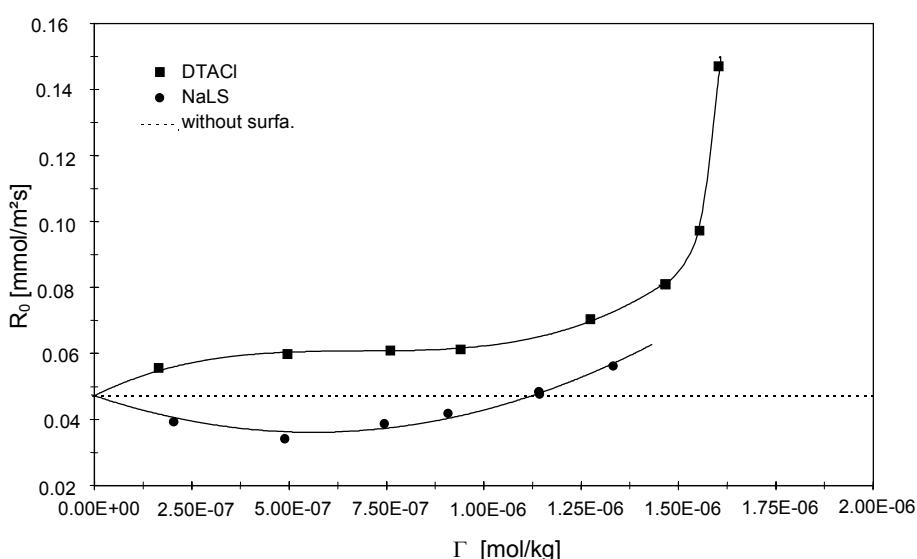

Figure 3. Influence of surfactants on the reaction limited regime, variation of  $\Gamma$  (1 % acetic acid, 10 % tri-n-octylamine in isododecane, 298 K,  $n_{or} = 180 \text{ rpm}$ ).

At surfactant concentrations near the cmc, an enhanced blocking of the surface and change of interfacial rheology and thus reduction of mass transfer may occur [30]. However, even low surfactant concentrations with species of high adsorption affinity may show a similar effect. As to this, it is essential to know the adsorption behaviour of single or mixed adsorption layers to properly predict their impact on interfacial transfer kinetics.

Similar results to those with surfactants can be obtained when applying DC fields. The mass transfer of ionic species in an electric field, when there is no current applied, is according to the Nernst-Planck equation [13]:

$$N_i = -D_i \cdot \nabla c_i - D_i \cdot c_i \cdot \nabla \ln \gamma_i + \frac{t_i}{Z_i} \cdot \sum_{j=1}^{n-1} Z_j \cdot (D_j - D_n) \cdot \nabla c_j \\ + \frac{t_i}{Z_i} \cdot \sum_{j=1}^n Z_j \cdot c_j \cdot D_j \cdot \nabla \ln \gamma_j \quad (15)$$

where  $z$  is the valence and the transference number of species  $j$  is:

$$t_j = \frac{\kappa_j}{\kappa} \quad (16)$$

composed from the equivalent conductivity  $\kappa_j$  of species  $i$  and of the mixture  $\kappa$ . In a reaction controlled regime the first two diffusion related terms are zero and only the migration term and its thermodynamic correction term remains. A comparison of the model calculations with a field-free system is in Figure 4 [15].

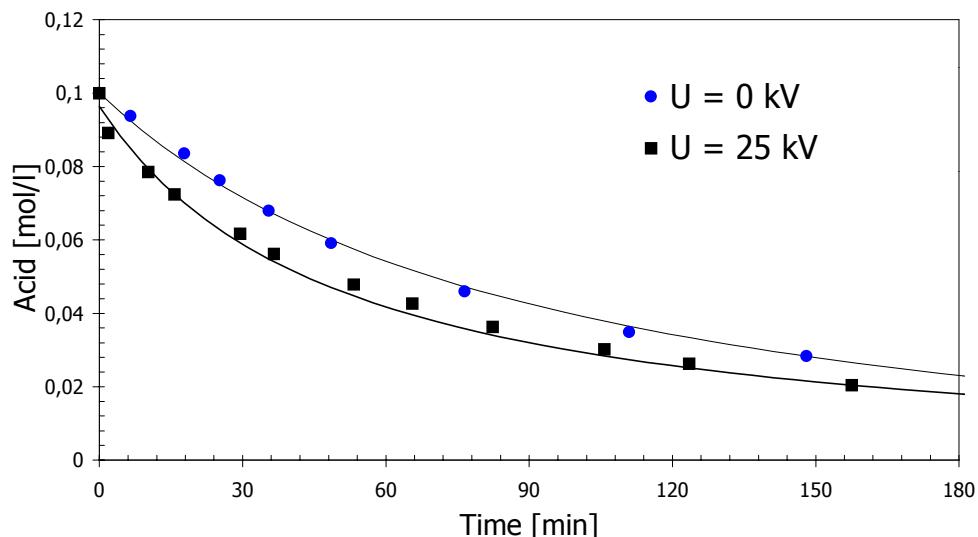

Figure 4. Mass transfer enhancement of acid extraction by a DC field (0.1 mol/l acid, 5 % tri-n-octylamine in toluene, 298 K).

The influence of electrical fields on hydrodynamics and thus on mass transfer has been discussed in an excellent review by Yamaguchi [3, 4]. It is thus possible to produce monodispersed droplet swarms up to extreme viscosities in the nano-scale (see Figure 5 [15]). Here the force balance on a nozzle leads to a disruption of drops. Under similar conditions breakage of an emulsion will occur, when due to polarization droplets form chains and will coalesce to bigger droplets [31]. Thus coalescence and droplet formation in the electric field is sensitive to minor changes in geometry or system parameters involved. This may be the one of the reasons that despite the attractiveness of the use of electrical fields there is no major application seen in conventional solvent extraction.

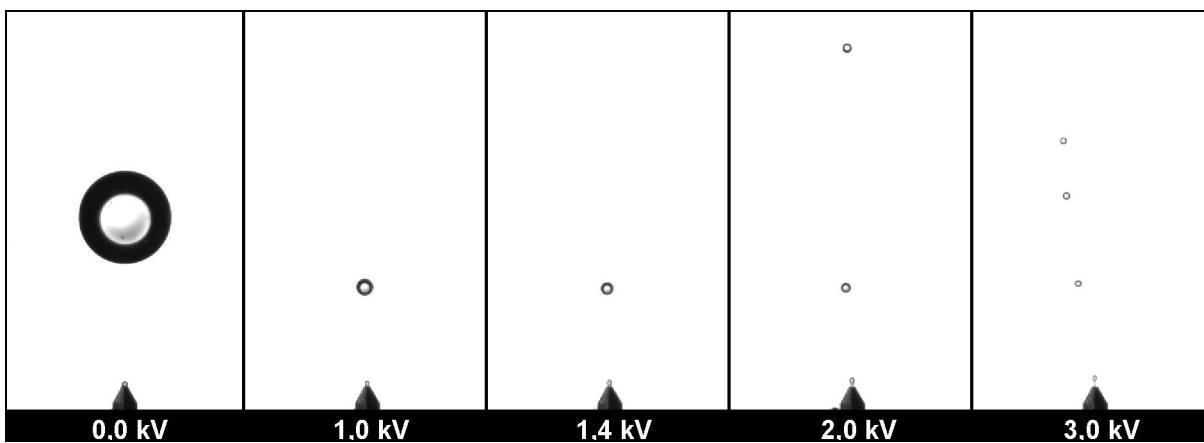

Figure 5. Drop formation in an AC field with silicone oil (298 K,  $\eta = 1000 \text{ mPas}$ ) in water.

## CONCLUSIONS

Solvent extraction is a mature unit operation and non-conventional applications like membrane extractors, aqueous-two-phase systems etc. are in the focus of research and development. As to that, electric fields as additional driving force for ionic species affect mass transfer rates. This can be due to ionic migration and polarization layers at the interface with a change of interfacial concentrations and thus reaction kinetic rates. Even Marangoni instabilities at charged interfaces have been reported. Moreover, electric fields have impact on droplet formation and coalescence and thus droplet diameter and mass transfer. As has been shown, even nanoscale particles can be produced with minor efforts and high reproducibility for special applications. As to that, there are several niches concerning electrical fields in solvent extraction, which are of industrial relevance and of interest for further exploitation.

## BEHAVIOR OF INTERFACIAL TENSION AT AN OIL-WATER INTERFACE IN THE PRESENCE OF AN APPLIED ELECTRICAL FIELD

Pardon K. Kuipa and Michael A. Hughes\*

Department of Chemical Engineering, National University of Science and Technology,  
Bulawayo, Zimbabwe

\*Department of Chemical Engineering, University of Bradford, Bradford, UK

The effect of an applied electrical field on the interfacial tension at an oil/water interface has been explored. Water droplets were formed at a charged nozzle immersed in a low dielectric constant liquid. The diameters of detaching water droplets were measured by recording the volume of a given number of detaching droplets and interfacial tension was calculated from the drop diameter using the Harkins-Brown formula. The oil phase in our studies was heptane with and without a metal extractant. The metal extractant studied was P50 (5-nonylsalicylaldoxime). In another range of experiments the oil phase was a mixture of heptane and octanol in different proportions. A decrease in drop diameter (corresponding to a decrease in the interfacial tension) with increased applied voltage was observed in all instances. The decrease in interfacial tension, which denotes the accumulation of charge carriers (ions) at the interface, depends upon the transport numbers and concentrations of the ions in the two phases and also upon the current. The behavior of interfacial tension in the presence of an applied electrical field is the same for systems with and without extractant in the organic phase. The purpose of the study was to gain an insight into the phenomenon of mass transfer intensification of a solute across an interface of two immiscible liquids by an electric field applied normal to the interface.

### INTRODUCTION

Several workers have studied a variation in the interfacial tension due to an applied potential difference between two immiscible liquids in contact. The observed interfacial tension changes were termed "electrocapillarity" by Lippman [1], who studied the mercury-aqueous phase interface. This phenomenon when observed at the interface of two immiscible nonmetallic liquid phases, such that one of the phases is electrically conducting whilst the other one is not, e.g. water-organic phase system, was termed "electroadsorption" by Guastalla [2]. The mercury-water interface behaves quite differently from the water-organic interface since the former is entirely polarizable, whilst the latter is hardly polarizable. At the mercury water interface, interfacial polarization takes place by the excess or deficit of electrons at the metal surface, which accompanies an unsymmetrical distribution of ions on the solution side of the interface. Charge transfer across the interface is negligible in such a system. Since we cannot expect the presence of free electronic charge at an oil-water interface, the polarization and thus formation of double layers in such a system is due only to unsymmetrical distribution of cationic and anionic species at the interface. The observed phenomenon is similar to concentration polarization as is clear from the passage of a small current in our systems.

When an electric field is applied across an ionic solution there are changes in concentration in the vicinity of the electrodes but not in the region between the electrodes. In a solvent extraction system there can be concentration changes at the liquid-liquid interface as well as at the electrodes, since an ion generally has different transport numbers in the two solvents. The change in charge carrier concentration at the liquid-liquid interface depends on the rate of flow of ions through the interface and the rate of diffusion to and from the interface. Accumulation of charges at the interface results in local variations in interfacial tension that may lead to instabilities of the Marangoni type to set in [3]. When both phases are perfectly insulating there is no free charge at the interface.

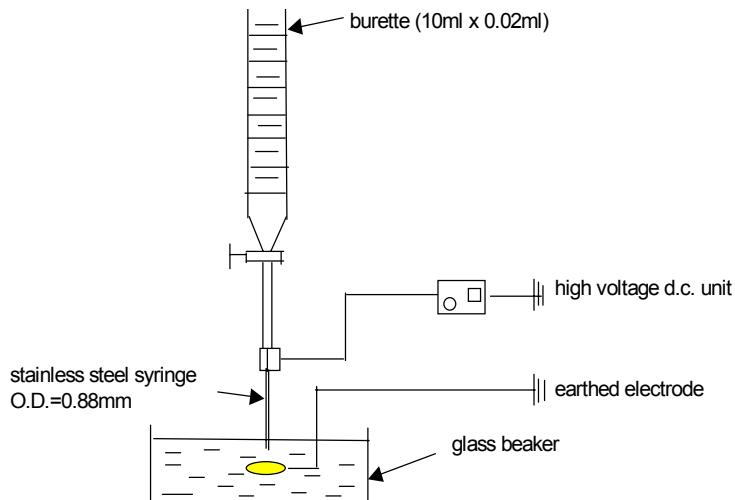

## EXPERIMENTAL PROCEDURE

### Reagents

The diluents (heptane and octanol) used for this work were of Analar grade. P50 (5-nonylsalicylaldoxime) was 98% pure. Water for interfacial tension measurements was double distilled.

### Interfacial Tension Measurements

The effective interfacial tension between the organic and aqueous phases in the presence of applied electric fields was measured by a modified drop volume method, equipped with a high voltage unit. Figure 1 is a schematic diagram of the experimental device used. The volume of liquid corresponding to a number of drops was read off from a 10 ml x 0.02 ml burette. All measurements were performed at room temperature,  $25 \pm 1^\circ\text{C}$ .

*Figure 1. Schematic of the apparatus used for interfacial tension measurements.*

The drop volume method was chosen because it could easily be adapted to work involving charged droplets. A variable voltage of up to 2000 V was applied to the base of the stainless steel syringe. The outside diameter of the tip of the stainless steel syringe was measured with a traveling microscope and found to be 0.88 mm; this is where the drops were formed. The disc electrode in the organic phase was earthed and its diameter was 25 mm. If the average drop volume at a particular electric field strength is known, the effective interfacial tension can be roughly estimated by the Harkins-Brown formula [4],

$$\gamma_e = V_E (\rho_1 - \rho_2) g F / r \quad (1)$$

where,  $\rho_1$  and  $\rho_2$  are the densities of the aqueous and organic phases respectively,  $r$  is the outer radius of the tip of the stainless steel syringe,  $g$  is the acceleration due to gravity,  $V_E$  is the average drop volume of the aqueous phase at a particular field strength and  $F$  is the Harkins-Brown correction term for the small amount of liquid that is left behind when the drop falls off the nozzle and is a function of  $V_E/r^3$ , the value of the latter ( $V_E/r^3$ ) ranging from 1.0 to 270 in this work. The range of values for  $V_E/r^3$  from 1.0 to 270 corresponds to drop volumes of  $0.68 \text{ mm}^3$  and  $184 \text{ mm}^3$  and  $F$  values of 0.2603 and 0.1979, respectively. Values of  $F$  were obtained through the extrapolation of tabulated values of  $F$  against  $v/r^3$ ,  $v$  being the drop volume [5]. In general,  $F$  values range from 0.159 to 0.2559 for corresponding  $v/r^3$  values of  $\infty$  and 0.403, respectively.

In this work, the use of the Harkins-Brown formula to estimate the effective interfacial tension in the presence of an applied electrical field assumes that the correction factor,  $F$ , is the same for a drop which is detaching from both an uncharged and a charged nozzle. In reality, the drop will be subjected not only to an acceleration force due to gravity but also to an acceleration force ( $QE_0$ ) due to the electric field, where  $Q$  is the droplet charge and  $E_0$  is the actual field strength acting on the drop. However, the use of the Harkins-Brown formula for the calculation of the effective interfacial tension of a system under electrical stress, *i.e.*, electrical field, will give a good approximation of the real values.

## RESULTS

The effect of the applied voltage on the effective interfacial tension of the liquid-liquid systems investigated in this work is summarized in Figures 2 and 3 for the water/0.05M P50/octanol-heptane diluent mixture and the water /octanol-heptane diluent mixture systems, respectively.

The effect of applied voltages on observed current passing between 0.05 M P50 octanol-heptane solvent mixtures and water with the high voltage electrode situated in the organic phase and the earthed electrode in the aqueous phase, is summarized in Figure 4.

## DISCUSSION

If thermodynamic equilibrium is assumed at the interface, the Gibbs adsorption isotherm extended to include the electrostatic term may be written as:

$$-d\gamma = \sum_i \Gamma_i RT d \ln C_i + q dV^a \quad (2)$$

where,  $\Gamma_i$  is the surface excess of the component  $i$ ,  $C_i$  its bulk concentration,  $q$  the surface charge density and  $V^a$  is the interfacial potential difference.  $R$  is the gas constant and  $T$  is the absolute temperature. For systems whose electrical conductance is high,  $V^a$  is approximately the same as the applied voltage  $V$ , whilst for the systems in our study the actual potential difference is different from the applied voltage so that

$$V^a = kV, \quad 0 < k < 1 \quad (3)$$

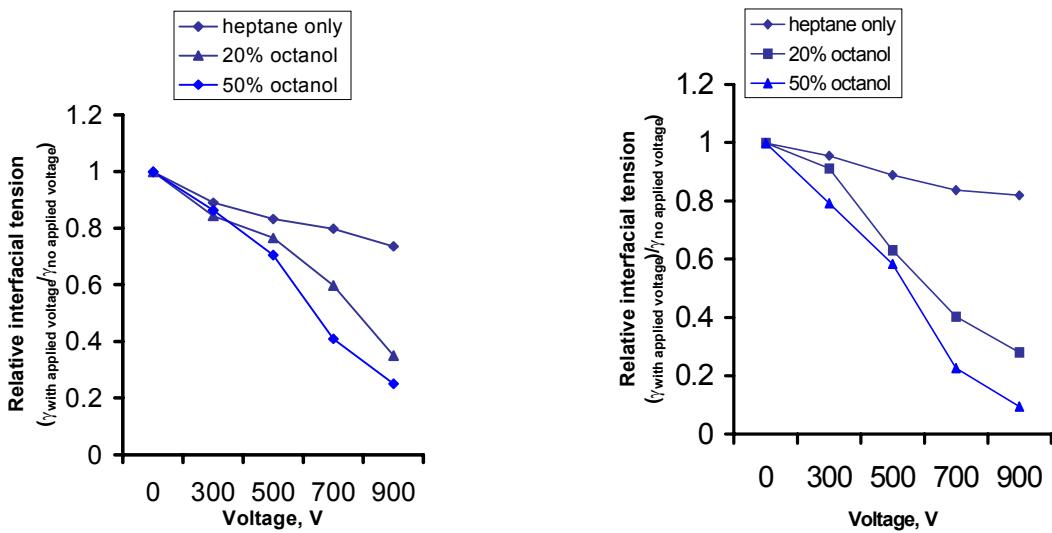

Figure 2. Voltage-interfacial tension relationship for the water/P50/(heptane-octanol mixture) system.

Figure 3. Voltage-interfacial tension relationship for the water/(heptane-octanol mixture) system.

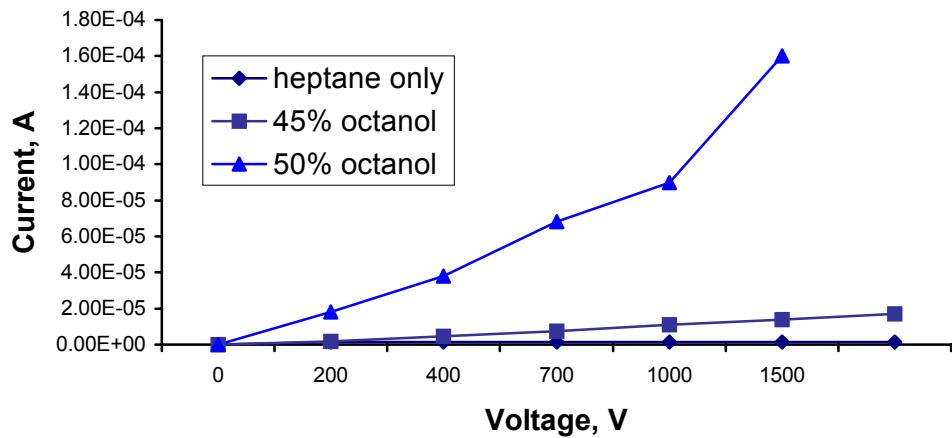

Figure 4. Effect of applied voltage on the observed current for the water/0.05M P50/(heptane-octanol mixture) system.

For a constant composition of the system  $d \ln C_i = 0$ , so that

$$-\left(\frac{d\gamma}{dV^a}\right)_{C_i} = q \quad (4)$$

where,  $q$  is the surface charge density. According to our results, for the systems studied, the interfacial tension decreases with increasing applied voltage ( $\gamma_{\text{with applied voltage}} < \gamma_{\text{without applied voltage}}$ ) so that the term in brackets in equation (4) is negative and thus  $q$  is positive. Then we have a picture of the interfacial double layer consisting of an array of cations on the aqueous side and that of surface-active agent anions on the oil side of the interface. These conclusions are based upon the Helmholtz double layer model. It is envisaged that the

systems studied will in real terms consist of the Gouy-Chapman diffuse double layers on both sides of the interface with the possibility of the Stern adsorption layer being formed if surface active components are present.

We have previously reported [6] that a change in the sign of the applied voltage does not result in a suppression or enhancement of the observed extraction rate across the liquid-liquid interface. This seems to imply that the surface-active anions accumulating on the organic side of the interface are not necessarily those of the extractant but rather those of the charge carriers, which are present within the bulk of the organic phase. The surface charge densities for our systems were not calculated, since the value of the constant,  $k$  in equation (3), is unknown.

For octanol-heptane diluent mixtures, we have reported previously [6] that extraction rates are enhanced with increasing applied voltages when the amount of *n*-octanol in the organic phase exceeds 45%. Octanol is readily adsorbed and desorbed at the oil/water interface [7] so that the cohesion and packing of the extractant are lowered. The fast renewals of extractant at the liquid-liquid interface resulting from the circulation produced by octanol desorption and adsorption is responsible for the extraction rate enhancement. Alternatively, the enhancement could be associated with the number of charge carriers associated with the octanol. Accumulation of charge carriers at the interface makes it unstable, resulting in fast renewal of extractant, since interfacial turbulence is created as a result of the instability.

## CONCLUSIONS

The behavior of interfacial tension in the presence of an applied electrical field is the same for systems with and without extractant in the organic phase. This could imply that the observed decrease in interfacial tension of a liquid-liquid system under the influence of an applied electrical field is due to the accumulation of charge carriers at the interface (owing to the difference in transport numbers of the charge carriers in each phase) rather than the accumulation of extractant at the liquid-liquid interface. Accumulation of charges at the interface makes the interface unstable, resulting in local variations in interfacial tension which may cause instabilities of the Marangoni type and consequently interfacial turbulence to set in. In solvent extraction systems the interfacial turbulence should result in better renewal of the interface between the aqueous and organic phases, thereby increasing the rates of mass transfer, as has been observed by several researchers.

# INTERFACIAL ORIENTATION OF PORPHYRIN AT THE LIQUID-LIQUID INTERFACE USING UV-VIS EXTERNAL REFLECTION SPECTROSCOPY

Nobuaki Ogawa, Yoshio Moriya and Shinichi Nakata

Faculty of Engineering and Resource Science, Akita University, Akita City, Japan

The adsorption state of diprotonated tetraphenylporphyrin at the toluene-aqueous acid interface was investigated by the UV-vis external reflection (ER) spectroscopy. The degree of aggregation and the orientation angle were estimated to be 4 and 19°, respectively. The tilting orientation was supported by *p*-polarized spectrum where the 473 and 720 nm bands were observed positively and the 412 nm band negatively at a higher angle of incidence than Brewster's angle, which was explained by the assignments of bands and the interfacial selection rule. The ER method can yield not only a spectrum of the interfacial species itself, but also information on its interfacial orientation.

## INTRODUCTION

The *in situ* measurements of adsorbed species at the liquid-liquid interface may give us significant information relating to the states of aggregation and orientation, which may not occur in homogeneous bulk phase. In recent years, various spectroscopic methods for the measurements of interfacial adsorbed species have been facilitated remarkably. Two typical methods are attenuated total internal reflection (ATR) [1,2] and double phase transmission spectroscopy, represented by a centrifugal liquid membrane method [3] within the visible wavelength region.

The organic phase encountered in solvent extraction systems usually contains strongly light-absorbing solute, and hence the spectrum of interfacial species may be considerably affected by the absorption bands of organic bulk species. Our previous work [4], therefore, proposed the external reflection (ER) method, by which we could observe an ER spectrum with some negative absorption bands relating only to the interfacial adsorbed species, as for the diprotonated porphyrin in a *J*-aggregate at the toluene-4 M sulfuric acid interface.

In this report, we studied in detail the aggregation and orientation states of tetraphenylporphyrin (TPP) in diprotonated form adsorbed at the same liquid-liquid interface, based on the decreased absorbance in the organic phase with the interfacial adsorption. Furthermore, we obtained a characteristic spectrum of the interfacial adsorbed species in polarization ER spectroscopy and qualitatively discussed the interfacial orientation.

## EXPERIMENTAL

A simple device, which we call the Prism-Cell method, is schematically illustrated in Figure 1, and was used for the quantitative analysis of the interfacial adsorption. After pouring the same volume ( $3 \text{ cm}^3$ ) of 4 M sulfuric acid and toluene into the Prism-Cell, a small portion of the solution of TPP ( $20 \mu\text{M}$ ) was added stepwise and homogenized within the upper toluene phase. The absorption spectrum of organic phase ( $A_{\text{org}}$ ) (as well as that of aqueous phase ( $A_{\text{aq}}$ )) and the spectrum of ER (as well as ATR) were measured by a vertical shift of the prism-cell as described previously [4]. The fixed angle of incidence ( $\theta$ ) for ER and ATR measurements on our system were calculated to be  $\theta_E = 73.0^\circ$  and  $\theta_A = 74.4^\circ$ , respectively. A double beam spectrometer (Perkin Elmer, Lambda 40) was used for this work. For the measurement of polarized ER spectrum, a pair of dichroic sheet polarizer was inserted across the incident beam in front of the detector. The measurements were carried out at the temperature 298 K.

A new apparatus for the measurements of liquid-liquid interfacial species at the variable angle of incidence was devised as shown in Figure 2, which we call the Optical Fiber method. It was assembled from focus lens (L), optical fiber (F) of  $600 \text{ mm}\phi$  (purchased from Perkin Elmer), a Gran-Thompson polarizing prism (P) attached on the mobile arms around the center of a goniometer where a cylindrical cell of  $2 \text{ cm}$  diameter (C) was positioned by xyz-stage. The monochromatic light directly conducted into the fiber was reflected at the liquid-liquid interface, polarized by P, depolarized by a depolarizer (D) and then derived into detector. A single beam spectrometer (Hitachi 239) was used for this work. The measurements were carried out at room temperature,  $298 \pm 2 \text{ K}$ .

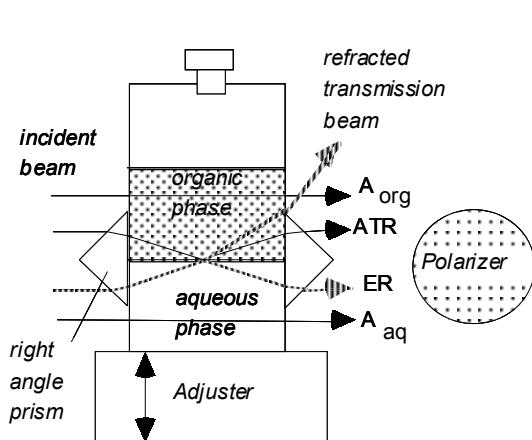

Figure 1. The Prism-Cell method.

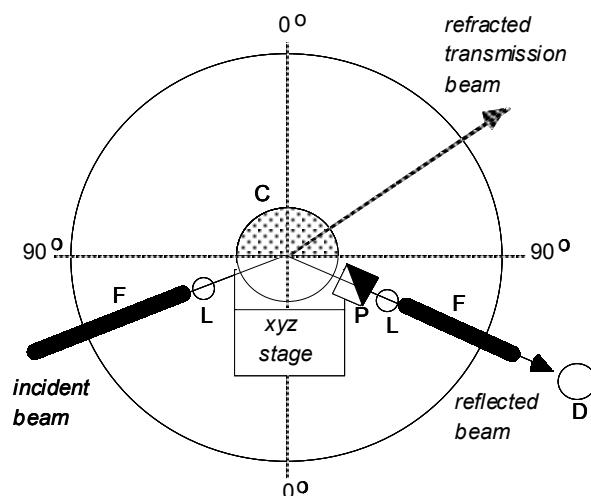

Figure 2. The Optical Fiber method.

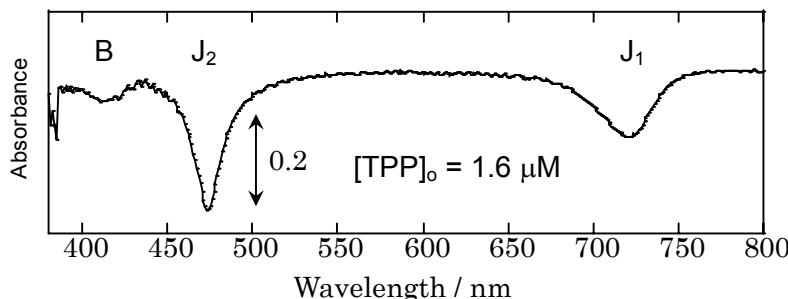

## RESULTS AND DISCUSSION

### Interfacial Species and the ER spectrum

The tetraphenylporphyrin (TPP) is diprotonated and adsorbed at the toluene-4 M sulfuric acid interface as  $(\text{H}_2\text{TPP}^{2+})_n$  in a J-aggregate [5] under the equilibration represented as

where the subscript o and i refer to the bulk organic phase and the interface, respectively. The diprotonation and aggregation attained quasi-equilibrium after  $\sim 1 \text{ h}$ , and the ER spectrum measured by the Prism-Cell method with no polarizer was observed in the same manner as described previously [4]. That is, the negative absorption bands at 720, 473 and 412 nm were observed without the interference of strong Soret band in the organic bulk phase as shown in Figure 3.

*Figure 3. External reflection spectrum of J-aggregate.*

For understanding the origin of spectral bands, we can refer to the discussion on the J-aggregate of water-soluble tetra(4-sulfophenyl) porphyrin ( $\text{TPPS}^{4-}$ ) in acidic aqueous media [6]. According to the work, two absorption bands at 707 nm (J<sub>1</sub> band) and 492 nm (J<sub>2</sub> band) were assigned to the characteristic transition of linear oscillator polarized in the long axis of rod-like aggregate ( $(\text{H}_2\text{TPPS}^{2+})_n$ ,  $n=11$ ) in a slipped face-to-face stacking structure where the participation of inter-porphyrin charge resonance excited states should be taken into account. Another diffuse absorption band around at 420 nm (B band) was assigned to the transition inner pyrrole ring plane (in the short axis), where the counterpart of the 491 nm band of porphyrin Soret origin was appeared. In our spectra, the former two should correspond to the bands at 720 nm (J<sub>1</sub> band) and 473 nm (J<sub>2</sub> band), and the later to the band at 412 nm (B band).

#### **Estimation of Orientation Angle and the Degree of Aggregation**

The spectra of ER and  $A_{\text{org}}$  were measured under the varied conditions of the initial concentrations of TPP,  $[\text{TPP}]_0$ , as well as that of initial solution  $A_{\text{soln}}$ , in order to analyze the saturated interfacial concentration of the  $\text{H}_2\text{TPP}^{2+}$  and the degree of aggregation ( $n$ ) for the  $(\text{H}_2\text{TPP}^{2+})_n$  in our experimental system. Absorption intensity at the minimum absorption wavelength ( $\lambda_{\text{min}}/\text{nm}$ ) was represented by  $\Delta A_E^{\lambda}$  hereafter, which was estimated by the difference between the absorbance at the  $\lambda_{\text{min}}$  and that at 530 nm where no band was observed. The ratio of the  $\Delta A_E^{\lambda}$  among the three bands was constant in the concentration region of  $0.2 < [\text{TPP}]_0/\mu\text{M} < 2.5$ . It means all of the three bands belong to only one species and also suggests that the interfacial orientation is consistent in the concentration region.

The interfacial concentration ( $\text{mol cm}^{-2}$ ) of the  $\text{H}_2\text{TPP}^{2+}$  could be estimated from the reduced absorbance in the organic phase by neglecting a trace amount of aqueous species, and by taking into account the organic bulk volume  $V_o$  ( $\text{dm}^3$ ) and the interfacial area  $S_i$  ( $\text{cm}^2$ ). The relation between the  $\Delta A_E^{473}$  and the interfacial concentration of the  $\text{H}_2\text{TPP}^{2+}$  was shown in Figure 4, where a linear relation was observed in the lower concentration region. On the assumption of a monolayer adsorption state, the saturated interfacial concentration was estimated to be  $2.67 \times 10^{10} \text{ mol cm}^{-2}$ . The value means the occupied area per molecule to be  $0.63 \text{ nm}^2$  at the interfacial saturation. When a roughly estimated value of  $3 \text{ nm}^2$  was used as a molecular area ( $a$ ) occupied by  $\text{H}_2\text{TPP}^{2+}$  from the value  $3.2 \text{ nm}^2$  as that for tetrakis(*N*-methyl-4-pyridyl)porphine [7], the orientation angle of the pyrrole ring plane against the surface normal to be  $12^\circ$  [8], though a different value  $19.4^\circ$  was obtained by a value of  $a=1.9 \text{ nm}^2$  from the molecular mechanics (MM2) calculation [3]. In any event, the pyrrole ring plane must be appreciably tilting at the interface.

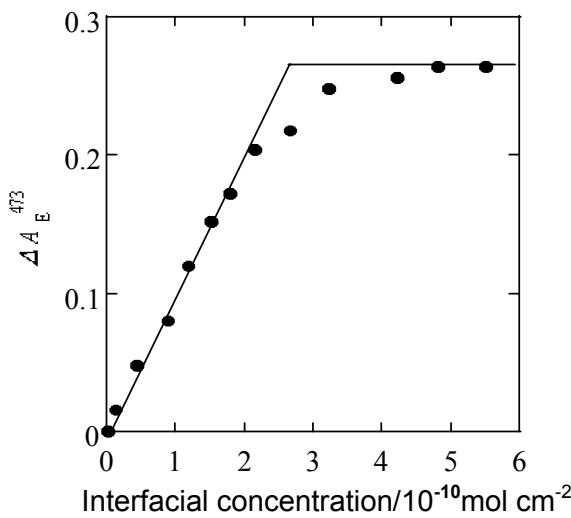

Figure 4. Intensity of ER absorption at 473 nm vs. interfacial concentration

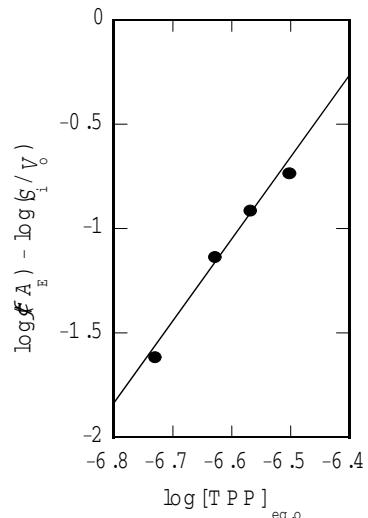

Figure 5. Determination of the degree of aggregation.

The degree of aggregation ( $n$ ) was estimated using data within the low concentration region. The quasi-equilibration constant  $K$  for Eq. (1) would be represented as

$$K = [(\text{H}_2\text{TPP}^{2+})_n]_i [\text{TPP}]_{e,o}^{-n} [\text{H}^{+}]^{-2n}, \quad (2)$$

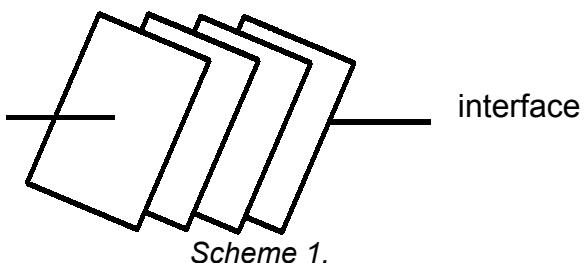

using the equilibrated concentrations of TPP in the organic phase ( $[\text{TPP}]_{e,o}$ ). The value of  $\Delta A_E^\lambda$  could be expressed by

$$\Delta A_E^\lambda = \rho n [(\text{H}_2\text{TPP}^{2+})_n]_i (S_i/V_o) \quad (3)$$

where the  $\rho$  refer to a coefficient ( $M^{-1}$ ) at  $\lambda$ . Then we could obtain the following equation:

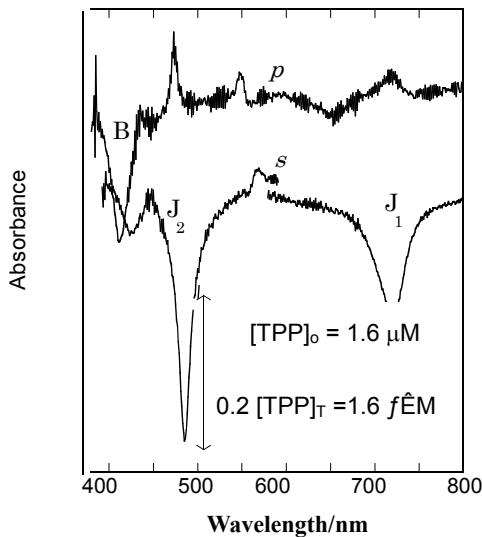

$$\log(\Delta A_E^\lambda) - \log(S_i/V_o) = n \log[\text{TPP}]_{e,o} + \log(\rho n K) + 2n \log[\text{H}^+] \quad (4)$$

where the last two terms could be constant under our experimental conditions. The plot of  $\log(\Delta A_E^{473}) - \log(S_i/V_o)$  vs.  $\log[\text{TPP}]_{e,o}$  within the range  $0.18 < [\text{TPP}]_{e,o}/\mu\text{M} < 0.32$  was shown in Figure 5. The plot gave a slope 3.9, hence the J-aggregate could be represented as  $(\text{H}_2\text{TPP}^{2+})_4$  [8]. Therefore, we can imagine the interfacial adsorption state of the J-aggregate as drawn in Scheme 1.

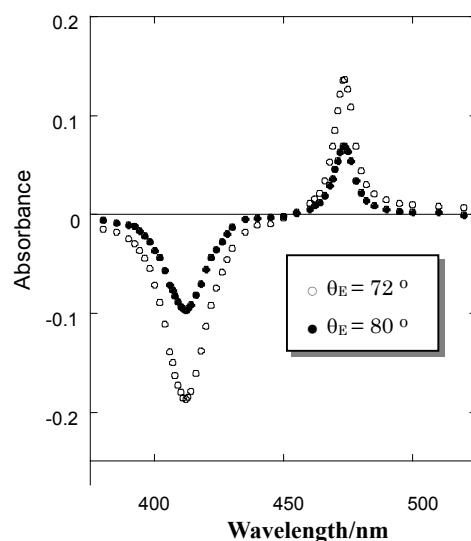

### Measurements of Polarized Spectra

The polarized ER spectra were measured by the Prism-Cell method with polarizer. Figure 6 shows the s- and p-polarized ER spectra (where a signal around 550 nm is not a spectral band) at the fixed angle ( $73^\circ$ ) of incidence by the Prism-Cell method under the condition of initial concentration  $[\text{TPP}]_0 = 1.6 \mu\text{M}$ . In the s-polarized spectrum denoted by s in Figure 6, the absolute intensities of  $J_1$  and  $J_2$  bands were strengthened while that of B band was reduced as compared with the spectrum depicted in Figure 3. In the p-polarized spectrum denoted by p in Figure 6, on the other hand, the two bands of  $J_1$  and  $J_2$  appeared with positive absorbance while the B-band was negatively strengthened [8]. This positive/negative band observation may be the first example observed in the liquid-liquid boundary system, as far as we know.

*Figure 6. The s- and p-polarized ER Spectra of interfacial species (by the Prism-Cell method).*

*Figure 7. The p-polarized ER spectra at the angle of incidence 72° and 80° (by the Optical Fiber method).*

The ER spectroscopic measurements, in general, suffer from the defect that the reflection factor at the interface may be low and produce a low ratio of signal/noise (S/N). It was amplified especially in the *p*-polarized spectrum measured by the Prism-Cell method using double beam spectrometer as depicted in Figure 6. Therefore, some measurements for *p*-polarized spectra were carried out also by the Optical Fiber method (see Figure 2) using a single beam spectrometer. The reflection intensities of blank ( $I_0$ ) and of sample ( $I$ ) were measured, respectively, within 380-520 nm at  $\theta_E = 72^\circ$  and  $80^\circ$ , and then the absorbance value as  $\log(I_0/I)$  was plotted against the wavelength. Figure 7 represents the *p*-polarization spectra measured after the contact of the same volume ( $4 \text{ cm}^3$ ) of 4 M sulfuric acid and  $1 \mu\text{M}$  TPP solution within a cylindrical cell. In the figure, a positive absorption band ( $J_2$ ) and a negative one (B) were clearly shown, where the intensity of both  $J_2$  and B at  $\theta_E = 72^\circ$  was higher than that at  $80^\circ$ .

#### Qualitative Orientation using the Interface Selection Rule

The observation of positive/negative absorption bands for surface-boundary substances can be an intrinsic phenomenon, which appears only within the *p*-polarized ER method. The feasibility of the positive/negative appearance was shown by Hansen's approximate formulae for the three phase system in the literature [9]. Using the IR-ER method for the LB film of cadmium stearate on GaAs substrate, Hasegawa [10] showed that the characteristic IR bands of functional groups appeared with positive/negative absorbance according to the interface selection rule [9] where absorption bands could intensified when the  $\theta_E$  approached the Brewster's angel ( $\theta_B$ ), and also that the orientation angle against the surface normal could be determined by the use of anisotropic principle [10]. Taking into account the difficulties of IR-ER measurements for the oil-water system, it will be very useful for us to get spectral information on the interfacial molecular orientation by a polarized vis-ER measurement. Therefore, our new observation of *p*-polarized ER spectrum with positive/negative bands will be significant for the qualitative orientation analysis of interfacial species, from where the sense of electronic transition moment for each of chromophores will be obtained.

According to the interface selection rule for ER method, the positive absorption band of  $J_2$  as well as  $J_1$  could be assigned to the chromophores having a parallel electron-transition moment to the interface while another band B to that having a perpendicular moment under our experimental condition of  $\theta_E > \theta_B$  ( $47.4^\circ$  for our interfacial system). The decrease tendency of absorbance at the higher angle of incidence ( $80^\circ$ ) in Figure 7 was consistent with the interface selection rule already mentioned. Then, it would be concluded that the pyrrole ring plane of  $\text{H}_2\text{TPP}^{2+}$  in *J*-aggregate must be oriented vertically or obliquely against the interface, since the

B-band has already assigned as the electron transition inner pyrrole ring plane. Therefore, the tilting orientation model depicted in Scheme 1 was supported by the observation of *p*-polarization ER spectroscopy, though a quantitative analysis on the orientation by ER spectroscopy would have to be carried out by a method as shown in the literature [11]. We also did the preliminary experiment for a porphyrin in dodecane-aqueous acid system. In detail, we will discuss the data in near future.

## CONCLUSIONS

The application of ER method to *in situ* measurements of a liquid-liquid interface enables us not only to obtain a spectrum of an interfacial species itself, without any interference of organic bulk phase, but also to have much information about the interfacial molecular orientation. Thus, the degree of aggregation and orientation angle of diprotonated tetraphenylporphyrin adsorbed at the liquid-liquid interface were estimated. Furthermore, a tilting orientation model was supported by the *p*-polarized ER spectrum.

## MASS SPECTROMETRY AND LASER-MICROSCOPY FOR THE STUDY OF INTERFACIAL REACTION IN SOLVENT EXTRACTION SYSTEMS

Hitoshi Watarai

University of Osaka, Toyonaka, Japan

For the study of formation reactions of metal-complexes at the liquid-liquid interfaces of solvent extraction systems, new experimental approaches using mass spectrometry and laser-induced fluorometry of micro-flow two-phase systems were developed. Mass spectrometry of the directly introduced two-phase micro-flow system can measure the compositions or structures of complex species formed in the interface as well as in the bulk phases. In the extraction of Cu(II) with a pyridylazo extractant (L), the formations of  $\text{CuL}^+$  and  $\text{CuL}_2$  were detected simultaneously. A remarkable solvent effect was found in the distribution among the species measured by this method. On the other hand, laser-induced fluorometry of a two-phase sheath flow system succeeded in measuring fast interfacial reactions. In the extraction of Zn(II) with *n*-alkyl substituted oxine, the interfacial complexation within 5 ms could be measured.

### INTRODUCTION

Interfacial reaction has been recognised as an important reaction step which determines kinetic extraction mechanisms of metal ions [1]. Some specific reactions were found at liquid-liquid interfaces, for example, the formation of the binuclear complex of europium(III) [2] and the formation of the aggregate of Pd(II)-binding porphyrins [3]. For the development of interfacial chemistry of liquid-liquid interfaces, it is necessary to invent new measurement methods for interfacial reactions. So far, we have developed various measurement methods including a high-speed stirring method [4] and a centrifugal liquid membrane method [5].

In the present report, we describe two novel methods developed for the measurement of interfacial reactions: two-phase micro-flow electrospray ionization/ mass spectrometry and two-phase sheath flow/laser-induced fluorometry. These two methods can afford new information which has never been obtained by the other techniques.

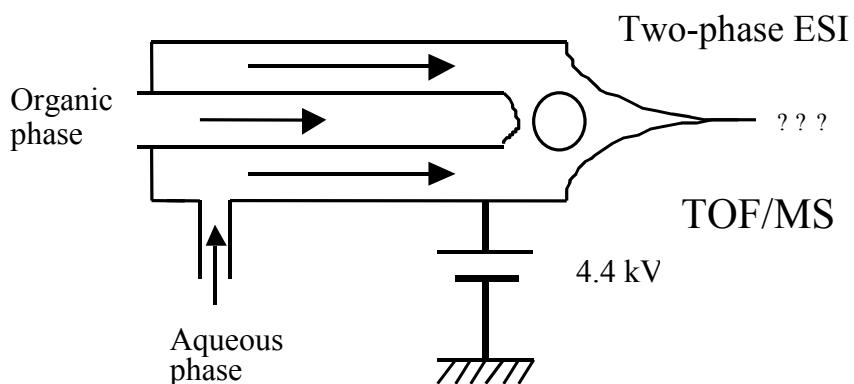

Electrospray ionization (ESI) is a versatile and effective ionization technique for liquid samples for various mass spectrometric (MS) measurements. Advantages of ESI/MS in solution chemistry research are well recognised because of its high potential in structural identification or chemical speciation of the compounds in a dilute solution. In some cases, chemical equilibria and kinetics of complexation in solution could be discussed by ESI/MS. However, the solvents used in ESI/MS are usually limited to polar or protic solvents such as methanol, acetonitrile, dimethylsulfoxide and water. Non-polar organic solvents such as heptane and toluene, which are used very often in solvent extraction of metal ions, cannot be introduced directly to the ESI, because of their very low conductivities [6]. If these kinds of inert solvents could be used in ESI/MS, the realm of MS measurement will be significantly extended. In the present study, a novel method was invented which introduced an inert organic solvent phase into ESI/MS by producing organic droplets in a flowing aqueous phase at the position just prior to the ionization.

Various kinetic measurement methods have been developed for the study of extraction rates and complexation at the liquid/liquid interface. For example, the two-phase stopped flow method has succeeded in measuring the interfacial reaction in a time range of 0.1 s to a few seconds [7]. The centrifugal liquid membrane method and the high-speed stirring method proved to be useful for measurements of processes longer than several seconds. However, for fast reactions that finish within several ms, the previous methods cannot be applied. In the present study, laser-induced fluorometry of a two-phase sheath flow system was invented for the measurement of the interfacial complexation rates within 5 ms.

## EXPERIMENTAL

### Two-Phase Micro-Flow Electrospray Ionisation/Mass Spectrometry

The device for the two-phase micro-flow electrospray ionization was made by using a stainless steel outer capillary (0.4 mm o.d., 0.2 mm i.d.) and an inner silica capillary (0.158 mm o.d., 0.050 mm i.d.). A schematic drawing of the device is shown in Figure 1. The tip of the silica capillary was made as fine as 13 µm o.d. and 7 µm i.d. by pulling it under heating with a CO<sub>2</sub> laser (SYNRAD, 10.5 µm, 12.0 W). The silica capillary tip was positioned about 1 mm inside of the tip of the stainless capillary. Water-saturated toluene phase containing 1.0 x 10<sup>-3</sup> M 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (5-Br-PADAP) was pumped into the inner silica capillary with a flow rate of 0.001- 0.02 ml/h. Into the stainless steel capillary, 5.0 x 10<sup>-6</sup> M Cu(II) in aqueous 0.0010 M acetic acid was introduced from the tee connector with the flow rate of 0.1 ml/h as an outer phase. For the pumping of both phases, syringe pumps (Harvard 11) were used. A high voltage of 4.4 kV was applied to the stainless steel for the generation of electrospray. The ESI interface was positioned about 2 cm apart from the inlet hole in the interface (controlled at 600 V) of the TOF/MS (Jaguar, Sensar, Utah). Nitrogen curtain gas was flowed at the rate of 1000 ml/min between the interface and a nozzle positioned inside the interface. The nozzle voltage was changed in the range of 100 – 500 V and the voltage in the skimmer was set at 70 V.

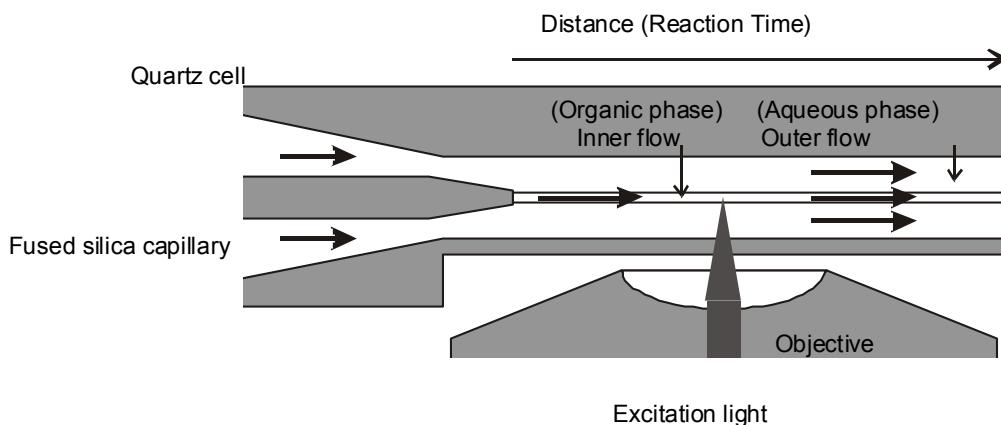

*Figure 1. Schematic drawing of the electrospray ionization interface of the two-phase micro-flow oil/water system.*

### Two-Phase Sheath Flow/Laser-Induced Fluorometry [8]

Figure 2 is the schematic representation of the fluorescence measurement cell of the two-phase sheath flow system. The inner phase is the organic solution flow and the outer phase is the aqueous solution flow. When the linear velocities of two solutions are matched, a stable and turbulence-free two-phase flow was formed. When these conditions were satisfied, the interface was regarded as a steady interface except moving from left to right in Figure 2. In this configuration, the distance along the flows from the capillary outlet can be

converted to the reaction time at a constant linear velocity. This unique feature of the sheath flow system allows us to integrate fluorescence at a certain distance for a long time. The inside cross section of the quartz cell was  $250\text{ }\mu\text{m} \times 250\text{ }\mu\text{m}$  square, and one side of the cell wall was scraped for the observation with a high NA objective. The organic solution was introduced into the cell through a fused silica capillary, whose inner and outer diameters were  $50\text{ }\mu\text{m}$  and  $150\text{ }\mu\text{m}$ , respectively, and whose outlet was narrowed to  $30\text{ }\mu\text{m}$  by pulling under irradiation with a CO<sub>2</sub> laser. The cell was placed on the stage of an inverted microscope (TE300, Nikon).

*Figure 2. Schematic representation of the laser-induced fluorometric measurement cell of the two-phase sheath flow extraction system [8].*

In the present study, the 1-butanol/water system was employed as an extraction solvent due to its low interfacial tension ( $1.8\text{ mN m}^{-1}$ ). When the inner organic phase is a solvent with higher interfacial tension such as toluene ( $36.2\text{ mN m}^{-1}$ ), the organic phase tended to become droplets at a low flow rate. The extraction system of Zn<sup>2+</sup> with 5-octyloxymethyl-8-quinolinol (Hocqn) was chosen as a test sample, because the complex formed was highly fluorescent [9]. To detect quite small amounts of the complex, laser-induced fluorescence microscopy was employed.

The organic solution was  $1.3 \times 10^{-3}\text{ mol dm}^{-3}$  Hocqn in 1-butanol, and the aqueous solution containing  $1.1 \times 10^{-2}\text{ mol dm}^{-3}$  ZnCl<sub>2</sub> and  $1.0 \times 10^{-3}\text{ mol dm}^{-3}$  2-morpholinoethanesulfonic acid (MES) as a buffer. The pH of the aqueous solution was kept within 6.0 – 6.4. Prior to two-phase sheath flow experiments, the aqueous solution was stirred with pure 1-butanol for saturation.

For excitation of the complex in the sheath flow system, the second harmonic light (pulse width, 150 fs; 400 nm; 70 mW; 82 MHz) of a Ti:sapphire laser (Tsunami, Spectra-Physics) was used. The excitation light was reflected by a dichroic mirror (DM455, Nikon) toward the cell and focused on the pillar-shaped organic phase flow by a 20× objective (SuperFluor, Nikon). An intensified cooled CCD camera (PentaMax, Princeton Instruments) detected the fluorescence emitted from the complex formed in the organic phase flow. To measure its fluorescence spectra, a streak scope (C4334, Hamamatsu Photonics) was used. Undesirable light caused by the scattering of excitation light and the Raman scattering of the solvent was removed by the dichroic mirror and a barrier filter (535AF45, Omega Optical; passing 550 – 580 nm) placed in front of the CCD camera. By travelling the microscope stage, the excitation point at the interface was shifted along the flow and the fluorescence intensities of the points were measured as a function of time.

## RESULTS AND DISCUSSION

### Mass Spectra of Cu(II) Extraction System by the Two-Phase Flow ESI/MS

Under the conditions of 0.02 ml/h flow rate of the organic phase and 400 V in the nozzle voltage, a good ESI/MS spectrum was obtained as shown in Figure 3. The 1:1 complex ( $m/z = 410$ ) and 1:2 complex ( $m/z = 760$ ) of Cu(II) with 5-Br-PADAP as well as the free extractant ( $m/z = 349$ ) were detected clearly. These peaks were measured only when aqueous Cu(II) solution and organic 5-Br-PADAP solution were flowed. From this result, it was shown that the two-phase flow ESI/MS could detect the complexes formed in the two-phase system and that a highly hydrophobic solute like a 5-Br-PADAP was detected by ESI/MS for the first time in the present method.

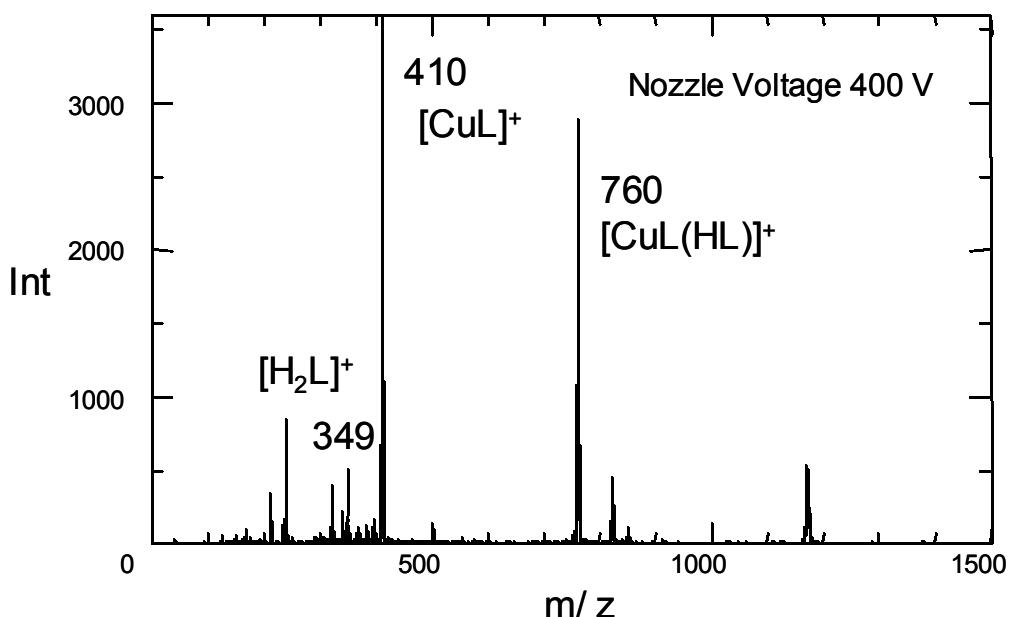

Figure 3. Mass spectra of the copper(II)-5-Br-PADAP complexes in micro-flow toluene-water system including  $1.0 \times 10^{-3}$  M 5-Br-PADAP in the organic phase with a flow rate of 0.02 ml/h and  $5.0 \times 10^{-6}$  M Cu(II) in the aqueous 0.0010 M acetic acid with a flow rate of 0.1 ml/h.

The nozzle voltage was one of the critical conditions to detect the complexes. When the nozzle voltage was less than 300 V, solvent cluster peaks became larger and the signal of the complex was not observed. At 500 V, both complex peaks and solvent cluster peaks were decreased. In 400 V, the complex signals were highest and the solvent cluster peaks were lowest. These effects were explained in terms of the collision activated dissociation (CAD). The CAD was increased in the higher nozzle voltage, so that the higher voltage reduced effectively the back-ground signals of solvent clusters and enhanced the complex signals.

The flow rate of the organic phase was another critical condition to be optimised. Accompanied by the increase of the flow rate of the organic phase from 0.001 ml/h to 0.02 ml/h, the signals of the complex were increased. The reaction probability between Cu(II) ion and 5-Br-PADAP was thought to be increased at the higher flow rate. Under the three different flow rates, the time-resolved MS was measured for the signal of 1:1 complex. The time-resolved MS revealed that the organic phase was flowed as droplets giving 500 counts in an average per 10 second per single droplet. This result allowed us to calculate the volume of the single organic droplet as 18 nl in an average.

### **Measurement of Fast Interfacial Reaction of Zn(II)**

The linear velocities of the both phases were matched at  $0.2 \text{ m s}^{-1}$  by controlling the flow rate. The diameter of the inner flow was  $30 \mu\text{m}$  and the specific interfacial area, defined as the interfacial area per unit volume of the organic phase, was calculated as  $1.3 \times 10^3 \text{ cm}^{-1}$ . Figure 4 shows the results of the kinetic measurement. The fluorescence intensity was converted to the complex concentration by the use of the fluorescence intensities of  $\text{Zn}(\text{ocqn})_2$  in 1-butanol of the concentration of  $1.1 \times 10^{-5} \text{ mol dm}^{-3}$  used as an inner phase. The distance from the capillary outlet to the observing spot was converted to the reaction time. The spectra of fluorescence emitted from the observing spots measured by the streak scope were in agreement with that of  $\text{Zn}(\text{ocqn})_2$  extracted into 1-butanol phase, proving that the detected fluorescence was generated only from the complex. In the system shown in Figure 4, the observed fluorescence intensity was increased with the reaction time, and the slope of  $5.4 \times 10^{-4} \text{ mol dm}^{-3} \text{ s}^{-1}$  was thought to be the complexation rate of  $\text{Zn}^{2+}$  with Hocqn.

In a short contact time less than 5 ms as in the present case, the distribution of Hocqn between the bulk phases is not completed. Simple calculation by assuming  $5 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$  as a diffusion coefficient of Hocqn in water estimated about  $2 \mu\text{m}$  as its diffusion depth in aqueous phase after 5 ms. Therefore, the complexation was postulated to take place only in the interfacial reaction zone, which might be depending on the diffusion coefficient and the concentration of the reactant. The rate-determining step of this complexation reaction can be assumed to be the formation of a 1:1 complex of  $\text{Zn}^{2+}$  and Hocqn. When Hocqn is distributed in the aqueous interfacial reaction zone according to the local distribution equilibrium and reacts with  $\text{Zn}^{2+}$  in the interfacial region, the extraction rate of  $\text{Zn}(\text{ocqn})_2$  in the organic interfacial region might be given by:

$$\frac{d[\text{Zn}(\text{ocqn})_2]_{\text{oi}}}{dt} = k[\text{Zn}^{2+}]_{\text{ai}}[\text{Hocqn}]_{\text{ai}} \quad (1)$$

where  $[\text{Zn}(\text{ocqn})_2]$ ,  $[\text{Zn}^{2+}]$ , and  $[\text{Hocqn}]$  represent the concentrations of the  $\text{Zn}(\text{ocqn})_2$ ,  $\text{Zn}^{2+}$ , and Hocqn, respectively. The subscripts oi and ai refer to the organic interfacial region and aqueous interfacial region, respectively. The distribution constant of Hocqn in the interfacial region of 1-butanol/water system was estimated to be about  $10^{4.5}$ . Hence, the rate constant  $k$  was calculated as  $1 \times 10^6 \text{ mol}^{-1} \text{ dm}^3 \text{ s}^{-1}$ . The magnitude of this value is thought to be close to the values reported in the Eigen mechanism.

### **CONCLUSIONS**

Two-phase micro-flow electrospray ionization/mass spectrometry was invented and proved as a promising technique in the study of complexation in the solvent extraction systems. It was suggested that not only the bulk phase species but also the interfacial species could be detected by this method.

The measurement of the fast (within 5 ms) extraction process of  $\text{Zn}^{2+}$  with Hocqn was demonstrated by the two-phase sheath flow method with laser-induced fluorometry. The interface in the flow system was stable, and the specific interfacial area was  $1.3 \times 10^3 \text{ cm}^{-1}$ .

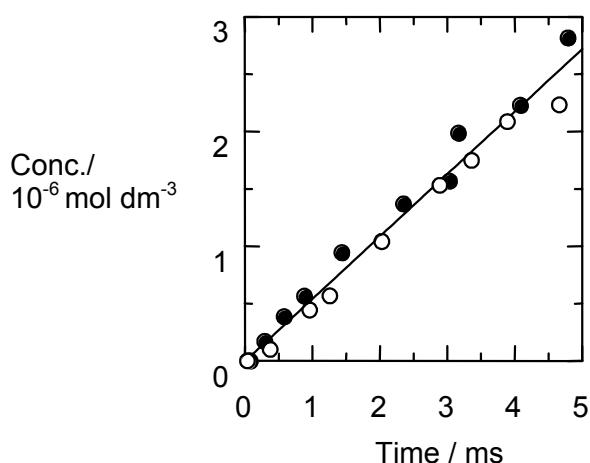

Figure 4. Formation rate of the fluorescent Zn-ocqn complex in the 1-butanol/water interfacial region. The linear flow velocities are  $0.26 \text{ m s}^{-1}$  (●), and  $0.20 \text{ m s}^{-1}$  (○). Organic phase was  $1.3 \times 10^{-3} \text{ mol dm}^{-3}$  Hocqn in 1-butanol. Aqueous phase included  $1.1 \times 10^{-2} \text{ mol dm}^{-3}$   $\text{Zn}^{2+}$  and  $1.0 \times 10^{-3} \text{ mol dm}^{-3}$  MES, and pH was 6.3.

Since the contribution of interfacial reaction is extremely multiplied under the condition of the high specific interfacial area, the two-phase micro-flow method proposed in the present study is strongly promising for the study of liquid/liquid interfacial reactions in various extraction systems.

## THE DRAINAGE AND RUPTURE OF THE FILM BETWEEN COLLIDING DROPS IN THE PRESENCE OF SURFACTANT

Leslie Y. Yeo, Omar K. Matar, E. Susana Perez de Ortiz and Geoffrey F. Hewitt

Department of Chemical Engineering & Chemical Technology  
Imperial College of Science, Technology & Medicine, London, U.K.

The understanding of the coalescence process between two drops is essential in determining the stability of liquid-liquid systems. By solving the equation governing the evolution of the continuous phase film trapped between two drops colliding at constant velocity coupled with that describing the surfactant interfacial concentration in the lubrication approximation, we show that the interface is rendered immobile due to the presence of a small amount of surfactant. Film rupture is therefore delayed due to the Marangoni effect retarding the drainage of the film. In this study, the effects of the viscosity ratio, surface diffusivity, approach velocity and the van der Waals interaction force are reported.

### INTRODUCTION

During the approach of two drops in a dispersion of two immiscible liquids, a thin film of the continuous phase is trapped between the interface of the drops. This film then proceeds to drain as the interfaces deform under the influence of the interaction forces acting on the drops. If the film succeeds in draining to a thickness at which van der Waals forces become significant in the time at which the drops are in contact with each other, the film ruptures resulting in the coalescence of the drops. The study of the film drainage and rupture process is therefore vital in the determination of the stability of liquid-liquid systems.

In practical systems of interest, surface active agents are often present. Due to spontaneous deformations at the drop interface, concentration gradients arise resulting in the Marangoni effect. The influence of surfactant on the drainage and rupture of the film between two drops colliding at a constant approach force has been investigated by Chesters and Bazhlekov [1]. In this paper, we consider the constant approach velocity case which is more appropriate for inertial collisions, which is often more relevant in practical liquid-liquid systems.

### PROBLEM FORMULATION

The approach of two drops with radii,  $R_i^*$  ( $i = 1, 2$ ), at a velocity,  $V^*$  (\* indicating a dimensional quantity), is considered (Figure 1). The following simplifying approximations have been adopted:

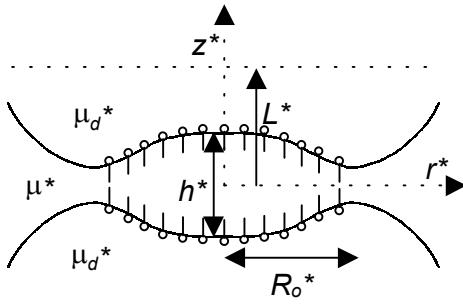

Figure 1. Schematic diagram of the film drainage region.

- The film is sufficiently thin compared to the radial extent ( $\epsilon = h_o^*/R_o^* \ll 1$ , where  $h_o^*$  is the initial film thickness and  $R_o^*$  is the initial rim radius of the film) such that the lubrication approximation applies. Symmetry relative to the plane  $z^* = 0$  can also be assumed since the effect of drop size on the film curvature is negligible as a result. An equivalent radius,  $R^*$ , can then be defined as follows:

$$\frac{1}{R^*} = \frac{1}{2} \left( \frac{1}{R_1^*} + \frac{1}{R_2^*} \right). \quad (1)$$

As a consequence of symmetry, it can also be assumed that the interfacial properties are the same at both interfaces and hence the interfacial concentration of surfactant,  $\Gamma^*$ , and the interfacial tension,  $\gamma^*$ , are equal at both the drop interfaces [2].

- In the drop, there is a characteristic penetration length,  $L^*$ , of magnitude  $\epsilon R^*$  from the interface at which the velocity and the velocity gradient approach zero [2,3].
- A dilute and uniformly distributed amount of surfactant is present at the interface initially. The surfactant is assumed to be insoluble in both the dispersed and continuous phases. A linear surfactant equation of state, justifiable for dilute concentrations, is adopted:

$$\gamma^* = \gamma_o^* - \left( \frac{\partial \gamma^*}{\partial \Gamma^*} \right) \Gamma^*, \quad (2)$$

where  $\gamma_o^*$  is the interfacial tension when the interface is free of surfactant.

The following transformations are applied to render the variables dimensionless:

$$\begin{aligned} r &\equiv \frac{r^*}{R_o^*}; & R_i &\equiv \frac{R_i^*}{R_o^*}; & z &\equiv \frac{z^*}{h_o^*}; & h &\equiv \frac{h^*}{h_o^*}; & t &\equiv \frac{\epsilon S^* t^*}{\mu^* R_o^*}; & p &\equiv \frac{h_o^* p^*}{S^*}; \\ \lambda &\equiv \frac{\mu^*}{\mu_d^*}; & \Gamma &\equiv \frac{\Gamma^*}{\Gamma_m^*}; & \gamma &\equiv \frac{(\gamma^* - \gamma_m^*)}{S^*}; & B &\equiv \frac{B^*}{S^* h_o^{m-1}}; & S^* &\equiv \gamma_o^* - \gamma_m^*, \end{aligned} \quad (3)$$

where  $h$  is the film thickness,  $t$  is the time,  $S^*$  the spreading pressure and  $p$  the film pressure;  $\mu^*$  and  $\mu_d^*$  are the continuous and the dispersed phase viscosities, respectively;  $\gamma_m^*$  is the interfacial tension when the interfacial surfactant concentration is at its saturation,  $\Gamma_m^*$ .  $B$  is the dimensionless Hamaker constant and  $m$  is a parameter for which value of 3 is assumed [4].

The lubrication equations can then be written both for the film and in the drops:

$$\frac{\partial p}{\partial r} = \frac{\partial^2 v}{\partial z^2}; \quad \frac{\partial p_i}{\partial r} = \lambda \frac{\partial^2 v_i}{\partial z^2}, \quad (4)$$

where  $v$  is the radial velocity in the film, and,  $p_i$  and  $v_i$  are the pressure and radial velocity in drop  $i$ , respectively. Taking into account the tangential shear stress balance at the interfaces,

$$\frac{\partial v}{\partial z} - \lambda \frac{\partial v_1}{\partial z} = \frac{\partial \gamma}{\partial r}, \quad (5)$$

$$\lambda \frac{\partial v_2}{\partial z} - \frac{\partial v}{\partial z} = \frac{\partial \gamma}{\partial r}, \quad (6)$$

where equation (5) applies to the interface above  $z = 0$  and equation (6) applying to the bottom interface, it can then be shown [2,5] by integration of the lubrication equations (the boundary conditions being the velocity and velocity gradient in the drop diminishing at the characteristic penetration length, symmetry at  $z = 0$  and continuity of velocities at the interface) that:

$$\frac{\partial h}{\partial t} = \frac{1}{12r} \frac{\partial}{\partial r} \left( rh^3 \frac{\partial p}{\partial r} \right) - \frac{1}{r} \frac{\partial}{\partial r} (rhv_{int}). \quad (7)$$

Here,  $v_{int}$  is the interfacial velocity which is given by:

$$v_{int} = \frac{R}{2\lambda} \frac{\partial \gamma}{\partial r} - \frac{hR}{4\lambda} \frac{\partial p}{\partial r}. \quad (8)$$

The dimensionless film pressure can be written as:

$$p = \frac{2 \epsilon \gamma_m^*}{RS^*} - \frac{1}{2} \frac{\epsilon^2 \gamma_m^*}{S^*} \left[ \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial h}{\partial r} \right) \right] + \frac{B}{h^m}, \quad (9)$$

and the equation describing the evolution of surfactant interfacial concentration reads:

$$\frac{\partial \Gamma}{\partial t} = \frac{1}{Pe_s} \left[ \frac{1}{r} \frac{\partial}{\partial r} \left( r \frac{\partial \Gamma}{\partial r} \right) \right] - \frac{1}{r} \frac{\partial}{\partial r} (rv_{int} \Gamma), \quad (10)$$

where  $Pe_s$  is the surface Péclet number ( $Pe_s = S^* h_o^* / \mu^* D_s$  where  $D_s$  is the surface diffusivity).

Given an initially undeformed spherical drop with uniform concentration,  $\Gamma_o$ ,

$$h = h_{oo} + \frac{r^2}{\epsilon R} \quad \text{and} \quad \Gamma = \Gamma_o \quad \text{at } t = 0, \quad (11)$$

where  $h_{oo}$  is the initial film thickness at  $t = 0$ . The following boundary conditions apply:

$$\begin{aligned} \frac{\partial h}{\partial r} &= 0; \quad \frac{\partial^3 h}{\partial r^3} = 0; \quad \frac{\partial \Gamma}{\partial r} = 0 \quad \text{at } r = 0, \\ \frac{\partial h}{\partial t} &= -V; \quad p = 0; \quad \frac{\partial \Gamma}{\partial r} = 0 \quad \text{at } r = \infty, \end{aligned} \quad (12)$$

where  $V = V^* \mu^* / \epsilon^2 S^*$ .

The two coupled fourth-order nonlinear parabolic partial differential equations describing the evolution of the film and the interfacial concentration of surfactant as given by equations (7) and (10) were solved starting from the initial conditions, equation (11), subject to the boundary conditions, equation (12), using the numerical Method of Lines [6]. Spatial derivatives were discretised using fourth-order centred differences and Gear's method was used to advance the solution in time. A uniform grid of up to 1000 points was used, the grid being refined to achieve convergence. In the case of film rupture, the computations were halted at a film thickness of approximately 0.1 as the increasingly singular spatial derivatives near the rupture region posed a difficulty for it to be resolved. In the simulations, we assume  $R = 4$  [3] and  $\gamma_m^* = S^* = 40$  dynes/cm;  $h_{\infty}$  was taken to be 1 unless otherwise stated.

## RESULTS

### Interface Immobilisation

The effect of surfactant on film drainage can be seen in Figure 2. It is seen that the drainage of the film is retarded even at the addition of a small amount of surfactant. As the initial concentration of surfactant is increased, the drainage profile tends to that of a surfactant-free system with immobile interfaces (*i.e.*,  $v_{int} = 0$ ) for which the flow is only driven by the radial pressure gradient. These results are in agreement with previous theoretical and experimental findings [7-9] which report interfacial immobilisation in the presence of a small quantity of surfactant. A typical surfactant interfacial concentration evolution profile is illustrated in Figure 3(a) indicating that the initial deformation of the interface due to the approach of the drops results in depletion of surfactant at the centre. This gives rise to the Marangoni effect where interfacial tension gradients arise to oppose the flow of liquid out from the drainage region. Consequently, the surfactant gets replenished in the deformation region. The corresponding film thickness evolution profile is shown in Figure 3(b) showing the formation of a dimple. Surfactant is observed to deplete at the dimple rim as fluid is expelled away from this region.

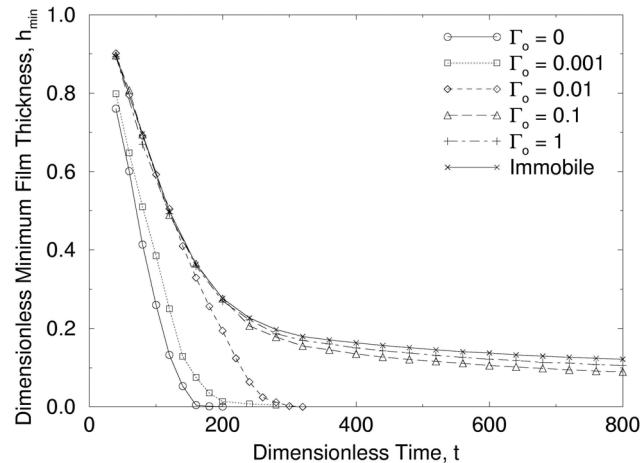

Figure 2. Minimum film thickness as a function of time for various surfactant loadings. The rest of the parameters are  $\lambda = 1$ ,  $Pe_s = 1000$  (where applicable),  $B = 0$  &  $V = 0.01$ . Also shown is the solution for the surfactant-free immobile interface.

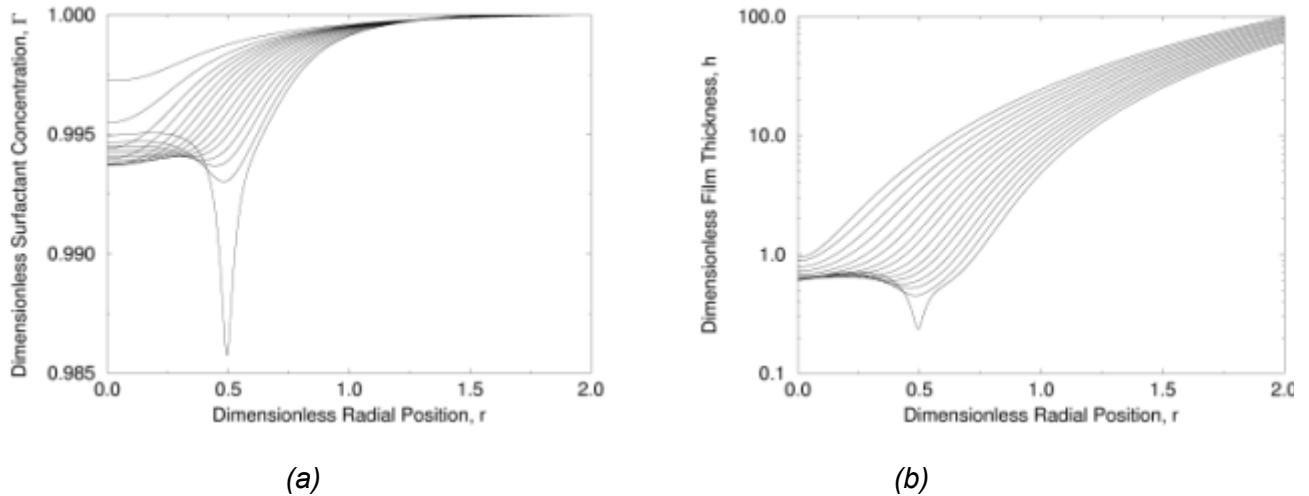

Figure 3. Surfactant concentration (a) & film thickness (b) evolution profiles for 15 equal time steps up to  $t = 117.1$ . Other parameters are  $\lambda = 1$ ,  $Pe_s = 1000$ ,  $\Gamma_o = 1$ ,  $B = 10^{-3}$  &  $V = 0.5$ .

### Viscosity Ratio

The effect of the viscosity ratio on the drainage process is illustrated in Figure 4. It can be seen that the viscosity ratio has little effect on film drainage. This is consistent with the experimental observations in [9]. The viscosity ratio is not expected to significantly influence the drainage of the film because of the resulting immobility of the interface due to the presence of surfactant, as discussed previously [1,9]. Since the flow in the dispersed phase is insignificant for immobile interfaces, the drop phase viscosity therefore no longer influences the interface.

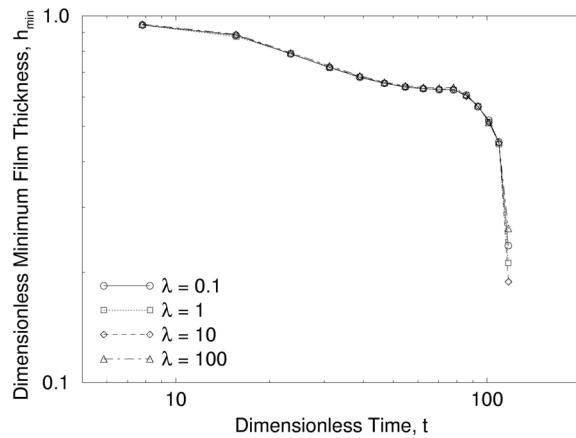

Figure 4. Effect of viscosity ratio,  $\lambda$ , on the minimum film thickness. The rest of the parameter values are  $Pe_s = 1000$ ,  $\Gamma_o = 1$ ,  $V = 0.5$  &  $B = 10^{-3}$ .

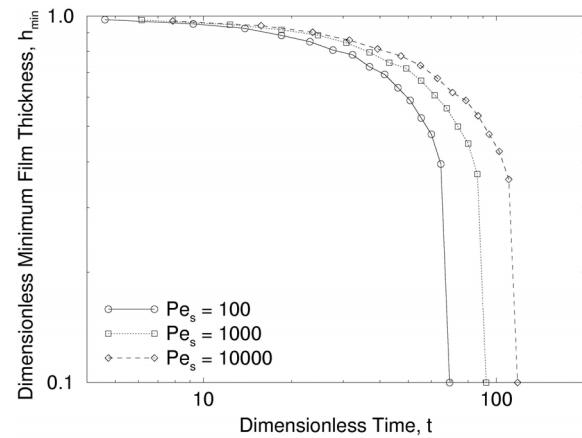

Figure 5. Minimum film thickness as a function of the surface Péclet number  $Pe_s$ . Other parameter values are  $\lambda = 1$ ,  $\Gamma_o = 0.0025$ ,  $V = 0.01$  &  $B = 10^{-4}$ .

### Surface Péclet Number

The surface Péclet number,  $Pe_s$ , represents the significance of surfactant transport by Marangoni convection relative to that by surface diffusion. Low  $Pe_s$  values indicate the dominance of surface diffusion whereas high  $Pe_s$  values indicate that the spreading of surfactant due to Marangoni stresses is the dominant mechanism. Figure 5 depicts the effect of  $Pe_s$  on the dynamics of the film drainage process. As Marangoni convection becomes increasingly significant with increasing

$\text{Pe}_s$ , it can be seen that the latter stages of film drainage is affected, the film taking longer to drain. It should be noted that there is little difference in the early stages of the film drainage because the surfactant concentration gradient at the interface is small. However, as the drops approach each other, interfacial deformation takes place leading to a large negative concentration gradient being present in the drainage region. For systems with high  $\text{Pe}_s$ , the Marangoni stresses that arise as a consequence of these concentration gradients act to retard the interfacial velocity and thus the drainage of the film. For systems with low  $\text{Pe}_s$  on the other hand, there is little effect of the surfactant on the interfacial dynamics since diffusion serves to distribute the surfactant quickly with little disturbance caused to the interface.

### Approach Velocity

The role of the approach velocity on the dynamics of film thinning is described in Figure 6. As the drops collide with increasing velocities, dimpling begins to occur as seen by the rim position for larger velocities in the figure. For low velocities, dimpling does not occur since there are insufficient hydrodynamic forces to cause deformation to the film. As such, the film drains quickly and proceeds towards rupture, as shown by the minimum film thickness curves in Figure 6.

### van der Waals Interaction Forces

As the film thins to thicknesses of the order 1000 Angstroms, intermolecular interactions such as the van der Waals attraction become significant. As a result, there is a negative contribution to the disjoining pressure leading towards the rupture of the film as observed in Figure 3(b). The liquid in the film is expelled together with surfactant away from the rupture region thereby causing a sharp depletion of surfactant as shown in Figure 3(a). Figure 7 shows the rate of film thinning as a function of the dimensionless Hamaker constant,  $B$ . Clearly, as the magnitude of  $B$  increases, the film tends to rupture quickly at a large critical rupture thickness since the van der Waals attraction is strong. In Figure 7, it can be seen that for  $B = 10^{-6}$ , the effect of the van der Waals force, which is extremely weak in this case, is not significant even at a film thickness of 0.1 dimensionless units and hence rupture does not occur even at this stage.

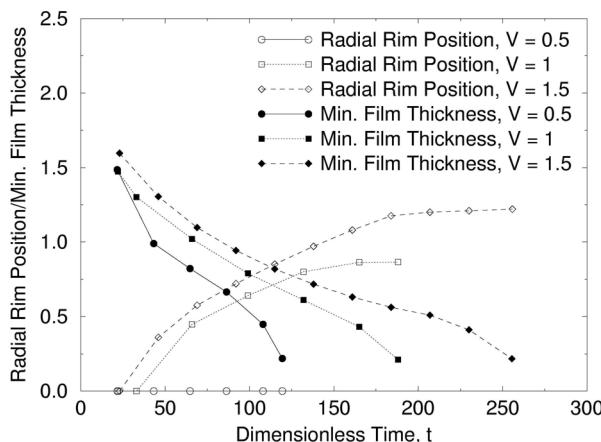

Figure 6. Radial rim position & minimum film thickness as a function of the approach velocity  $V$ . The rest of the parameters are  $\lambda = 1$ ,  $\text{Pe}_s = 1000$ ,  $\Gamma_o = 1$ ,  $B = 10^{-3}$  &  $h_{oo} = 2.63$ .

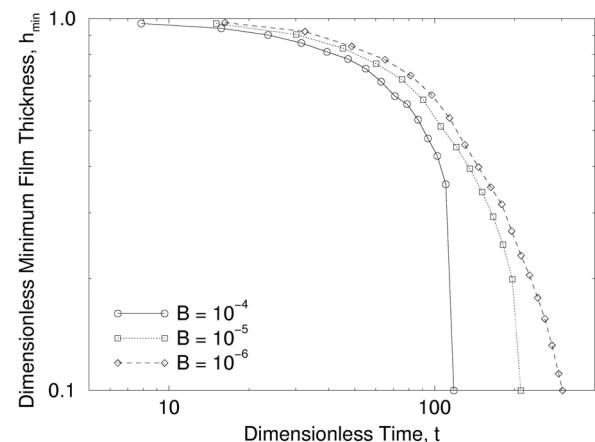

Figure 7. Variation of the minimum film thickness with the dimensionless Hamaker constant  $B$ . The other parameters are  $\lambda = 1$ ,  $\text{Pe}_s = 10000$ ,  $\Gamma_o = 0.0025$  &  $V = 0.01$ .

## CONCLUSIONS

The drainage of the film trapped between two drops colliding at constant approach velocity in the presence of insoluble surfactant has been studied. The interface is rendered immobile even when small amounts of surfactant are present, thereby retarding the drainage of the film and hence film rupture. This is a consequence of concentration gradients that arise out of deformations caused to the film during the approach of the drops. These concentration gradients seek to replenish the surfactant locally depleted in the film deformation region therefore retarding interfacial mobility by opposing the flow of the liquid outwards.

The role of the viscosity ratio, surface Péclet number, approach velocity and van der Waals force have been investigated. Viscosity ratio is not found to have any influence on film drainage since the interface is immobilised and thus there is no flow in the dispersed phase. As the surface Péclet number is increased, Marangoni forces become increasingly dominant thereby retarding the drainage of the film. When the drops collide at higher approach velocities, dimpling of the film is observed and hence the film takes longer to drain as compared to low velocity collisions. Finally, the effect of van der Waals forces on film drainage and rupture was examined.

## ESTIMATION OF COALESCENCE PARAMETERS FOR POPULATION BALANCE MODELS

Martin Simon and Hans-Jörg Bart

Institute of Thermal Process Engineering, University of Kaiserslautern,  
Kaiserslautern, Germany

The description of the hydrodynamics of extraction columns is increasingly done with population balance models. The droplet population balance model describes the axial change of local column hold-up and local droplet size distributions due to the basic phenomena like droplet rising, axial dispersion, droplet breakage, and coalescence. The experimental set-up on the basis of a simple apparatus with low experimental effort will be shown for the investigation of the coalescence parameters depending on inlet droplet diameter and hold - up. The experimental results and an correlation describing the coalescence phenomena for the system n-butylacetate / water will be presented.

### INTRODUCTION

Up to now the design of an extraction column is not feasible without widespread experiments. The usually applied back-mixing model cannot describe the real hydrodynamic behaviour because of its simplicity. The dispersed phase hold - up and the droplet size distribution change with time and column height due to the dynamic processes droplet rising  $v_d$ , axial dispersion  $D_{ax}$ , droplet breakage  $S_B$  and random inter-droplet coalescence  $S_C$ . The droplet population balance model developed since the Eighties [1] takes these kinetic processes into account and gives a more realistic picture of the local hydrodynamics:

$$\frac{\partial P(t, z, d)}{\partial t} = v_d \frac{\partial P(t, z, d)}{\partial z} + D_{ax} \frac{\partial^2 P(t, z, d)}{\partial z^2} + S_B + S_C \quad (1)$$

Let  $P(t, z, d) \Delta d$  be the volume fraction of drops of diameter between  $d \pm \Delta d/2$  at column height  $z$  at time  $t$ .  $P(t, z, d)$  may also be interpreted as the probability density to find a droplet of diameter  $d \pm \Delta d/2$  located at time  $t$  at column level  $z$ . The first term on the right hand side of equation (1) represents the transport of droplets due to droplet diameter depended rising velocity  $v_d$ , the second part describes the axial dispersion of droplets. The source terms  $S_B$  and  $S_C$  take the death and birth of droplets with size  $d \pm \Delta d/2$  due to the breakage and the coalescence of droplets into account. The basis for each simulation is the estimation of the above mentioned model parameters. The model parameters droplet rising velocity  $v_d$ , the axial dispersion coefficient  $D_{ax}$  and the breakage term  $S_B$  are already topics of investigations in a RDC geometry [2]. But due to a lack of data, special attention has to be paid to determine the parameters incorporated in the coalescence term  $S_C$ .

The number of coalescence events of droplets of diameter between  $d_1 \pm \Delta d_1/2$  with droplets of diameter between  $d_2 \pm \Delta d_2/2$  per unit volume and per unit time is given by  $\omega(d_1, d_2)N(d_1)\Delta d_1 N(d_2)\Delta d_2$ , where  $N(d)\Delta d$  denotes the number of droplets per unit volume and  $\omega(d_1, d_2)$  is the so called coalescence frequency. The loss of droplets due to coalescence with other drops is:

$$S_c^-(t, z, d, P)\Delta d = P(t, z, d)\Delta d \int_0^{\sqrt[3]{d_{\max}^3 - d^3}} \omega(d_1, d_2) \frac{P(t, z, d_1)}{V(d_1)} dd_1 \quad (2)$$

The gain of droplets of diameter between  $d \pm \Delta d/2$  is given by the integration over all possible pairs of droplets ( $d_1 \pm \Delta d_1/2, d_2 \pm \Delta d_2/2$ ) with the droplet volume  $V(d_1) + V(d_2) = V(d)$ :

$$S_c^+(t, z, d, P)\Delta d = \frac{1}{2} V(d)\Delta d \int_0^d \omega(d_1, d_2) \frac{P(t, z, d_1)}{V(d_1)} \frac{P(t, z, d_2)}{V(d_2)} \left( \frac{d}{d_2} \right)^2 dd_1 \quad (3)$$

Since the integral counts every event twice, the factor  $\frac{1}{2}$  has to be inserted. To determine the coalescence term  $S_c$  the model parameter  $\omega(d_1, d_2)$  must be known. The coalescence frequency  $\omega(d_1, d_2)$  can be calculated from the coalescence probability  $p$ , the residence time  $t_r$  of the droplets in a volume  $V$  and the volume  $V$  itself where coalescence occurs.

## EXPERIMENTAL

To determine the coalescence frequency it must be guaranteed that only coalescence occurs during an experiment. Otherwise, it is not possible to determine correctly the coalescence frequency. In Figure 1 the experimental set-up ( $D = 80$  mm) is shown which fulfills the requirements.

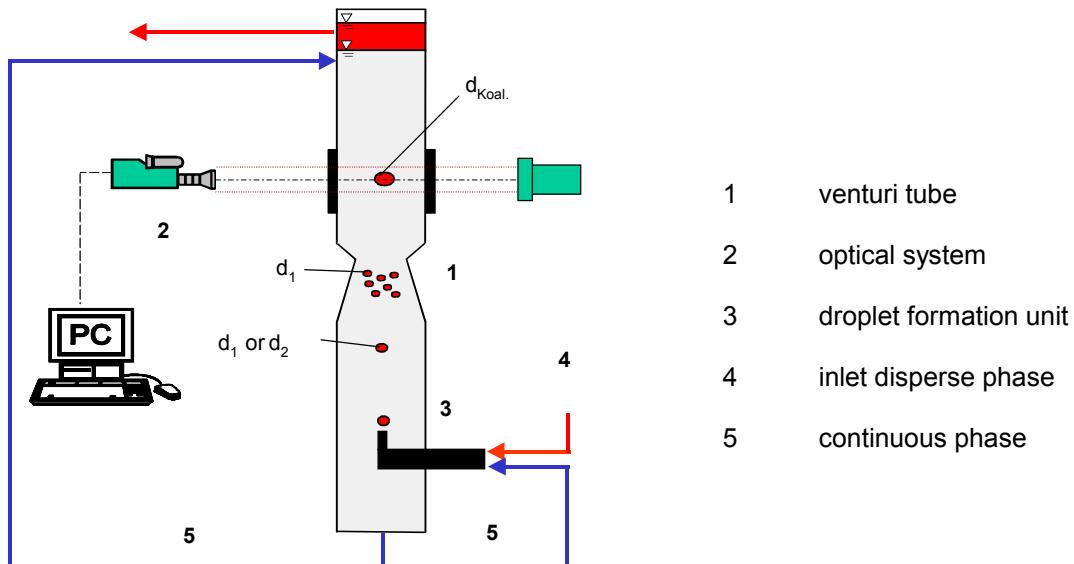

Figure 1. Experimental set – up for coalescence experiments.

The core of the apparatus is a venturi tube with a length of  $L = 250$  mm and a diameter ratio of  $D_s / D = 0.45$  (the smallest diameter of the venturi tube to the apparatus diameter). The continuous phase flows from the top to the bottom of the apparatus and the dispersed phase vice versa.

The droplet formation unit generates monodispersed droplets which is important for the analysis later. Due to the smaller cross section of the venturi tube the velocity of the continuous phase is higher than in the other cross section areas. In this way it is possible to capture the droplets of different diameters depending on the continuous throughput flow in the venturi tube. In this volume the droplets can only interact in such a way that they coalesce.

For a typical experiment swarm droplets of diameter  $d_1$  will be generated. The throughput of the continuous phase is set in that way that the droplets  $d_1$  can not pass the smallest cross section of the venturi tube. When a minimum hold-up is realized coalescence will occur in the venturi tube. After the formation of the swarm droplet class  $d_1$ , droplets of diameter  $d_2 < d_1$  are formed. As a result of the turbulence and the droplet swarm influence, both droplet classes are mixed within the venturi tube. Coalescence events between equal or different sized swarm droplets may occur. Instead of a second droplet swarm  $d_2$  it is possible to form single droplets of diameter  $d_3 > d_1 > d_2$  which pass the venturi tube due to the higher buoyancy force.

The droplet diameters of all droplets which pass the venturi tube can be detected with the optical system above the venturi tube. Following the detection the digital image processing calculate the position, the rising velocity and the size of the droplets. In this way, it is possible to investigate the coalescence probability between swarm droplets  $d_1$  and single droplets  $d_3$  or between equal and different sized swarm droplets of diameter  $d_1$  and  $d_2$  depending on the hold-up,  $\Phi$ , of the dispersed phase. Furthermore, with this procedure it can be determined whether the different rising velocities of two droplets ( $v_3 > v_1$ ) or the residence time,  $t_r$ , and the random movement of droplets in a certain volume,  $V$ , have more influence on the coalescence frequency.

The coalescence experiments are realized with the salt conditioned ( $I = 10^{-4}$  mol/l NaCl) EFCE standard test system n-butylacetate / water. To avoid mass transfer the phases are saturated. The droplet diameter was varied in the range of  $1.5\text{ mm} < d_i < 3.0\text{ mm}$  for the swarm droplets and  $2.5\text{ mm} < d_3 < 3.5\text{ mm}$  in the case of single droplets. Additionally, the hold-up was varied between 0.5% and 5%.

## RESULTS

The coalescence probability of droplets strongly depends on the droplet size and the hold-up. In Figure 2 it can be seen that the coalescence probability generally increases with the hold-up. In contrast to this, the dependency of the coalescence probability on the droplet diameter is different. Up to a swarm droplet diameter of  $d_1 = 2.0\text{ mm}$  the coalescence probability increases as the droplet diameter increases. Although the number of droplets of  $d_1 = 1.5\text{ mm}$  realizing a definite hold-up is greater than realizing the same hold-up with a droplet diameter of  $d_1 = 2.0\text{ mm}$ , its coalescence probability is less. It seems that only the volume of dispersed phase (hold-up) in combination with the droplet diameter is important. The number of droplets seems to have not such a great influence on the coalescence probability.

But beyond droplet diameters of  $d_1 = 2.0\text{ mm}$  the coalescence probability shows another dependency on the droplet diameter. Realizing comparable hold-up values the coalescence probability decreases with larger droplet diameters (dotted line in Figure 2). This can be explained by the rigid sphere of the smaller droplets. Using the information of the droplet detection system (Figure 1) droplets up to  $d_1 = 2.0\text{ mm}$  have the shape of a sphere. But above this diameter the droplet shape becomes more and more deformable. This leads to an enlargement of the film drainage time between two droplets during the coalescence process so that the residence time of two droplets staying side by side is not sufficient to cause coalescence [3].

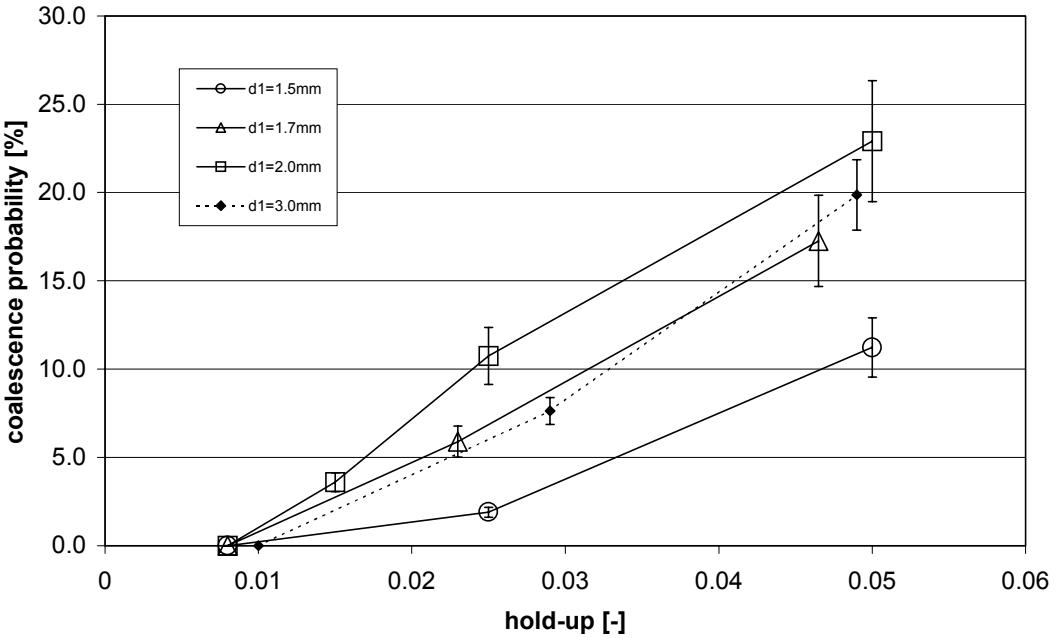

Figure 2. Coalescence probability vs. hold-up for equal sized droplets.

Furthermore, it could be observed that the effect of coalescence between a swarm droplet  $d_1$  and a single droplet  $d_3$  as a result of different rising velocities can be neglected as found elsewhere [4]. Therefore, the idea that the coalescence phenomenon is a random process which mainly depends on the residence time of droplets in a certain volume becomes more important. Coalescence will especially occur in regions where the residence time of droplets is high and the energy input is not in the breakage range. This is, for example, under the stators of agitated columns.

## MODELLING

The modelling and simulation of the inter-droplet coalescence process is done since the Sixties. The investigations start with the works in stirred vessels by Howarth [5] and Coualaloglou and Tavlarides [6]. Coualaloglou and Tavlarides developed a phenomenological model which based on the drainage film theory. Based on this work Sovova [7] and Ramkrishna *et al.* [3] enhanced the model to improve the prediction of the droplet size distribution and the hold-up in liquid – liquid dispersion. They proposed models that take factors like droplet size, system properties and turbulence intensity into account. But in respect of their complexity empirical models were developed [8] which are simpler than those mentioned above.

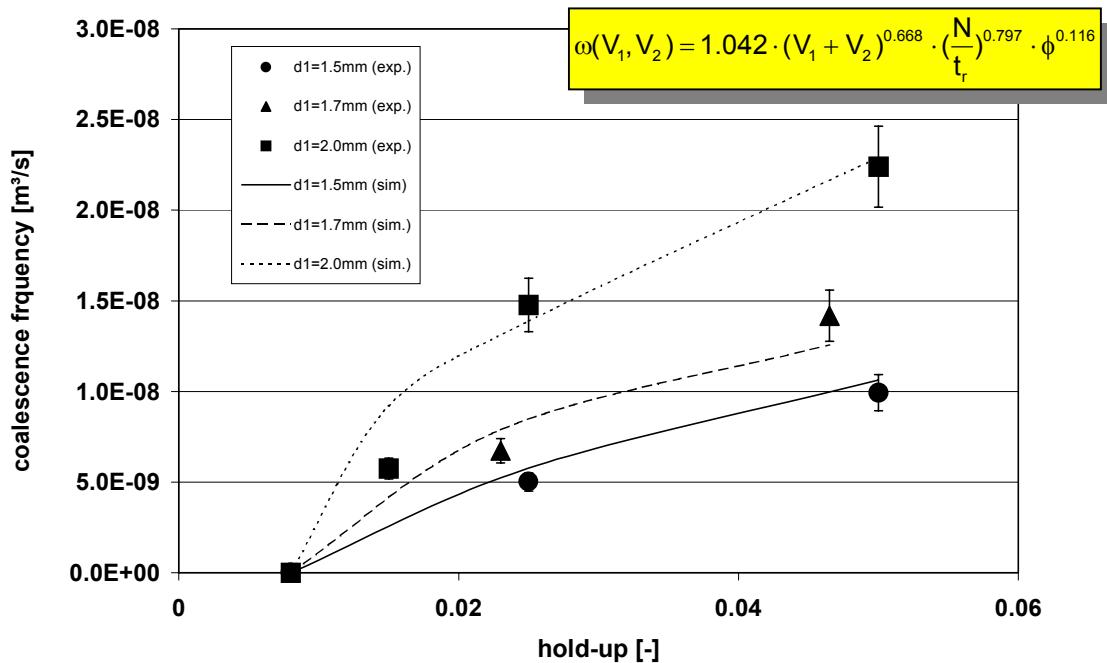

As a result of the experiments presented above it can be pointed out that the coalescence frequency depends on the droplet diameter, the hold-up and the residence time if the system properties do not change with time. The system properties of the system used are too complex as they could be completely taken into account in the model.

Therefore a simple model is used to describe the coalescence behaviour in liquid – liquid dispersion:

$$\omega(V_1, V_2) = k_1 (V_1 + V_2)^{k_2} \left(\frac{N}{t_r}\right)^{k_3} \phi^{k_4} \quad (4)$$

It takes the swarm droplet volumes,  $V_1$ , and,  $V_2$ , the number of coalesced droplets,  $N$ , the hold-up,  $\Phi$ , and the mean residence time,  $t_r$ , into account. The number of coalescence events per unit time is relating to the minimum residence time in a column compartment to observe coalescence. The constants  $k_i$  represent the fitting parameters.

As it can be seen in Figure 3, the coalescence frequency of equal sized droplets increases with hold-up and droplet diameter up to  $d_1 = 2.0\text{mm}$ . The model shows a good comparison to the experimental data within an accuracy of 10%.

*Figure 3. Theoretical and experimental coalescence frequency vs. hold-up for equal sized droplets.*

But the coalescence frequency of larger and different sized droplets can not be calculated with this model. The deformable shape of the larger droplets totally changes the coalescence procedure.

## CONCLUSIONS

As has been shown, the determination of coalescence frequencies is possible with the presented experimental set-up. Coalescence increases with the increase of the droplet volumes up to a diameter of  $d_1 = 2.0\text{ mm}$ , the hold-up and the residence time. To guarantee the reproducibility of the experimental data it is essential to condition the system. Concerning the modelling of the experimental data it must be said that further experiments are necessary to describe the coalescence phenomena of larger sized droplets. To validate the experimental data of the venturi tube, coalescence experiments should be done in a real RDC compartment. Furthermore it is necessary to investigate other standard test systems with and without mass transfer.

## ACKNOWLEDGEMENTS

The authors wish to thank the DFG for financial support and Mrs. T. Schiek and Mr. T. Dreher for their help with the experiments.

## FLOTATION-ASSISTED ELECTROSTATIC COALESCENCE

Philip J. Bailes and Arian Edalat

University of Bradford, Bradford, United Kingdom

A novel electrostatic coalescer is described in which the resolution of a stable water-in-oil emulsion is augmented by sparging air into the system. Batch experiments have been carried out using two types of high voltage alternating waveform to energise the electrodes in a study which covers a range of applied voltages and frequencies. The extent of coalescence in the emulsion is measured by the intensity of light transmitted through the separator and is reported in terms of the mean greyness of digital video images of the emulsion. The results confirm the efficacy of flotation-assisted electrostatic coalescence for stable, high water content emulsion and demonstrate the influence of applied voltage waveform.

### INTRODUCTION

There are several areas of process engineering where considerable benefits accrue from being able to enhance the rate at which droplets of one liquid can be removed from another liquid in which they are substantially immiscible. Amongst the physical methods available for achieving such enhancement, electrostatic coalescence offers cost effective separation and minimal environmental impact for systems where the continuous phase is electrically insulating. Such circumstances arise in solvent extraction operations, emulsion liquid membrane processes, and in the desalting and dehydration of crude oil emulsions. Of particular interest in all these applications is the possibility of using electric fields to treat systems in which the volume fraction of the electrically conducting dispersed phase is high and perhaps stabilised by the presence of surface active agents.

The electric field augments phase separation by promoting coalescence between the droplets. Increased rates of separation have been observed using AC, DC and pulsed electric fields applied between electrodes which may be bare metal, insulation coated, or of composite construction [1]. The mechanisms whereby electrostatic coalescence occurs all involve the attraction of opposite charges on the surface of proximate droplets, the net effect of which is to increase the incidence of collision followed by coalescence. The overall increase in droplet size which results from this process improves the general rate of sedimentation and therefore increases the rate of phase separation. Although the benefits of using electric fields to create larger droplets from many smaller droplets are self-evident, there are still significant practical limitations on what can be accomplished with existing technology. For example, a major obstacle is the inhibiting effect that surface active agents, either naturally present or deliberately introduced, can have on the electrically augmented coalescence process. Another barrier may arise from the need to successfully treat such stable emulsions when the concentration of the conducting dispersed phase is relatively high, say 60% or thereabouts, since this increases the likelihood of a conduction path forming between the electrodes; the attendant current leakage and loss of electric field can have a very deleterious effect on separator efficiency.

Research with liquid systems of this type has recently shown [2,3] that electrically augmented coalescence occurs more rapidly when the stable emulsion to be treated is subject to simultaneous gas flotation. At this stage the explanation for the observed process improvement is not known but it is likely that the gas bubbles serve to remove excess surfactant from the coalescing system. The gas-liquid interface provides accommodation for the surface active molecules that are released back into the organic phase when many small liquid droplets coalesce to form fewer larger droplets and these droplets coalesce with the bulk interface. The use of gas sparging as an adjunct to electrical resolution is attractive from a practical point of view since it preserves the mechanical simplicity and low maintenance costs that are generally associated with electric treaters. Moreover, the technique offers scope for innovative separator design and it is in this context that a novel flotation-assisted electrostatic coalescer has been developed. The work reported here relates to batch tests that have been conducted with this prototype.

## EXPERIMENTAL

The test separator (depicted in Figure 1) was designed so that the upper high voltage electrode plate (30 mm × 180 mm) was horizontal and separated from the emulsion to be treated by a 5 mm air gap; whereas the lower earthed electrode plate was inclined to the horizontal plane and positioned beneath the emulsion. The lower electrode was wave-shaped and incorporated four separate copper tubes (3.2 mm o.d.) that followed the same profile for the purpose of sparging air into the water-in-oil emulsion. This electrode had slots cut through it at the bottom of the troughs in its profile to allow liquid to pass through the plate. The body of the vessel underneath the lower electrode was divided into three sections by two weirs which ensured that in operation the bulk water interface formed three steps each level with the bottom of the troughs in the wave-shaped electrode. The upper electrode and lower electrode plates were made from aluminium and brass, respectively; the walls and base of the separator were fabricated from Perspex™.

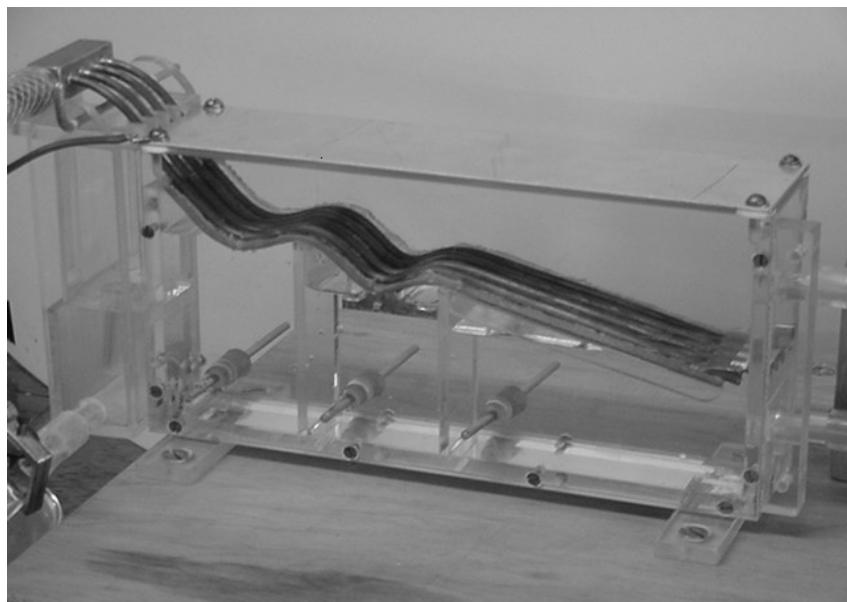

Figure 1. The experimental coalescer.

High voltage was supplied to the apparatus from a Trek 20/20C high voltage amplifier which was used in conjunction with a low voltage function generator. The high voltage waveform was monitored by employing 1/2000 voltage divider coupled to an oscilloscope.

The test emulsions were prepared under ambient conditions by mixing distilled water (40 vol %) into the organic phase (mineral oil - heavy white/odourless kerosene in the ratio 4 : 1, 58 vol %) in the presence of anhydrous lanolin (2 vol %) in the proportions shown. This formulation for the water-in-oil emulsion was developed after extensive trial and error investigations in a previous study [4]. Mixing was accomplished using a Silverson L4RT homogeniser with the impeller speed gradually increased to  $10200\text{ s}^{-1}$  while the aqueous phase was slowly added to the agitated organic phase. The mixing time for a 500 ml batch was 10 minutes and the resultant emulsion was stable for at least 2.5 h.

Phase separation performance was quantified by a light transmission method. For this purpose the separator was illuminated from behind the section where the emulsion depth was greatest and digital video images were recorded through the front face of the separator. The lighting and the size and location of the area being recorded were maintained constant throughout the study. For the work reported here, the video camera was used with a 16 mm focal length lens. The camera was connected to a Kodak Motion Corder Analyzer (Model 1000 B) which has a 1086 frame memory, a resolution of 640 by 480 pixels and a trigger facility. The sequence of images stored on the Motion Corder was transferred to OPTIMAS, an image analysis package which can be used to analyse images based on the different shades of grey of each pixel. The frame storage capability of the Motion Corder meant that it was not possible to record images continuously for the whole of a batch experiment. Instead the progress of each batch was observed at intervals using a sequence of 10 short video samples each made up of 10 frames which were then analysed for their mean greyness. For each sample this information, together with the time of its recording (including the initial pre-treatment zero time value), was exported to an Excel sheet for further analysis.

The procedure for each experiment was that a 196 ml batch of freshly made emulsion was placed in the separator which already contained distilled water up to the maximum level in each section. Once digital images of the untreated emulsion had been recorded, an air flow of  $133\text{ ml s}^{-1}$  was introduced to the emulsion and at the same time the designated electric field was applied. Images of the emulsion were then recorded and saved as the demulsification process proceeded. Each batch was evaluated for 665 s divided for image sampling purposes into the following intervals 15 s, 90 s, 200 s, 320 s, 382 s, 443 s, 507 s, 600 s and 665 s. The field and the flotation were switched off at the end of 600s recording. The state of the emulsion after treatment was recorded at the 665 s image sample. If required a physical sample of the emulsion was removed at this time for observation under a microscope. The applied electrostatic fields were of two alternating types as shown in Figure 2, with most of the experiments being conducted with the type B field.

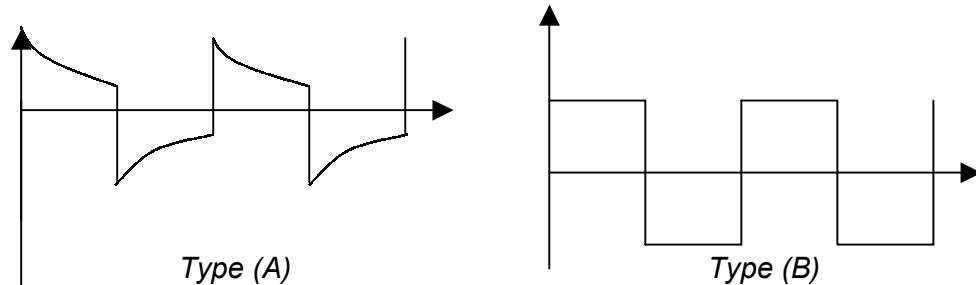

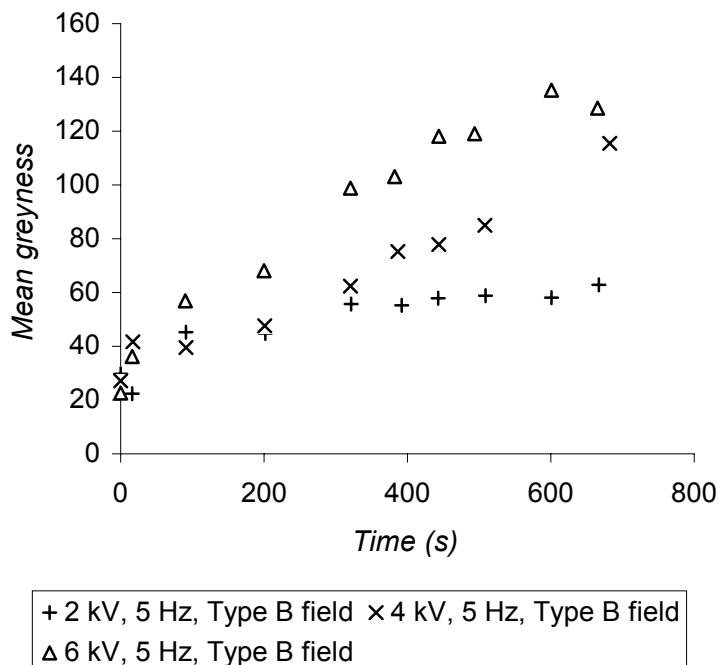

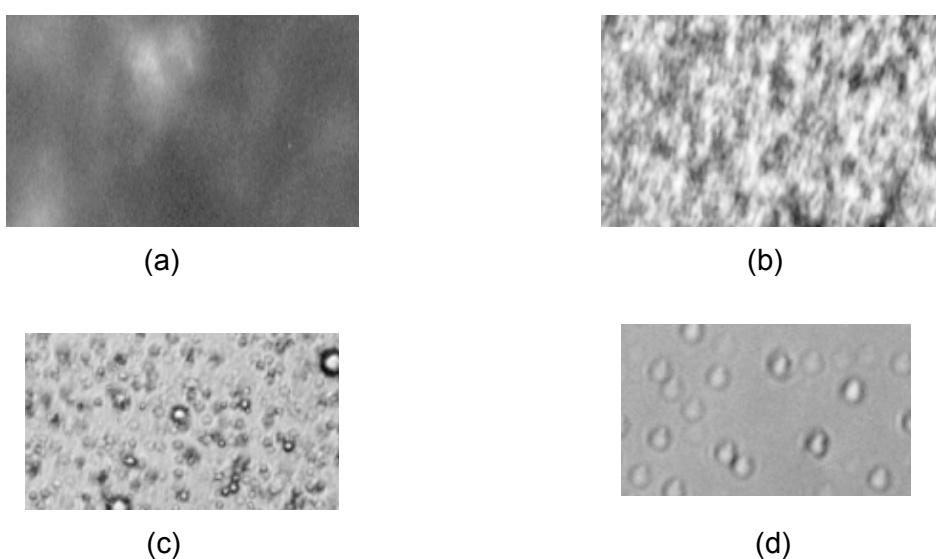

Figure 2. Electrostatic field types.

## RESULTS AND DISCUSSION

It is apparent from the data shown in Figure 3 that as the time of treatment proceeds mean greyness values increase, establishing a similar trend for each of the applied voltages. The mean greyness value indicates the extent of coalescence and therefore phase separation in the emulsion. Confirmation of this may be seen from the photomicrographs given in Figure 4 which depict the state of the system moments after the treatment end point. Also, it should be noted that in the absence of dispersed phase the light transmitted through the separator registered a mean greyness value of 176.5.

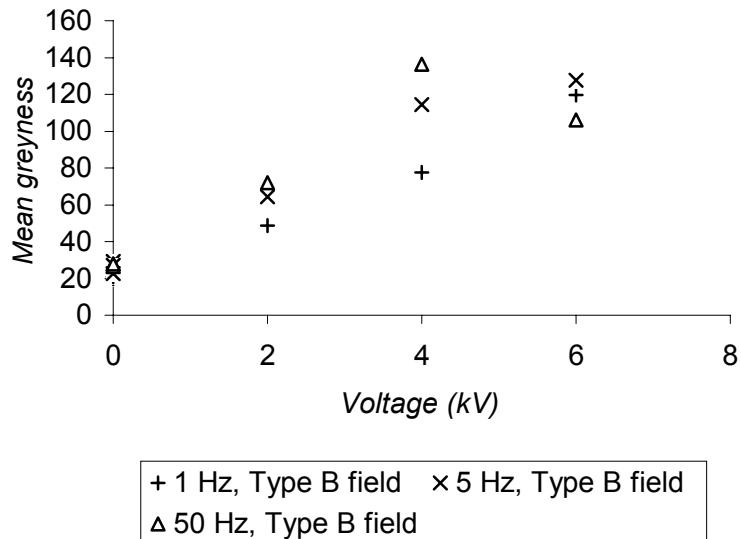

*Figure 3. Rate of change of mean greyness value as a function of applied voltage magnitude.*

*Figure 4. Micrographic images of (a) untreated emulsion; (b) 2 kV, 5 Hz, Type B field; (c) 4 kV, 5 Hz, Type B field; (d) 6 kV, 5 Hz, Type B field.*

Further evidence of the beneficial effect on coalescence of increasing the applied voltage magnitude is given in Figure 5 which shows the mean greyness values obtained at 665 s for three different frequencies. For a given frequency, voltage comparisons are valid since each batch has received energisation by the same number of cycles. It is clear that for the range of frequencies used the best phase separation occurs at 50Hz except at the highest applied voltage. Here it is possible that the sudden fall in performance may be explained by the combined effects of voltage magnitude and rate of change being such as to cause Rayleigh instability and hence droplet break-up. As far as the general trend with frequency is concerned, it is known from the electrical analysis of a broadly equivalent circuit [5] that the dynamic response of the circuit influences the magnitudes of the electric field appearing in the emulsion. In particular, because the equivalent resistance of the emulsion is negligible compared to that of the air gap, the voltage drop across the emulsion is relatively small compared to the applied voltage source for an appreciable time in each cycle. At low frequencies, resistive currents dominate for most of the cycle except immediately after a change in direction of the applied voltage at which time the displacement currents are important. At moderate and higher frequencies the displacement current components remain important throughout the cycle and therefore the magnitude of the voltage applied between the electrodes and across the emulsion itself are comparable.

*Figure 5. Mean greyness at 665 s after the application of different voltages as a function of frequency.*

In the context of the present work where the same potential difference is applied across the electrodes for frequencies of 1 Hz, 5 Hz and 50 Hz it is therefore to be expected that the field in the emulsion would increase accordingly. The higher field strength then experienced by the droplets being the reason for the observed improvement in phase separation with increasing frequency.

Further evidence of the importance to be attached to the dynamic response of the coalescer may be seen in Figure 6 where the performance of the flotation-assisted electrostatic coalescer is improved by changing the waveform of the source voltage. Somewhat surprisingly, the type A waveform outperforms the type B waveform perhaps indicating that the temporal field profile experienced by the droplets in the emulsion is also a factor in achieving good coalescence.

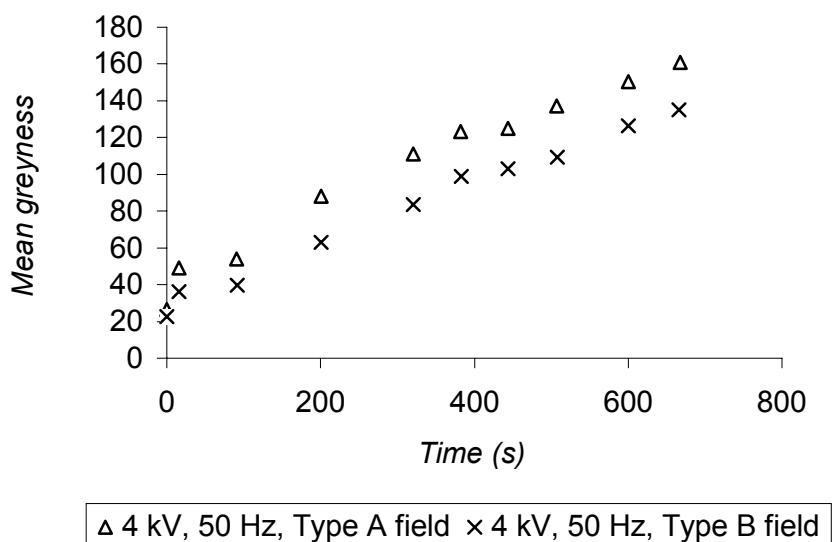

Figure 6. Mean greyness as a function of the shape of the applied waveform.

## CONCLUSIONS

A novel flotation-assisted electrostatic coalescer has been demonstrated to give efficient resolution of a stable water-in-oil emulsion. Phase separation, monitored by a non-invasive method employing digital video image analysis, is shown to be a function of source voltage waveform, magnitude, and frequency.

## DROP COALESCENCE BEHAVIOR FOR EXTRACTION SYSTEMS CONTAINING INDUSTRIAL EXTRACTANTS

Takahiko Ban, Fumio Kawaizumi, Susumu Nii and Katsuroku Takahashi

Department of Chemical Engineering, Nagoya University, Nagoya, Japan

A prediction of drop coalescence behavior based on HLB values of extractants has been examined for industrial liquid-liquid extractant systems. Similar experiment was conducted with surfactants, SPAN systems, for which HLB values are known. The dependence of drop coalescence behavior on HLB of extractant systems is similar to that of the surfactant systems. HLB of the extractants works as one controlling factor for drop coalescence. Additionally, drop size of dispersed phase has been measured in a single stage mixer-settler column for three extractant systems, TOPO, TOA and PC88A. The change of drop size with extractant concentration can be explained qualitatively from drop coalescence behavior.

### INTRODUCTION

Liquid-liquid dispersions play an essential role in separation processes and reaction systems. This is because large interfacial area due to dispersion promotes mass transfer and reaction rates. Estimation of the drop size controlling the interfacial area in liquid-liquid extraction columns is important for both extraction efficiency and operation of the apparatus. Thus a number of relationships have been proposed to describe the effect of column geometry, agitation conditions, physical properties of the liquid-liquid system, and direction of mass transfer on the drop size [1, 2]. It should be noted, however, that the observed holdup effects of dispersed phase on the drop size are different, depending on the authors. This fact suggests that the drop coalescence behavior depends on the liquid-liquid systems investigated. The drop size is affected greatly by the coalescence of dispersed drops. Thus a number of theoretical and experimental researches have been reported of drop coalescence [3-9]. The predictions of drop coalescence behavior treated in these papers are based on the film drainage theory in which only the physical properties of fluids (interfacial tension, density and viscosity) are taken into consideration. Experimental data reported are those obtained in limited situations. Equations for prediction of coalescence are complicated and contain parameters which are practically unavailable. For this reason predicting the coalescence behavior in some of actual cases is extremely difficult.

In this work, among the physicochemical parameters of systems we paid special attention to HLB (hydrophile-lipophile balance) to apply it as an index to predict drop coalescence behavior in practical cases. Drop coalescence behavior in liquid-liquid system has been monitored for ten systems containing industrial extractants, e.g., PC88A (2-ethylhexyl-phosphonic acid mono-2-ethylhexyl ester), D2EHPA (di(2-ethylhexyl)phosphoric acid), TBP (tri-*n*-butyl phosphate), MIBK (methylisobutyl ketone), LIX 84I (2-hydroxy-5-nonylacetophenone oxime), LIX 860IC (5-dodecylsalicylaldoxime), TOA (triocetylamine), Et2CO (diethylketone), BA (benzoylacetone) and TOPO (tri-*n*-octylphosphine oxide). Factors investigated are concentration and HLB of the extractants. Similar experiment was conducted with surfactants, SPAN systems, for which HLB values are known. Average coalescence times for the extractants are compared with those for the surfactants.

Additionally, drop size of dispersed phase has been measured in a single stage mixer-settler column for three systems containing industrial extractants, e.g., TOPO, TOA and PC88A.

## EXPERIMENTAL

### Measurement of Coalescence Time

Coalescence times of two droplets growing at the adjacent glass nozzles standing in parallel were measured. Details of coalescence cell are shown in Figure 1. This apparatus is wholly made of glass and PTFE. Two nozzles **B** with an inner diameter 1.9 mm are introduced in the coalescence cell **A** with an inner diameter 22 mm. The whole apparatus was set in a thermostat air bath to have a good temperature control.

Dispersed phase was fed to both nozzles **B** using a micro-feeder which pushes two syringes simultaneously at the rate 0.5 mm/s. Continuous phase is fed downward into the coalescence cell at flow rate 1.5 mm/s. The drop diameter is 3-5 mm. A video camera was used to monitor the time course of coalescence for the droplets formed at the top of adjacent nozzles in water.

Coalescence time is here defined as the period from the contact time to coalescence time. About 10 runs of measurements of time for coalescence were carried out for each condition. If no drop coalescence occurred in five minute, the measurement was stopped.

### Measurement of Drop Size

The mixer settler column is 100 mm in diameter and 100 mm in height. Single stage of the column (see Figure 2) consists of a lower mixer part and an upper settler part, and a drop coalescer is set between them. The coalescer is a three-dimensional lattice made of glass fiber mesh coated with PTFE. A 6-blade lifter turbine is installed in the mixer.

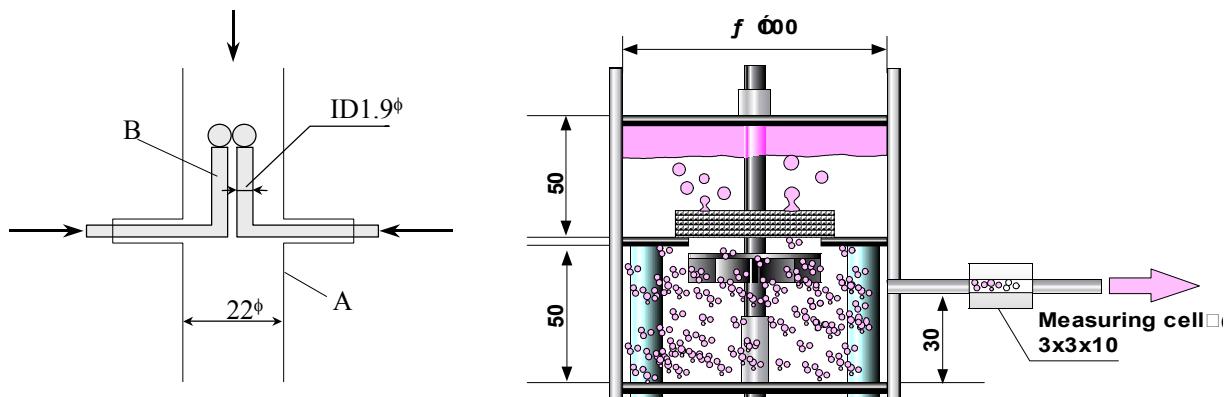

Figure 1. Details of coalescence cell.

Figure 2. Single stage of mixer-settler extraction column.

Aqueous phase (continuous phase) is led to the bottom of mixer through two pipes (not shown in Figure 2) and is discharged from the bottom of the settler through two down spouts. Organic phase (dispersed phase) is also introduced from bottom of the mixer and is drawn from the top of the settler. Liquid samples in the mixer are drawn out from the pipe passing through the rectangular measuring cell. The volume of dispersed phase as well as the total amount of the liquid sample were measured to determine holdup of dispersed phase. Drop size was determined from photograph of the rectangular measuring cell.

## RESULTS AND DISCUSSION

### Relation between coalescence time and HLB

Experimental system is heptane-extractants-water. Figure 3 refers to average coalescence time plotted against extractants concentration (wt%) for various extractants. Average coalescence times,  $t_c$ , for PC88A are very smaller even at their low concentrations. TOPO showed no drop coalescence in the concentration range measured. The values of  $t_c$  for TOA decrease with the increase in the concentration. In general the presence of surface-active substance retards droplets from coalescing. This is because the interfacial tension gradient arising from the concentration difference in the film by natural drainage opposes the film drainage. However, the drop coalescence times decrease with increasing the extractants concentration except for TOPO. The similar result was obtained when a solute is transferred from dispersed phase to continuous phase [11]. As a result of slight solubility of these extractants in water, the effect of mass transfer of these extractants may promote drop coalescence. TOPO having strong hydrophobicity show no effect on the drop coalescence. In heptane-water system, i.e., without extractants, drop coalescence never occurred in the present experimental condition.

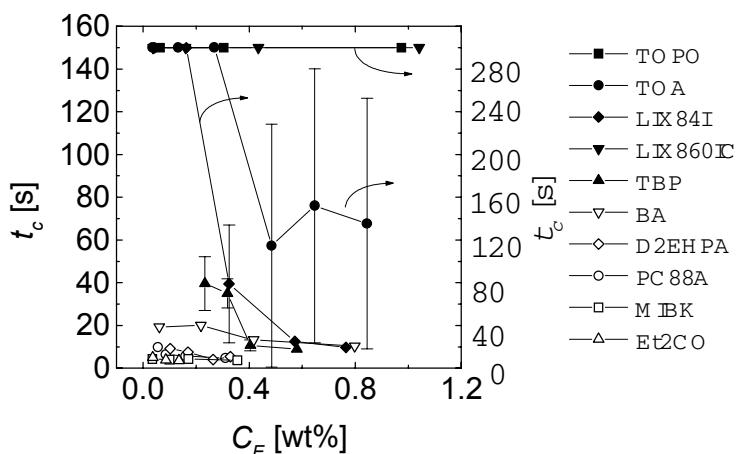

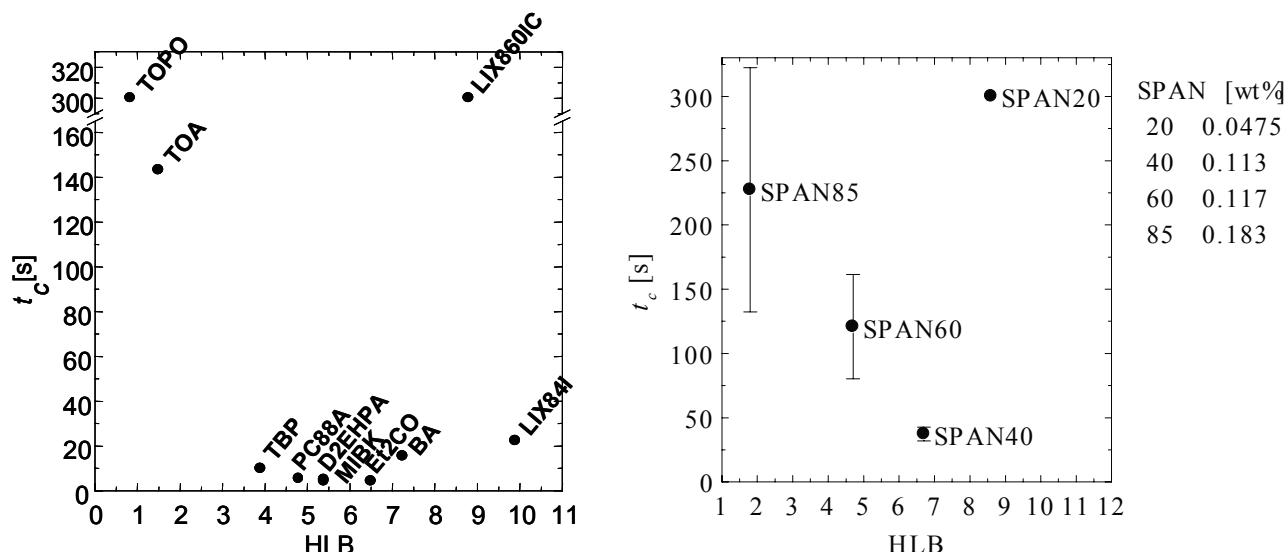

Figure 3. Effect of concentration on coalescence time.

HLB values of extractants were calculated by Oda method [11]. The relation between coalescence time and HLB in the extractant systems is shown in Figure 4(a). Coalescence time in Figure 3 refers to coalescence time averaged for the concentration range where the change in coalescence times with the concentration is small. When no coalescence occurs, coalescence time is taken as 300 s. Average coalescence time decreases with increase in HLB for HLB values lower than about 8. BA having HLB value 7.3 and LIX84I having HLB value 9.9 retard droplets coalescing. LIX860IC having HLB value 8.8 shows no drop coalescence. Coalescence times for TOPO and TOA having strong hydrophobicity are very long. Substances with HLB value above 8 are appropriate for use as o/w emulsifier with the results that the oil droplets are prevented from coalescing. The results for surfactants for which HLB values are available are shown in Figure 4(b). Since the surfactants are insoluble in heptane, the measurement of coalescence time was done in toluene-surfactants-water system.

The most remarkable finding is the strong resemblance between the result for the extractants and that for the surfactants system. SPAN85 having HLB value 1.8 significantly retards droplets coalescing. The higher the HLB values become, the shorter the coalescence times become for HLB values lower than 8. No drop coalescence was observed for SPAN 20 having HLB value 8.6. Our results indicate that irrespective of the kind of surface-active substance coalescence time decreases with the increase in HLB for HLB values lower than about 8, while

coalescence time increases at HLB values higher than 8. This implies that hydrophilicity or highly lipophilicity of extractants prevents the droplets from coalescing. Thus, HLB works as a clue to predict drop coalescence behavior for industrial extractants for which reliable data of physical and chemical properties are unavailable.

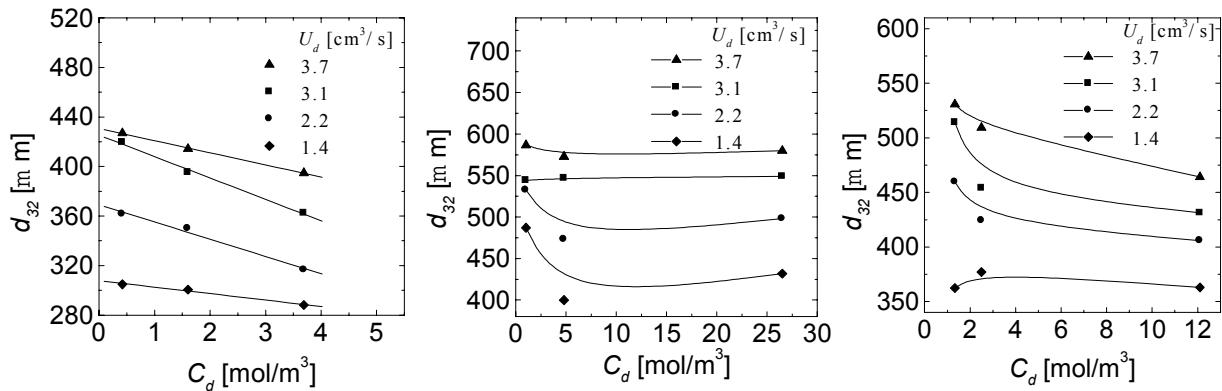

*Figure 4. Relation between coalescence time and HLB in extractant (a) and surfactant (b) systems.*

#### Relation between Drop Size and Holdup

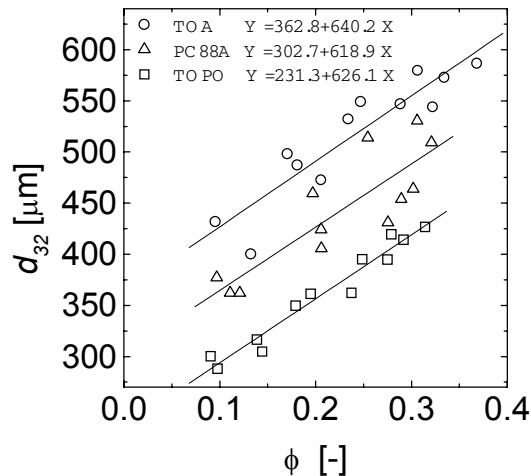

Drop size and holdup of dispersed phase were measured in TOPO, TOA and PC88A systems. As shown Figure 4(a), coalescence time for TOPO is the longest and that for PC88a is the shortest in these systems. The Sauter mean diameters,  $d_{32}$ , of dispersed phase are plotted against hold up in Figure 5. Sauter mean diameter for both TOPO and PC88A decreases with the concentration, while one for TOA remains constant with the concentration. Although PC88A shows very short coalescence time, the Sauter mean diameter decreases with the concentration, i.e. the coalescence effect is minor. As shown in Figure 3, coalescence behavior for both TOPO and PC88A is independent of the concentration. Thus the factor controlling drop size in these systems is breakage effect by their surface activity rather than coalescence effect. On the other hand coalescence time for TOA decreases with concentration. The enhancement of coalescence frequency by increasing the concentration maintains drop size at constant value.

Figure 6 represents the relation between Sauter mean diameter and holdup. The Sauter mean diameter increases linearly with holdup for all systems. In contrast to our expectation that PC88A will show the highest slope as a reflection of its shortest coalescence time among the three, the slopes of these lines in three systems are similar. Estimation of drop size needs consideration of the competition between coalescence and breakage effects.

*Figure 5. Effect of extractant concentration on Sauter mean diameter.*

(a) TOPO (b) TOA (c) PC88A.

*Figure 6. Relation between Sauter mean diameter and holdup.*

## CONCLUSION

The relation between coalescence times and HLB in both the extractants and surfactants systems was investigated in the present work. The results for the extractants show that coalescence time decreases with the increase in HLB for HLB values lower than about 8, while it increases with HLB value higher than 8. The similar result was obtained for industrial surfactants SPAN. HLB of the extractants works as a reference for prediction of coalescence.

Drop size of dispersed phase was measured in the single stage mixer-settler column. The results show that the change of drop size with extractant concentration can be explained qualitatively from drop coalescence behavior. However, the assumption that drop size is predictable from drop coalescence behavior was unsuccessful for the system investigated.

## NON-INVASIVE EXPERIMENTAL STUDY AND PHENOMENOLOGICAL MODELLING OF TOLUENE-IN-WATER TURBULENTLY AGITATED LIQUID-LIQUID DISPERSIONS

M. M. Ribeiro, M. Baptista, P. Teixeira\*, J. M. Soeiro\*, L. M. Ribeiro\*,

Liquid-liquid dispersions usually show highly dynamic behaviour, marked by simultaneous drop size- and operating conditions-dependent breakage and coalescence. This complex behaviour is difficult to realistically model and accurately probe by non-invasive experimental means. In this work, an experimental batch/continuous agitated vessel with attendant dispersed phase imaging system was set-up, and is described here (together with drop size data treatment procedures), in order to non-invasively study toluene-in-water turbulently agitated liquid-liquid dispersions. The data is physically interpreted and compared with the results of numerical simulations using a specifically developed, population balance numerical algorithm, combined with a detailed description of the hydrodynamics according to three different drop interaction models, as developed by different authors (Coulaloglou and Tavlarides, Sovová, and Tsouris).

### INTRODUCTION

In process vessels, agitation-induced turbulence, which is required to create and maintain a dispersed phase with the specific interfacial area adequate for mass transfer, directly controls drop breakage and coalescence frequencies (and thus drop size and interfacial area distributions) as well as the instantaneous kinetics of the (transfer or reaction) process through the individual drop surfaces. Mass transfer efficiency of liquid-liquid mixers thus becomes highly dependent on these hydrodynamic phenomena. In multi-component systems, this behaviour is also of paramount importance to the overall rate and selectivity of the process.

Present knowledge of these processes is still embarrassingly scarce, in particular when contrasted with the present availability of physically realistic, fast and efficient algorithms with effective predictive power and suitable for real plant control applications [1, 2].

During the last decades several drop-size measurement techniques have been developed or adapted from solid particle size measurement. Bae and Tavlarides [3] discussed the operating range of several available techniques. Most of these were employed for measuring the drop size distribution (or average drop size) in lean dispersions under steady state conditions. However, techniques that involve sampling of the drops are not adequate for unsteady-state experiments. Even under steady state conditions, capillary techniques are very tedious and time consuming when very lean dispersions are involved. Recent experiments made in a Kühni column at the Technical University of Munich [4] highlighted and supported this assertion.

Recently, drop size studies have been made easier by developments in video and image processing technology [5], but still suffer from flaws originated from intrusion or wall effects, mainly at high volume fractions.

These experimental studies provide the factual basis for modelling procedures to describe drop size distribution by means of population balance techniques, and indicate that there are a number of different possible coalescence mechanisms [6]; however, there have been difficulties in identifying mechanisms that correlate well to the data collected.

Early computer simulations of agitated liquid-liquid systems were based on *ad hoc* heuristics to describe peculiarly idealised interactions within the dispersed phase. Most of the present day approaches, however, employ highly sophisticated models based on sound kinetic-statistical principles (Brownian collision and homogeneous turbulence, for instance) and describe the relevant material and equipment properties by means of phenomenologically significant parameters. Such approaches are usually based on population balance techniques and explicitly include detailed descriptions of environmental conditions on breakage and coalescence events. Among such models, Coulaloglou and Tavlarides' model [7], for the locally isotropic regime, enjoys well-deserved prominence, despite some acknowledged deficiencies. This model has been described as adequately accurate, both when mass transfer is present and absent, and has been extensively put to use for both stirred vessels and extraction columns. However, Sovová [8] and Tsouris [9] have cast doubts about its description of the coalescence event. We shall compare these three models with our experimental data.

All the above authors use the same expression for the breakage frequency,

$$g(d) = C_1 \cdot \frac{\varepsilon^{1/3} \cdot d^{-2/3}}{1+\phi} \exp\left(-\frac{C_2 \sigma \cdot (1+\phi)^2}{\rho_D \varepsilon^{2/3} \cdot d^{5/3}}\right) \quad (1)$$

and, for the collision frequency,

$$h(d, d') = C_3 \cdot \frac{\varepsilon^{1/3}}{(1+\phi)} \cdot (d^2 + d'^2) \cdot (d^{2/3} + d'^{2/3})^{1/2} \quad (2)$$

where  $C_1$ ,  $C_2$  and  $C_3$  are constants,  $d$  and  $d'$  are the diameters of the colliding drops,  $\phi$  is the dispersed phase holdup,  $\varepsilon$  is the energy dissipation per unit mass,  $\sigma$  is the interfacial tension and  $\rho_D$  is the dispersed phase density.

Coalescence frequency is modelled as a product of two factors, the collision frequency and the coalescence efficiency. To describe the coalescence efficiency, Coulalouglo and Tavlarides [7] have used a probabilistic model, based on the argument that coalescence occurs when the contact time between the two colliding drops exceeds the time necessary to drain the liquid film between them to rupture thickness. The expression obtained for the coalescence efficiency, considering drop size above the turbulence micro-scale, is

$$\lambda(d, d') = \exp\left[-C_4 \cdot \frac{\mu_c \cdot \rho_c \cdot \varepsilon}{\sigma^2 \cdot (1+\phi)^3} \left(\frac{d \cdot d'}{d + d'}\right)^4\right] \quad (3)$$

where  $C_4$  is a constant and  $\rho_c$  and  $\mu_c$  are, respectively, the density and viscosity of the continuous phase.

Based on the assumption that coalescence is controlled by the ratio between the interfacial energy and the energy of collision, Sovová [8] suggested the following equation for the coalescence efficiency:

$$\lambda(d, d') = \exp\left[-C_5 \frac{\sigma \cdot (d^2 + d'^2) \cdot (d^3 + d'^3) \cdot (1+\phi)^2}{\rho_D \cdot \varepsilon^{2/3} \cdot d^3 \cdot d'^3 \cdot (d^{2/3} + d'^{2/3})}\right] \quad (4)$$

where  $C_5$  is another constant.

Tsouris [9] argued that Sovová's equation (4) excessively inflates the coalescence frequency of the larger drop sizes, while Coulalouglou's expression (3) overestimates smaller drop coalescence. Therefore, he used another form of the coalescence efficiency function

$$\lambda(d, d') = \exp \left[ -c_6 \cdot \frac{\mu_C \cdot (1 + \phi)}{\rho_C \cdot \varepsilon^{1/3} \cdot (d + d')^{4/3}} \right] \quad (5)$$

where  $C_6$  is a constant.

## EXPERIMENTAL SETUP AND MEASUREMENT TECHNIQUE

The liquid-liquid system used for the experiments consists of toluene as the dispersed phase and distilled water as the continuous phase. The apparatus used is shown in Figure 1. A glass vessel with flat bottom and four baffles was used. A standard Rushton turbine of 0.1 m diameter (1/2 of vessel diameter) provided the agitation.

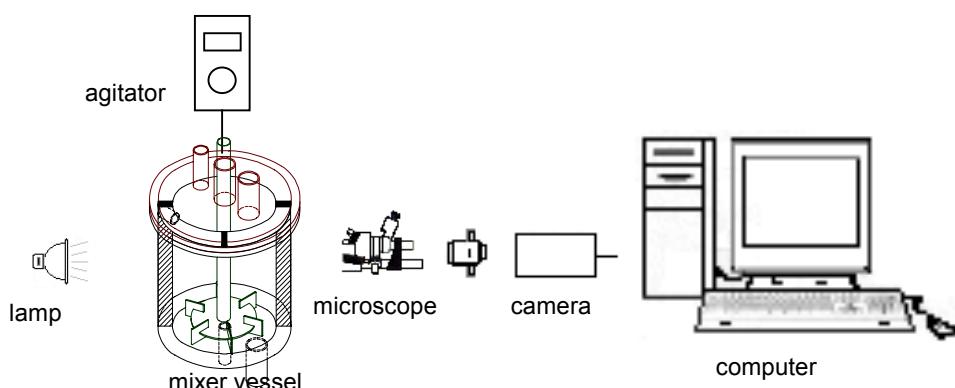

Figure 1. Schematic drawing of the mixer and data acquisition equipment.

In order to measure the drop size distribution, new techniques have been developed, based on image acquisition by means of a video camera and microscope. As mentioned above, Pacek [5] used such a technique but illuminated invasively, thus disturbing the local hydrodynamics. We aimed at a feasible non-invasive technique, even if limited to lower hold-ups. After exhaustively testing a large variety of video cameras available in the market, one of them was selected for its speed and sensitivity: the *Sensicam Long Exposure*. This camera was mounted behind a low magnification *Nikon SMZ-2T* microscope, supported by a purpose-built structure, enabling focusing and targeting. For the present work, the magnification was 25 times the actual size, and the focus was located approximately 15 mm behind the vessel wall.

Opposite, the lighting system was mounted. Several types of lighting systems were tried, from fluorescent tubes, to point sources, electronic flat lamps and halogen lamps. Only the latter exhibited consistently good results using four 12 Volt-lamps (focused beam, rear heat dissipation support, *Phillips ref. Masterline Plus*).

From the video pictures acquired, drop sizes were measured by means a routine developed in *Scion Image* software. In this specific routine, a mouse is used to place three points on the perimeter of each drop. The software then inserts a circle showing the size and the location of the drop, and these data are stored in an ASCII (.txt) file. If the operator misplaces one of the points, which would lead to a wrong size determination, he can visually detect it and repeat the three-point selection. After all drops have been measured for each experiment, the .txt file is exported to *Microsoft Excel* and the drop size in pixels recalculated to centimetres. The drop volumes were classified into 50 different logarithmic size fractions, from  $10^{-7} \text{ cm}^3$  to  $10^{-2} \text{ cm}^3$ .

## PROCEDURE AND RESULTS

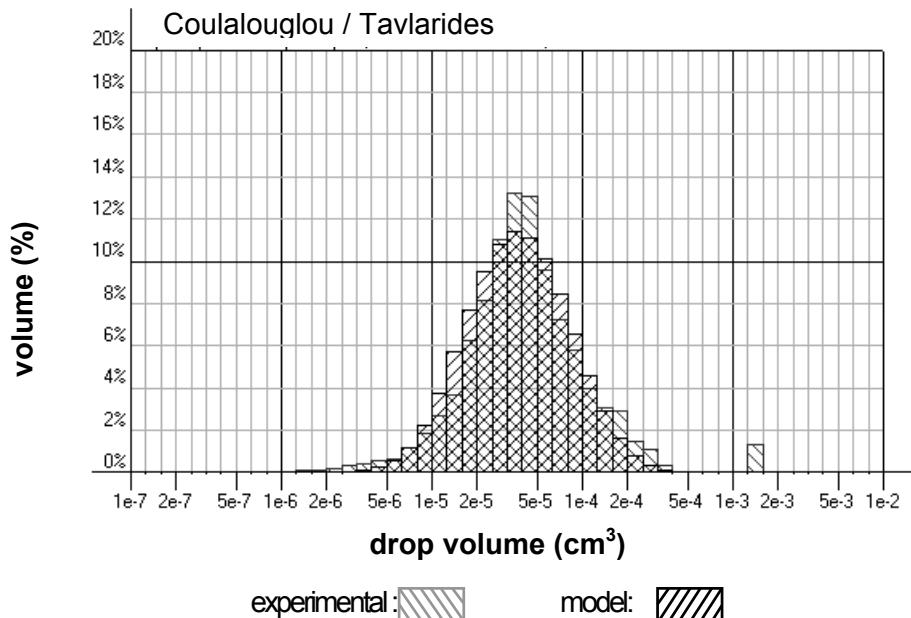

Experimental drop size distributions were compared with the results predicted by numerically solving three different coalescence models (Sovová, Tsouris and Coulalougou and Tavlarides).

Experimental batch runs under different sets of operating conditions (hold-up and agitation rates) were planned (agitation rates 99/111 rpm; hold-ups 1.85/2.17 %) and performed, taking into consideration the conflicting requirements for image quality (moderate hold-ups and not too small drops) and homogeneous dispersion in the vessel.

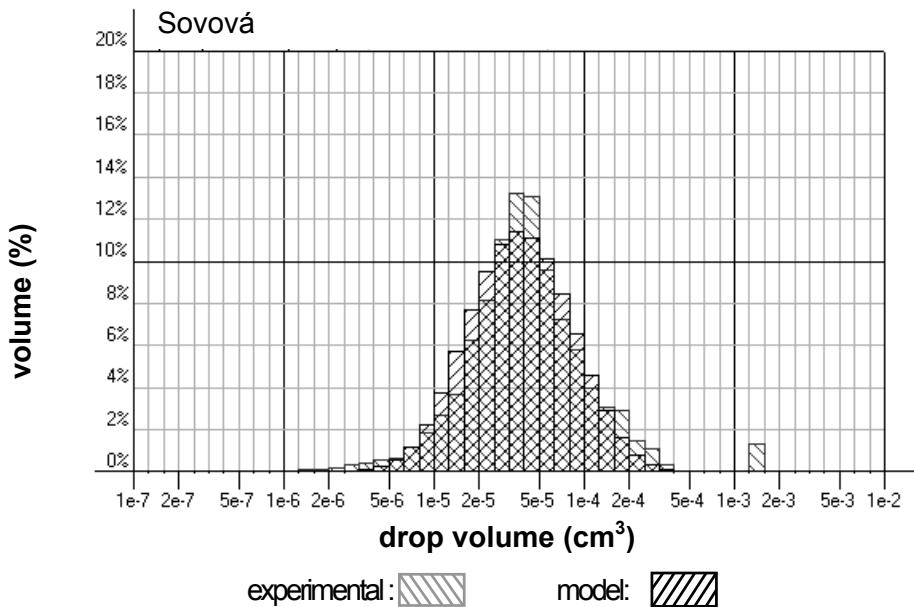

Common ( $C_1$ ,  $C_2$  and  $C_3$ ) and specific ( $C_4$ ,  $C_5$  and  $C_6$ ) model parameters were adjusted to the pooled data from four batch experiments, using a standard Levenberg-Marquardt routine and the visual and numerical (sum-of-squares of deviations) quality of the adjustments were noted and compared (see Table 1 and Figures 2, 3 and 4 for some examples).

*Table 1. Optimised breakage and coalescence parameters for the three different models.*

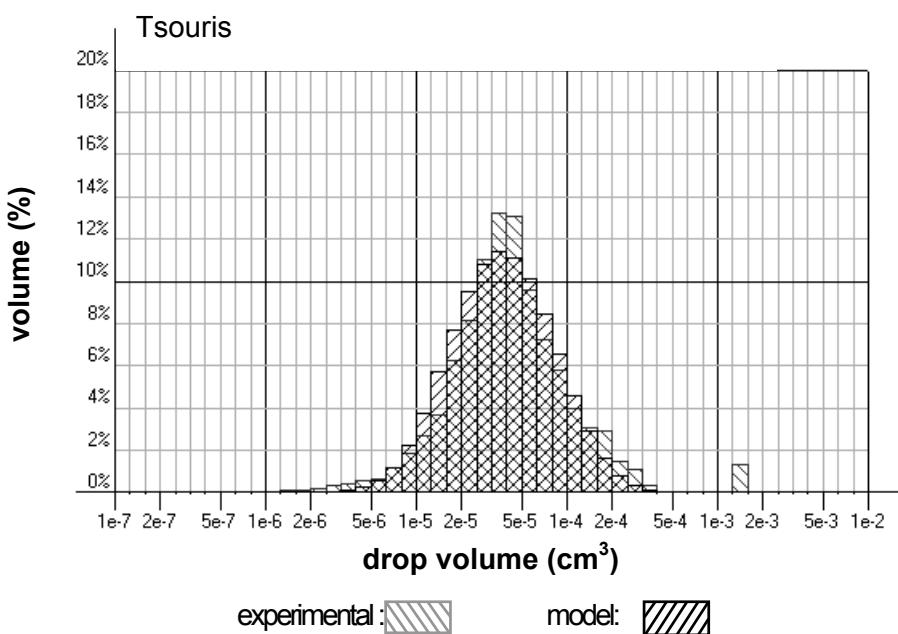

Coalescence Model	Ssq Deviation	Breakage $C_1$	Breakage $C_2$	Coalescence $C_3$	Coalescence
Coulalougou/ Tavlarides	1.32864e-5	2.37516e-3	3.16059e-2	1e-3	$C_4 = 1.8443e+1$
Sovová	1.32834e-5	2.37445e-3	3.16619e-2	1e-3	$C_5 = 1.50335e-5$
Tsouris	1.32863e-5	2.37505e-3	3.16068e-2	1e-3	$C_6 = 3.01719e-3$

*Figure 2. Experimental and simulated (according to Coulalougou and Tavlarides' model) histograms of size distributions, in a batch vessel, for 100 rpm and 1.85 % hold-up.*

*Figure 3. Experimental and simulated (according to Sovová's model) histograms of size distributions, in a batch vessel, for 100 rpm and 1.85 % hold-up.*

*Figure 4. Experimental and simulated (according to Tsouris' model) histograms of size distributions, in a batch vessel, for 100 rpm and 1.85 % hold-up.*

In order to test the predictive performance of the three models, 13 continuous runs (agitation rate 113 rpm, hold-up 1.85%, and residence time 167 s) were performed under the same operating conditions. Using the kinetic parameters from the batch runs, the averaged data were used to optimise the (unknown) drop feed distribution parameters ( $V_{\text{aver.feed}}$  and  $\sigma_{\text{feed}}/V_{\text{aver.feed}}$ ) and weighed sum-of-squares of the deviations (see Table 2).

*Table 2. Optimised feed drop distribution parameters for the three different models under continuous operating conditions.*

Model	Ssq of deviations	$V_{\text{aver.feed}}$	$\sigma_{\text{feed}}/V_{\text{aver.feed}}$
Coulalouglou/Tavlarides	2.26441e-5	9.33067e-4	2.99811e-1
Sovová	2.24796e-5	9.30824e-4	3.00424e-1
Tsouris	2.26381e-5	9.32955e-4	2.99840e-1

## DISCUSSION AND CONCLUSIONS

The quality of the adjustment of hydrodynamic parameters from the batch runs is excellent ( $\sim 10^{-5}$ ) for all three models as well as the agreement between the common parameters. Using the continuous runs as independent benchmarks, the predictive power of all three models is also remarkable, both as measured by the quality of the adjustment ( $\sim 2 \cdot 10^{-5}$ ) and by the agreement between the feed parameters' estimations.

Quite astonishing is the fact that such different models seem to have the same descriptive and predictive power. This may be ascribed to the narrow range of operating conditions used (and indeed required so far) by the size measurement set-up used.

## AC FIELDS IN SOLVENT EXTRACTION – INFLUENCE ON DROPLET FORMATION AND MASS TRANSFER

Guido Gneist and Hans-Jörg Bart

Institute of Thermal Process Engineering, University of Kaiserslautern, Germany

The influence of a high frequency electric field on droplet formation and mass transfer was investigated. Different parameters, such as capillary geometry and conductivity of the continuous water phase, were varied to study the influence on droplet size. As a result, the conical capillary leads to smaller Sauter-diameters in comparison to the flat one. In the same way, the lower conductivity of continuous phase resulted in smaller droplet sizes, as desired. Further, the dispersion of highly viscous liquids in water was demonstrated. Finally, mass transfer enhancement was visualized with an optical double flash system.

### INTRODUCTION

The application of different electric fields (DC, pulsed DC and AC) in solvent extraction is widely recorded in literature [1-6]. Herein an improvement of interfacial mass transfer is described by reducing the effective interfacial tension, increasing interfacial area for mass transfer and enhancing interfacial disturbance and drop circulation.

Concerning the increase of interfacial mass transfer area, mono-dispersed droplets of isododecane and toluene, down to 90 µm, were produced in distilled water using high frequency electric fields, with voltages up to 20 kV [7, 8]. Here for low dispersed phase flow rates (0.05 and 0.1 ml/min) a significant reduction of droplet diameter with increasing voltage was shown between 0 and 4 kV. In exceeding this limit, only a slight decrease was detected. A frequency change from 45 to 30 kHz was necessary to reach higher voltages above 4 kV and did not affect the droplet size. The two different flow rates did also not change the droplet size. In contrast, the different geometry of the capillaries used (glass capillary with axial electrode and stainless steel capillary) had a strong influence on droplet size. If the reverse dispersion type (water in organic) was investigated, the conductivity of the disperse water phase was an important factor in the spraying process.

In this paper the influence of capillary geometry and conductivity of the continuous water phase on droplet size, using in a high frequent AC field, were investigated. The conductivity was adjusted by adding NaCl to the continuous distilled water phase. Besides, the possibility of dispersing highly viscous liquids, such as Silicone Oil, in water was also studied. Additionally, the visualization of mass transfer enhancement under field conditions is given in the physical toluene/acetone/water system.

## EXPERIMENTAL PROCEDURE

The experimental set-up (see Figure 1) for droplet formation (1) is a double casing glass tube which is sealed with two Teflon plugs with boreholes for the nozzles. Herewith it is possible to disperse the heavy phase top down, as well as the light phase bottom-up to observe both dispersion types. The apparatus is placed inside a rectangular Plexiglas tank (2), thermostated with water at 298 K. The dispersed phase is fed into the nozzle by a dosing pump (5) with constant flow rate of 0.05 ml/min.

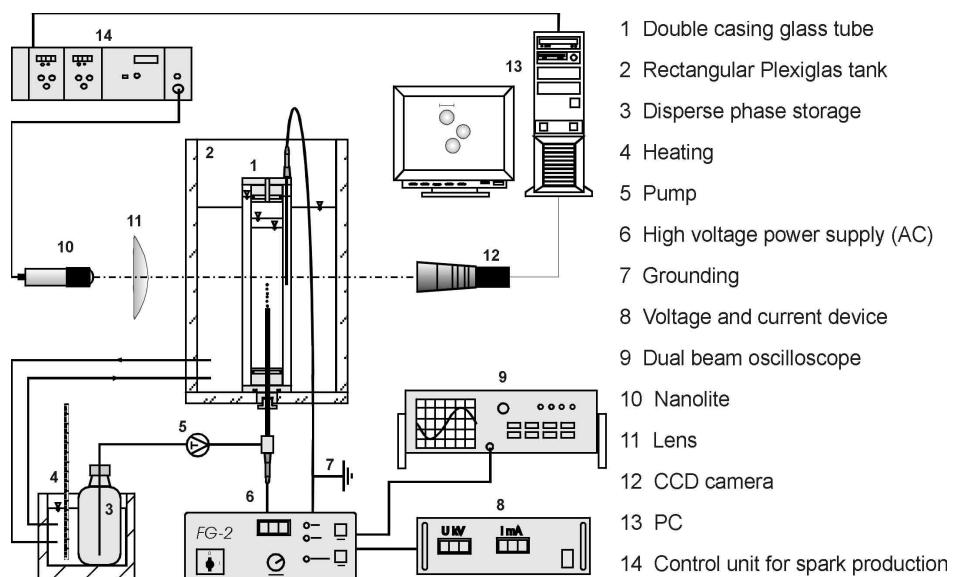

Figure 1. Experimental set-up.

For the experiments different types of isolated stainless steel capillaries are used (flat capillary (ID = 0.13 and 0.25 mm), cone shaped capillary (ID = 0.25 mm)). The high voltage power supply (6) is connected to the capillary and the ground electrode, where the double casing filled with an electrolyte (solution of 0.5 mol/l NaCl/H<sub>2</sub>O) acts as a grounded electrode (7). The applied voltage, the current and the AC frequency are then measured (8, 9). An optical double flash system is used for the analysis of droplet diameter. It comprises a nanolite (10) connected to a control unit (14), a planoconvex lens (11) and a CCD camera (12). Droplet images are taken under various experimental conditions and afterwards analysed with the use of digital image processing software (13). The measured droplet sizes are used to calculate droplet size distributions and Sauter-diameters. The physical properties of the liquids used are listed in Table 1.

Table 1. Physical properties of the liquids.

Liquid	Interfacial tension $\gamma$ [mN/m]**	Viscosity $\eta$ [mPa s]	Density $\rho$ [kg/m <sup>3</sup> ]
Isododecane	44.8	1.49	751
Isotridecanol	14.0	41.9	848
Silicone Oil 550	37.8	220.5	1060
Silicone Oil DC200	37.8	1000	970
Toluene	35.0	0.59	867
Acetone		0.316	791
Water		0.95	998

\*\* together with water

## CAPILLARY GEOMETRY

The results of droplet formation for isododecane in distilled water, using two different stainless steel capillaries, are shown in Figure 2. Both capillaries had the same inner diameter of 0.25 mm, but a different shape of the tips (flat and conical). For 0 kV the results strongly depend on the wetting of the material, which is influenced by the mechanical treatment of the tip and the cleaning procedure. Both capillaries were cut and machine polished and one of them afterwards received the conical shape by turning. The different finish of the tip could be an explanation for the deviation at 0 kV. If no wetting is expected, the droplets should have the same size. Between 0 and 1 kV, no stable voltage was available with the high voltage source. With increasing voltage the droplet size decreases and the wetting effect vanishes. A distinct influence of capillary geometry on droplet size is visible. Together with the conical capillary smaller droplets are formed. The relation between exposed cross-sectional area of liquid and cross-sectional area of capillary has to be considered in a correlation for droplet size.

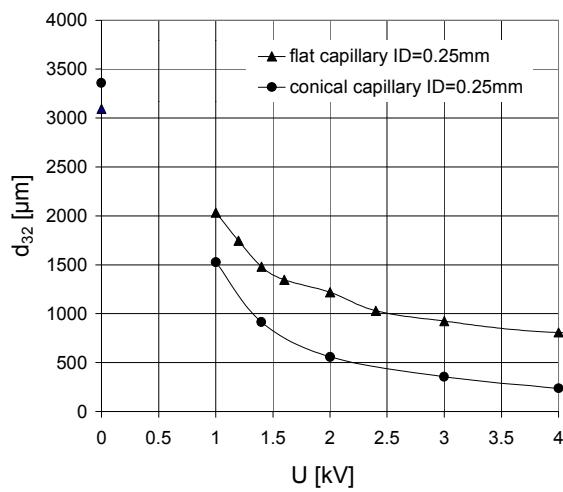

Figure 2. Sauter-diameter vs. applied voltage for different capillaries for isododecane droplets in distilled water.

## CONDUCTIVITY OF CONTINUOUS WATER PHASE

For all experiments the flow of current was measured as a function of applied voltage. In Figure 3 the typical current-voltage-plots are shown for varying conductivity of the continuous water phase at a constant frequency of 45 kHz.

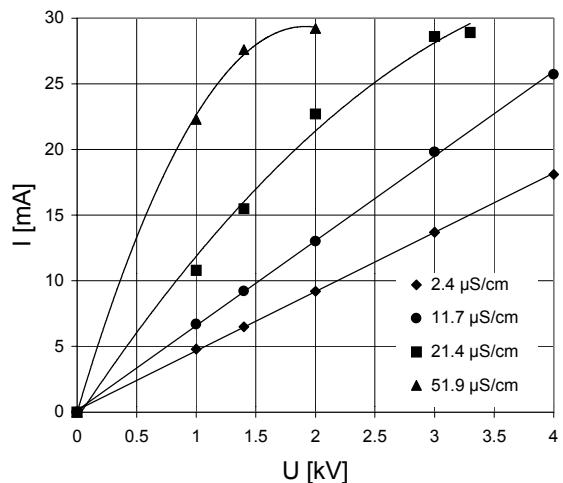

Figure 3. Flow of current vs. applied voltage for varying conductivity of continuous water phase.

Below 12  $\mu\text{S}/\text{cm}$  a linear relationship between current and voltage is visible, which loses its linearity with increasing conductivity. For 21.4  $\mu\text{S}/\text{cm}$  it was not possible to obtain higher voltages than 3.3 kV and for 51.9  $\mu\text{S}/\text{cm}$  not higher than 2.0 kV. Besides, increasing conductivity and current flow resulted in the production of heat in the apparatus.

The reducing effect of applied voltage on droplet size is neutralised with increasing conductivity of continuous water phase (Figure 4 (a)). The curves shift again to larger Sauter-diameters. Above 11.4  $\mu\text{S}/\text{cm}$  this effect is not negligible. With increasing conductivity the duration of charges at the droplet surface is minute, so that the resulting electric force, acting on the droplet, is reduced. The smallest droplets are produced together with the lowest conductivity. Additionally, with growing conductivity and flow of current, the power input is enhanced, which is directly visible in Figure 4 (b). At higher conductivity, the power input has to be raised to form the same droplet size.

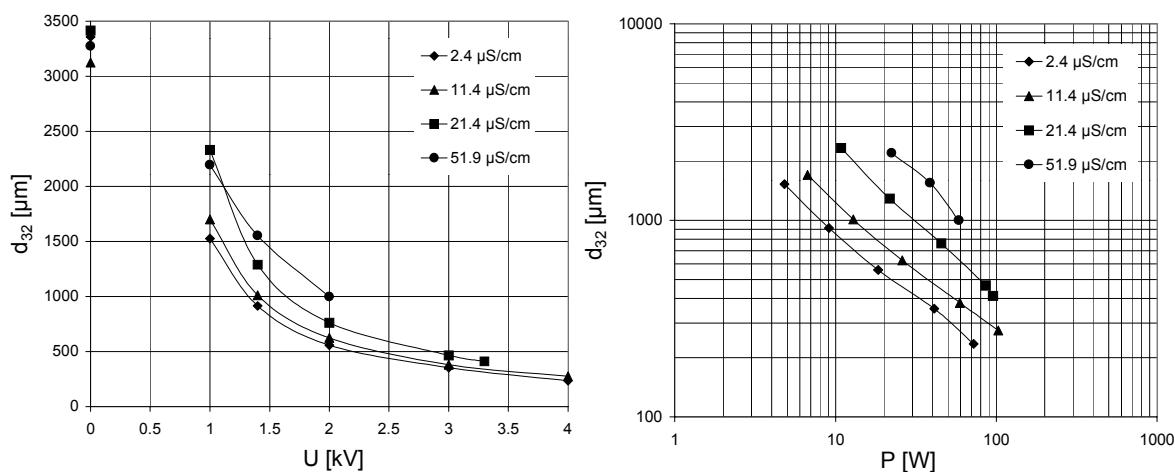

Figure 4. Sauter-diameter with respect to the applied voltage (a) and power input (b) for varying conductivity of continuous water phase (isododecane/water, cone shaped capillary ID=0.25mm).

## HIGHLY VISCOUS LIQUIDS

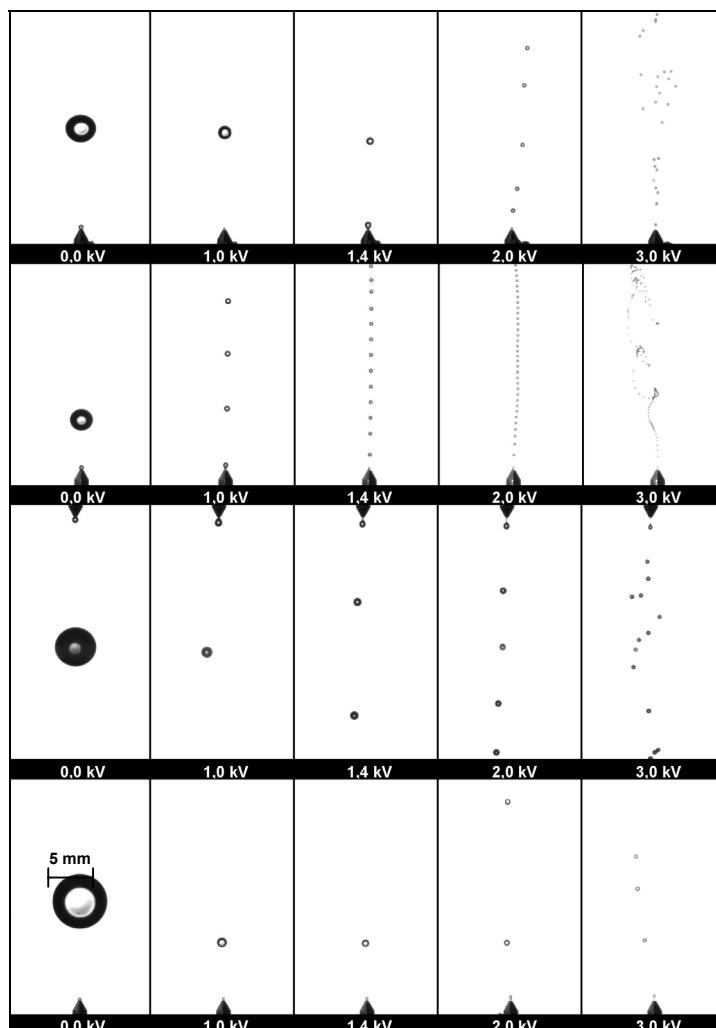

If dispersion of a highly viscous liquid into a medium of low viscosity, such as water, is achieved, some problems appear, because of low shear stress. Together with the presented method, it is possible to break the liquid-liquid surface and to form mono-sized droplets without any problem, as demonstrated in Figure 5.

The results of different organic solvents with a distinct variation of viscosity, shown in Figure 6, yield no clear dependence between viscosity and droplet size. For example, it is possible to calculate the different droplet sizes at 0 kV, without taking viscosity effects into account. The force balance between interfacial tension force and the force due to gravity are alone responsible for the resulting droplet size at 0 kV. With exceeding 0 kV, the electric field force prevails the force balance. The curves approach each other with increasing voltage.

## MASS TRANSFER

The electric field acts directly at the liquid-liquid interface. By changing the size and the shape of the interface, it is possible to influence the transfer of species between the liquids. Together with the optical system used, a relatively high concentration of acetone in water (3.7 mol/l) was chosen to visualize mass transfer inside a continuous toluene phase (Figure 7). With increasing voltage the droplet elongates, because of the electric stress, and the optical inhomogeneities

(schlieren) are greatly enhanced. These inhomogeneities are a result of density differences and therefore are an index for mass transfer. To get more insight into these interfacial phenomena under field conditions, a schlieren arrangement is being implemented at the moment and will be used for further investigations.

*Figure 5. Dispersion patterns with increasing voltage for different organic solvents in distilled water (images from top down: isododecane, isotridecanol, Silicone Oil 550, Silicone Oil DC200).*

## CONCLUSIONS

The influence of capillary geometry on droplet diameter was investigated in the isododecane/water system by applying a high frequency (45 kHz) electric field to the capillary. Using the conical capillary instead of the flat one, smaller droplets were formed, which indicates a relation between exposed cross-sectional area of the liquid and cross-sectional area of the capillary. The influence of continuous water phase conductivity on droplet size was also studied in the isododecane/water system. Here the lowest conductivity resulted in droplets with the smallest size. In this context, the conductivity of the water phase should not exceed 10  $\mu\text{S}/\text{cm}$ , to avoid a high flow of current and power input. Moreover, the presented technique, using high frequency AC fields, is successful, if highly viscous liquids have to be dispersed in low viscosity media, such as water. Concerning mass transfer enhancement, an observation of interfacial phenomena under field conditions was demonstrated with an optical double flash system and will be adjusted by a newly implemented schlieren arrangement.

# APPLICATION OF PREFERENTIAL SOLVATION CONCEPT FOR INTERPRETATION OF THE MECHANISMS OF SOLVENT EXTRACTION. I. ACID SOLVENT EXTRACTION BY AMINES. II. METAL SOLVENT EXTRACTION BY ACIDIC EXTRACTANTS

Vladimir Kislik

Casali Institute of Applied Chemistry, School of Applied Science and Technology,  
The Hebrew University of Jerusalem, Jerusalem, Israel

A novel competitive complexation/solvation modeling approach is introduced to explain the mechanisms of solvent extraction. The theory is based on the modified competitive preferential solvation theory, the concept of amphoteric properties of extractants and the concept of different aggregation structures' formation at increasing extractant loading. Four possible stages of extraction behavior, interacting mechanisms and aggregate structures formation, depending on solute-solvent affinity constant ratios and solvent concentrations, are discussed. Extractants are considered amphoteric and may perform as acids (electron acceptors) or bases (electron donors). A mathematical description for quantification of the results is also introduced. Based on the presented theory, analysis of different acid-amine and metal ion-organic acid extraction systems are presented. It gives a key for preliminary quantitative prediction of suitable extraction systems.

## INTRODUCTION

Solvent extraction is an efficient industrial scale technology for the separation and concentration of solutes from leachates, fermentation broths or industrial waste solutions. Complex chemistry of extraction processes is still not completely understood [1,2]. In some cases the complicated behavior of extraction systems conflicts with the stoichiometric ion-exchange models [3,4]. The difference in the extraction trends must be attributed to solvation (coordination) effects. In order to analyze solvation effects, identification, and most importantly, quantification of solvent-solute interactions must be accomplished. Coordination models, explaining qualitatively some mechanisms of metal solvent extraction, meet difficulties when modeling anion exchangers, acid solvent extraction and, especially, at the attempts of quantification of the models.

The Competitive complexation/solvation theory is based on the modified competitive preferential solvation (COPS) theory [5], the Lewis acid-base concept [1-4], the concept of amphoteric properties of extractants and the concept of different aggregation structures' formation at increasing extractant loading [3,4]. In this paper extraction of acids by amines and metal ions by acidic extractants is interpreted on the base of the new theory. The data, available from the literature [1,2] and our experiments [6,7], are used for interpretation.

## BASIC STATEMENTS OF THE THEORY

### I. As loading of organic phase by extracted solute increases, interacting mechanisms and compounds formed are changing

The most general extraction isotherm consists of four stages at loading of organic phase by extracted solute (see Figure 1):

Region 1: Comparatively low extraction at low solute concentration in the aqueous phase.

Region 2: Drastic rise of distribution curve where the small increase of solute concentration in the aqueous phase has a strong effect on its organic phase concentration.

Region 3: The distribution curve approaches saturation and levels-off to nearly a plateau.

Region 4: Above-stoichiometric extraction is pronounced at high solute concentrations with massive formation of the third phase. The distribution curve rises once more.

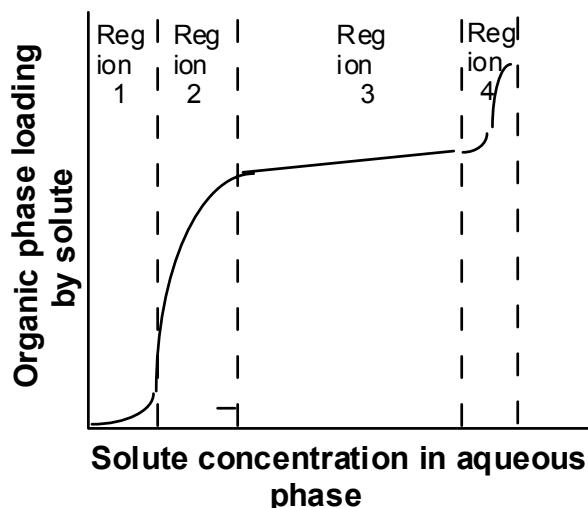

Figure 1. General scheme of organic phase loading as a function of solute concentration in the aqueous phase.

The division of the distribution curve between the regions depends on many factors, such as properties and concentrations of solute extracted, the properties of the extractants and solvents (modifiers, synergistic agents) used, temperature, acidity of the treated (feed) aqueous solutions and the structure of initial compounds, the structure of the organic compounds formed, aggregation, etc.

### II. Both strong (ion-exchange, "chemical", electrostatic) and weak (solvating, "physical", "intermolecular", hydrogen, coordinate) interactions have to be taken into consideration in all regions of the general extraction isotherm (Figure 1)

In the following, postulates of the COPS theory [3-5] are modified for extraction systems. Solute in the phases is surrounded by a solvation shell. This means that it interacts with all the constituents of the environment and, therefore, "free" solute, free extractant, or free solute-extractant complex do not exist. Components of the solvation shell compete to form a complex according to their electronic-geometric affinity  $k_i$  (interaction strength), which is constant at a given temperature and pressure. Coefficient,  $k_i$ , represents the total, complexing and solvating affinity constant.

Competition between the constituents of the solvation shell takes place according to their affinity constants  $k_i$  and the number of potentially available molecules of every component, i.e., on its actual concentration. The solute is partitioned among all constituents of the solvation shell medium. A set of equations [3,4] are developed for calculation of the solute

partitioning factors,  $P_{Si}$ , and its concentrations (molar fractions,  $C_{Si}$ ) in the mixed solvation shell (extractant, E, water (in organic), W, active adduct, A, and diluent, D) at equilibrium.

The value of the physicochemical property X (for example, chemical shift  $\delta$  in NMR, molar extinction coefficient  $\varepsilon$  in UV-VIS, changes in free energy  $\Delta G$ , etc.), measured in mixed solvents, is considered to be the weighed sum of this same property measured in pure solvent constituents. The contribution of each solvent on the shift of this property, X, is additive. Considering three component solute-extractant-water system we obtain, after some algebra, the linear equation for the measured property X [3-5]:

$$\frac{X_{SW} - X}{C_E} = \frac{k_{SE}}{k_{SW}} v_W (X_{SW} - X_{SE}) - [\frac{k_{SE}}{k_{SW}} v_W - v_E] (X_{SW} - X) \quad (1)$$

and the saturation factor Z at  $C_E > C_S^0$ :

$$Z = \frac{C_{Sorg}}{C_S^0 - C_{Sorg}} = \frac{X_{SW} - X}{X_{SW} - X_{SE}} = \frac{k_{SE} v_W C_E}{k_{SW} + (k_{SE} v_W - k_{SW} v_E) C_E} \quad (2)$$

where  $k_{SE}/k_{SW}$  is the affinity constant ratio;  $C_S^0$  is the initial (or total) concentration of the solute;  $C_{Saq}$ ,  $C_{Sorg}$ ,  $C_{SE}$ ,  $C_{SW}$  are the solute concentrations (molar fractions) in the aqueous phase, in the organic phase, in the mixed solvation shell of the organic phase (extractant, water, active adduct and diluent), respectively, at equilibrium;  $v_E$  and  $v_W$  are partial molar volumes of extractant and water.

### **III. Extractants are considered amphoteric and may perform as acids (electron acceptors) or bases (electron donors), depending on the structure of their functional groups and composition of the organic phase, and on the structure of the solutes and composition of the aqueous phase**

According to the Lewis and Pearson classification, many substances can be both bases and acids. Any specie with a  $pK_a$  value higher than the given one, may be conjugate base to it. An empirical quantum chemical method's approach is applied, which employs the concepts of donor-acceptor interactions. For example, at extraction with acidic organic extractants, titanium(IV) hydroxo-ion [4], hydrated (coordinated) by water molecules at the aqueous phase  $pH \geq 2$ , is considered as a conjugate base (electron donor) to extractant. In this case, the extractant in an inert organic diluent behaves as an electron acceptor (acid). At  $pH \leq -0.9$  ( $\geq 8$  mol/kg HCl) of the aqueous solutions, titanium ion, coordinated (solvated) by HCl molecules, behaves as a conjugate acid (electron acceptor) to the same acidic organic extractant. In this case, the extractant behaves as an electron donor (base).

### **IV. Aggregation, as a process that affects extraction, should be considered in all regions of the general extraction isotherm (Figure 1)**

At low solute concentrations in the organic phase, solute-extractant complex, surrounded by its solvation shell, forms a geometric structure which is denoted as a nucleus aggregate. According to the COPS theory the solute is partitioned between different solvents to form some kind of a virtual physical unity, called solvation shell. It is a statistical thermodynamics' denomination that is convenient for mathematical description. The nucleus aggregate describes the same but real physical unity with stereospecific bonds and orientation in the bulk organic solution. The nucleus aggregate is open to the bulk phase and is characterized by the fast exchange with the bulk solvents.

Region 1 is characterized by solute-extractant equivalent concentration ratios,  $C_{S\text{org}}/C_{SE} < 1$  (more than one equivalent of extractant to one equivalent of solute) and  $P_{SE\text{s}} \geq P_{SE\text{c}}$ , where  $P_{SE\text{c}}$  and  $P_{SE\text{s}}$  represent partitioning factors of the solute in the complexed and solvated forms, respectively [3]. The structures of the nuclei aggregates in this region are formed mainly through the weak interactions. pH dependence in this region is not pronounced, but stability pH limitations of the formed complexes are observed.

Region 2 is characterized by solute-extractant equivalent concentration ratios,  $C_{S\text{org}}/C_{SE} \approx 1$  and  $P_{SE\text{s}} \leq P_{SE\text{c}}$ . Formation of nuclei aggregates in this region is driven mainly by strong interactions. The interactions in this region are strongly dependent on pH or anion concentration in the aqueous phase. Divergence of the distribution curve slope from the 1/1 equivalents of the S-E complex is explained by weak interactions.

According to the presented theory, the difference between regions 1 and 2 is mainly in the magnitude of the affinity constant ratios:

$$\frac{k_{SE\text{c}}}{k_{SW}} / \frac{k_{SE\text{s}}}{k_{SW}} = \frac{k_{SE\text{c}}}{k_{SE\text{s}}} \quad (3)$$

at the same concentrations of extractant, water in organic phase and affinity coefficient of solute in pure water.  $k_{SE\text{c}}$  and  $k_{SE\text{s}}$  are affinity constants of the solute toward extractant in the complexed and in the solvating forms, respectively. So, all coordination structure schemes of the nuclei aggregates in Region 1 may belong to Region 2, but at  $k_{SE\text{c}} > k_{SE\text{s}}$ . It follows that the slopes of the distribution curve in Fig. 1 for Regions 1 and 2 may have all magnitudes between two extreme structures: at  $k_{SE\text{c}} \rightarrow 0$  and at  $k_{SE\text{s}} \rightarrow 0$ .

With increasing concentration of solute the nuclei aggregates interact, grow in size via a step-wise aggregation and form linear or ringed (cyclic) aggregates. This is Region 3, in which the equivalent of solute to the equivalent of extractant ratio is:  $C_{S\text{org}}/C_{SE} \geq 1$ . Region 3 is characterized mainly by bridging of the nuclei aggregates through the solute, extractant, or active adduct (including water) molecules. Competition between these components influences the slope value of the curve. All components of the linear aggregates are also open to the bulk phase, and exchange between the aggregate and the bulk solvents continues to be fast.

At high solute concentrations upon reaching a critical size, the structural reorganization of the linear (or cyclic) aggregates takes place, and supramolecular structures - reversed micelle-like, or crosslinked cluster-like, are formed. This is Region 4, characterized by  $P_{SE\text{s}} < P_{SE\text{c}}$  and  $C_{S\text{org}}/C_{SE} \gg 1$ . Above-stoichiometric loading and massive third phase formation are typical for this region. The exchange rate between the components of the solvation shell and the bulk phase depends on the orientation of the polar groups relative to the bulk phase, and, as a rule, is controlled by diffusion kinetics. Host-guest interaction models can be used for analysis of these systems. Region 4 is beyond the practical interest of technologists and will not be discussed in this paper.

### **Summarizing Remarks for the Presented Theory**

Affinity constant ratio  $k_{SE}/k_{SW}$  can be obtained from the slope of the equation (1) plots:  $(X_{SW} - X)/C_E$  vs  $(X_{SW} - X)$ . The intercept gives the hypothetical differences between the property, measured in pure extractant and in pure water. Thus, the agreement between the direct experimental determination of the measured property in pure solvents and their graphically obtained values of  $X_{SW}-X_{SE}$  may be examined. Only relative values (affinity constant ratios) can be measured in solution because of the ubiquitous nature of molecular interactions. Affinity constant ratio's value of unity suggests the same values of solvation effects of the

solute with extractant in the organic phase and with water in the aqueous phase; a large value of  $k_{SE}/k_{SW}$  means strong or very strong complexation-solvation effects with extractant. A positive sign of a slope means that the solvation of the reactant molecules is stronger than the product molecules. The negative slope shows that the solvation of product molecule is stronger than the reactant's.

The presented model overcomes some limitations of "chemical modeling approach" [1,2]. The last is a useful tool to describe the data quantitatively, if complexation is strong (as in the region 2). In the presented theory the separate mathematical descriptions are developed for different regions of the extraction system. Interchanges in the linearity of equation (1), or the different slopes in the loading curve over the solute concentration range, mean that the affinity constant ratios and/or concentrations of the components in the aggregate are different. It means, also, that the different charge-transfer complexation mechanisms, and consequently the different values of  $k_{SEc}$ , or the different solvation mechanisms, and consequently different values of  $k_{SEs}$ , take place at different solute concentrations. So, we have to use one more experimentally measured property, such as UV-VIS or quantitative IR measurements, to determine  $k_{SEc}/ k_{SEs}$ . Regions 1-4 in the distribution curve (Figure 1) with different values of the slopes testify different compositions of the aggregates formed.

## ACID SOLVENT EXTRACTION BY AMINES

### **Acid-Amine (in inert diluent)-Water (S-E-W) System**

Let us consider a relatively simple system: monobasic acid, S - monobasic amine, E - water, W - inert organic diluent, D (kerosene). Some preliminary assumptions: 1. All components of the system are monomers in a pure, initial state; 2. Volume change on mixing of the solvents is neglected; 3. Diluent D is inert enough and does not participate in solvation; 4. Solubility of water in the bulk organic solvents' mixture is excluded: water, after equilibration, separation and centrifugation is present only in the solvation shell.

A set of equations, derived from equation (1), were developed for different measured properties X [3,4]. For example, at measured chemical shift,  $X=\delta$  (NMR), the equation is:

$$\frac{\delta_{SW} - \delta}{C_E} = \frac{k_{SE} V_{Worg}}{k_{SW}} (\delta_{SW} - \delta_{SE}) - \left[ \frac{k_{SE}}{k_{SW}} V_{Worg} - V_E \right] (\delta_{SW} - \delta) \quad (4)$$

Experimentally obtained [2] data of lactic acid extraction by Alamine-336, and data, calculated according the presented theory [3], is compared in Figure 2. It shows that the presented theoretical approach satisfactorily quantitatively describes the studied extraction system.

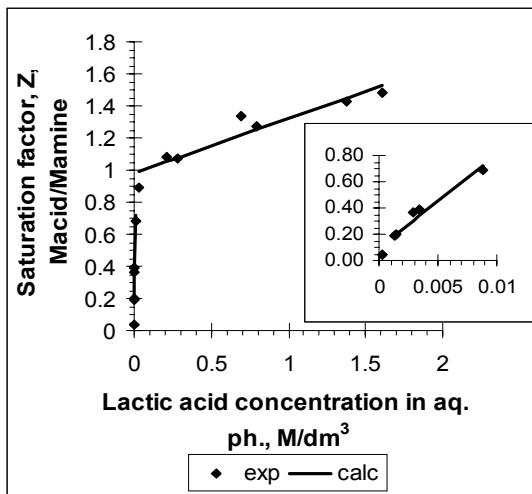

Figure 2. Comparison of experimental data [2] and calculated data [3] in regards to lactic acid extraction by Alamine 336.

### System with Mixture of Two Acids - Selectivity

If both monobasic acids,  $S_1$  and  $S_2$ , are miscible in the organic and aqueous phases and differ mainly in their acidity, expected interactions and associations, formed at extraction, are obeyed expression:

$$\frac{k_{S_1E} C_{S_1org}}{k_{S_1W} C_{S_1aq}} > \frac{k_{S_2E} C_{S_2org}}{k_{S_2W} C_{S_2aq}} \quad (5)$$

Two cases may be considered. At relatively low initial concentrations of both acids, expected interactions correspond to Regions 1 and 2 of the general extraction isotherm (Fig. 1) with nuclei aggregates forming. According to Statements II, III and IV of the presented theory, electrostatic, ion-pair interaction mechanisms (Region 2) will dominate with the stronger acid,  $S_1$ , and H-bonding (Region 1) will dominate with the weaker acid,  $S_2$ . The weaker acid plays here a synergistic, enhancing role for the distribution of a stronger acid into organic phase.  $\frac{k_{S_1E}}{k_{S_1W}}$  and  $\frac{k_{S_2E}}{k_{S_2W}}$  constant values are the same inside every region, therefore, the difference between magnitudes of concentration ratios (and selectivity) at equilibrium will increase with increasing initial concentrations of both acids.

At relatively high initial concentrations of both acids (prevailing stoichiometry 1-1 for stronger acid), expected interactions will correspond to Region 3 with linear (or cyclic) aggregates, formed preferentially through the H-bond bridging by the weaker acid. With the increase of initial concentrations the difference between magnitudes of concentration ratios (selectivity) at equilibrium will pass through a maximum because of the competition between the weaker  $S_2$  and the stronger  $S_1$  acids for the H-bonding. According to the presented theory (statements II and III), the maximal selectivity will be at different amine - stronger acid compositions for the same amine and every two acids used. Preliminary data for these compositions may be calculated, using relations derived from equations (1) and (2):

$$\frac{(X_{SW} - X)_{max}}{C_E} = \frac{k_{SE}}{k_{SW}} v_W (X_{SW} - X_{SE}) - [\frac{k_{SE}}{k_{SW}} v_W - v_E] (X_{SW} - X)_{max} \quad (6)$$

$$\frac{1}{Z_{max}} = 1 + \frac{k_{SW}}{k_{SE}} \times \frac{[C_{Worg}]_{max}}{C_E} \quad (7)$$

Determining experimentally  $[C_{Worg}]_{max}$  for both,  $S_1$  and  $S_2$  acids at already obtained affinity coefficient ratios, we can determine water concentration limits for selective separation of two acids. It is especially important when using amine - acid mixtures as extractants for the weak acids. The theory predicts and permits the preliminary evaluation of Water-swing separation.

### **System with Two Acids when One of them, $S_1$ , is Water Immiscible (Acid-Base-Coupled (ABC) extractants [3])**

Concentration of the water immiscible acid in the aqueous phase is  $C_{S1aq} \rightarrow 0$ . Therefore,

relationship  $\frac{C_{S1org}}{C_{S1aq}} \gg \frac{C_{S2org}}{C_{S2aq}}$  will be correct for almost all range of acid  $S_2$  concentration. This

means that the concentration of acid  $S_2$  in the solvation shell will be very small. Only at very high  $S_2$  concentrations in the aqueous phase the extraction of this acid will be detectable. The interactions and the aggregates forming are typical for Regions 3 and 4. The presented theory shows (without any experiments) that ABC may be useful extractants only for strong mineral or carboxylic acids.

### **System with a Mixture of Two Amines**

In the mixture of two monobasic amines, at  $\frac{k_{SE1}}{k_{SW}} \times \frac{C_{Sorg}}{C_{Saq}} > \frac{k_{SE2}}{k_{SW}} \times \frac{C_{Sorg}}{C_{Saq}}$  and  $\frac{k_{SE2}}{k_{SW}} < \frac{k_{SE1}}{k_{SW}}$  the

weaker amine  $E_2$  will perform as a weak acid (Statement III), and all considerations, presented in the section for two acids, are valid here. So, the weaker amine plays here a synergistic, enhancing effect on the distribution of the acid into the organic phase. It is evident from the theory that the initial concentration of the weak amine,  $E_2$ , has to be lower than amine  $E_1$  and acid  $S$ . If the amine  $E_2$  is immiscible in the aqueous phase, the above considerations for the two acids, where one is immiscible, are valid in this case as well. Preliminary data for these compositions may be calculated using independent experiments.

### **System with Active Solvent as an Adduct**

The solute-solvent interactions in the S-E-W-A system are different for every adduct and result in different affinity constant ratios:  $k_{SE}/k_{SW}$ ,  $k_{SE}/k_{SA}$ ,  $k_{SA}/k_{SW}$  and concentration ratios:  $C_{SE}/C_{SW}$ ,  $C_{SA}/C_{SW}$ ,  $C_{SE}/C_{SA}$  in the solvation shell. An active adduct may be water-immiscible, partly or completely soluble in both, organic and aqueous phases. In this case, the concentrations of  $C_{Worg}$ ,  $C_{Aorg}$ ,  $C_{Aaq}$  in the bulk organic and aqueous phases have to be measured at the absence of acid,  $S$ .

Using the equations of statement II, preliminary data may be calculated using independent experimental data, obtained for the simple three-component S-E-A, S-A-W and E-A-W systems, in analogy to the S-E-W system. According to the amphotropy of extractants (Statement III) an active solvent (adduct) at  $\frac{k_{AE}}{k_{AW}} > \frac{k_{SE}}{k_{SW}}$  performs as a weak acid and all

considerations, presented above for the two acids, are valid here. In this case, an active adduct,  $A$ , has a synergistic, enhancing effect on the distribution of the acid into the organic phase. This is explained by replacing a hydrogen bonded amine molecule by an active

adduct molecule in the solvation shell (nucleus aggregate). Therefore, apparent concentration of amine increases for acid-amine interactions. Headley and coworkers [8] denominate this phenomenon as a "relative increase of amine basicity". Evidently, the concentration of the adduct in the organic phase,  $C_{Aorg}$ , has to be lower than amine  $C_E$  and acid  $C_{Sorg}$ . Comparing values of the relations:  $\frac{k_{SE}}{k_{SW}} \times \frac{C_{Sorg}}{C_{Saq}}$ ,  $\frac{k_{SE}}{k_{SA}} \times \frac{C_E}{C_A}$  and  $\frac{k_{AE}}{k_{AW}} \times \frac{C_{Aorg}}{C_{Aaq}}$ , one can calculate  $[C_{Aorg}]_{max}$  and  $[C_{Aaq}]^0$  compositions for optimal extraction of the acid of interest at its different concentrations. The presented theory predicts the solvent-swing regeneration and permits its preliminary quantification.

It should be stressed that the presented theory predicts the synergistic, enhancing effect of weak amines or weak acids or neutral protic, polar/polarizable solvents as adducts to the basic amine extractant on extraction of acids. Classical theories do not indicate any direct knowledge regarding this effect.

## METAL SOLVENT EXTRACTION BY ACIDIC EXTRACTANTS

### Metal-Extractant-Water (M-E-W) System

Let us consider an M-E-W extraction system in which metal ion,  $M^{z+}$ , a molecules, monobasic acidic organic extractant,  $E=HL$ , b-molecules, water (W), c molecules participate in a single reaction act. Here, z is the oxidation state of metal ion. All assumptions presented in the previous section, are valid here as well. Using different measured properties, X, we obtain relations, derived from equation (1). For UV-VIS,  $X = \varepsilon$  is a molar extinction coefficient:

$$\frac{\varepsilon_{MW} - \varepsilon}{C_E} = \frac{k_{ME} v_W}{k_{MW}} (\varepsilon_{MW} - \varepsilon_{ME}) - \left[ \frac{k_{ME}}{k_{MW}} v_W - v_E \right] (\varepsilon_{MW} - \varepsilon) \quad (9)$$

where

$\frac{A}{C_{Morg}} = \varepsilon$ ,  $\frac{A_{ME}}{C_{Morg}} = \varepsilon_{ME}$ ,  $\frac{A_{MW}}{C_{Morg}} = \varepsilon_{MW}$  and A is a measured absorbency. At  $a=1$ , partitioning factors are  $P_{ME} = b/(n+1)$  and  $P_{MW} = (n-b)/(n+1)$ . The metal central ion is coordinated by z charged ligands  $L^-$ , by  $b-z$  neutral HL molecules and by c water molecules, filling metal ion coordination sites, n, up to saturation.

As an example, the re-investigated data of titanium(IV) extraction by DEHPA [6,7] are presented in Figure 3. The values of affinity constant ratios, average equilibrium constants and intercepts were calculated, using the presented theory equations, for different regions of the extraction isotherm. Figure 3 shows a good agreement between experimentally obtained (points) and calculated (lines) data.

The M-E-W is the simplest extraction system. Real systems are those with two or more metal ions ( $M_1$ ,  $M_2$ ,  $M_3$ ) have to be selectively separated, and/or with a mixture of extractants ( $E_1$ ,  $E_2$ ) and/or with different active solvents as adducts ( $A_1$ ,  $A_2$ ), used, for synergistic effect. These systems are analyzed in a way, described in the previous section. Analysis and predictions are based on the experimentally determined affinity constant ratios and coordination structures (numbers) of the aggregates, formed at different concentrations of the metals, extractants, adducts. For example, the contribution of every component in the complicated M-E-A-W system, where A is an active adduct, may be evaluated at the determined affinity constant ratios  $k_{ME}/k_{MW}$ ,  $k_{ME}/k_{MA}$ ,  $k_{MA}/k_{MW}$ . These data may be realized through a series of conventional equilibrium extraction experiments with simple three component systems M-E-W, M-E-A, M-A-W, and E-A-W.

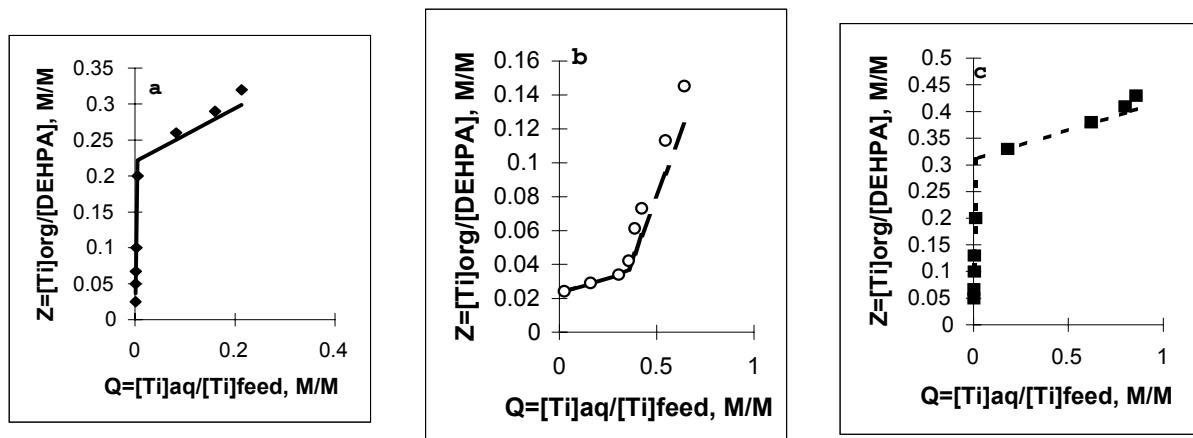

Figure 3. Comparison of experimentally obtained (points) and theoretically calculated (lines) data of extraction of titanium(IV) chlorides by DEHPA in benzene from the aqueous solutions at initial acidities (HCl): a) 0.1 mol/kg, b) 2.0 mol/kg and c) 7.6 mol/kg.

### ADVANTAGES OF THE PRESENTED THEORY

The presented theory constitutes a general framework for interpretation of ion-molecular interaction data in the solvent extraction systems. More parameters such as water and active adduct are introduced to the quantitative consideration of the extraction systems. A mathematical description for the process simulation is proposed.

Affinity constant ratios are easily acceptable through the independent measurements conducted with simple three-component-systems. Experimental determination of the affinity constant ratios and solvation shell compositions, quantitative, or even semi-quantitative spectrometric determination of solute in the complexed and solvated forms permits to set up an exact form of the aggregates formed. Composition and behavior predictions of the extraction system of interest may be analyzed. Relation

$$K_{SE} = \frac{k_{SE}}{k_{SW}} v_W - v_E \quad (10)$$

between equilibrium constant  $K_{Si}$  of the classical theories and affinity constant ratio,  $k_{Si}/k_{Sj}$ , obtained by the measurements of the same property, permits to use available equilibrium constant data for calculations in the presented theory.

The theory of partitioning in the homogenous media implies that the components act independently in their interaction with a given solute. In other words, the values of  $k_{SE}$  are independent of the values of  $k_{SW}$  or  $k_{SA}$ , and are transferable from one system to the other. Influence of different solvent adducts to extractant on the effectiveness and selectivity of the extraction process, is predictable once some solvent parameters are ascertained. Transferability can be proved by different independent experiments with three component systems through relations:

$$\frac{k_{SE}}{k_{S_2E}} = \frac{k_{(S_1E)_1}}{k_{(S_1W)_1}} \times \frac{k_{(S_2W)_2}}{k_{(S_2E)_2}} = \frac{k_{(S_1E)_1}}{k_{(S_1A)_1}} \times \frac{k_{(S_2A)_2}}{k_{(S_2E)_2}} \quad (11)$$

$$\frac{k_{SE_1}}{k_{SE_2}} = \frac{k_{(SE_1)_1}}{k_{(SW)_1}} \times \frac{k_{(SW)_2}}{k_{(SE_2)_2}} = \frac{k_{(SE_1)_1}}{k_{(SA)_1}} \times \frac{k_{(SA)_2}}{k_{(SE_2)_2}} \quad (12)$$

$$\frac{k_{SA_1}}{k_{SA_2}} = \frac{k_{(SA_1)_1}}{k_{(SW)_1}} \times \frac{k_{(SW)_2}}{k_{(SA_2)_2}} = \frac{k_{(SA_1)_1}}{k_{(SE)_1}} \times \frac{k_{(SE)_2}}{k_{(SA_2)_2}} \quad (13)$$

where the systems (all in the same inert diluent), experimentally verified, are: S<sub>1</sub>-E-W, S<sub>1</sub>-E-A and S<sub>2</sub>-E-W, S<sub>2</sub>-E-A, respectively, for equation (11); S-E<sub>1</sub>-W, S-E<sub>1</sub>-A and S-E<sub>2</sub>-W, S-E<sub>2</sub>-A, respectively, for equation (12); S-A<sub>1</sub>-E, S-A<sub>1</sub>-W, and S-A<sub>2</sub>-E, S-A<sub>2</sub>-W, respectively, for equation (13).

Co-solvent independence, established experimentally, allows us to compare directly the solvating-complexing power (competition order) of various extractants, adducts, diluents at a fixed other components of the system. Once determined and tabulated, the data may be used in any system, containing these components. Independence and transferability of affinity constants have been proved for many organic systems [5], using chromatographic techniques, NMR, UV-VIS, potentiometric titrations, kinetic measurement techniques. Nevertheless, it still remains to be proved for different extraction systems of interest.

The presented theory predicts the synergistic, enhancing effect of weak amines, weak acids and active solvents as adducts to the basic amine extractant on extraction effect of acids. Classical theories do not indicate any direct knowledge about this effect.

The presented competitive complexation/solvation modeling approach is an attempt to describe the mechanisms of solvent extraction with quantitative evaluation of different compounds, formed in the organic phase at different concentrations of the solute in the aqueous phase. Of course, the theory has many simplifications and limitations but it may be a starting point for the quantification of solvent extraction processes in aim to predict suitable extraction systems for different solutes separation.

## MICROEMULSIONS AND THIRD PHASE FORMATION

K. Osseo-Asare

Department of Materials Science and Engineering, Penn State University,  
University Park, PA, USA

The formation of a third phase, a process in which the organic phase splits into two immiscible liquids, has a detrimental effect on solvent extraction operations. The phase splitting is generally attributed to the limited solubility of the extracted complexes in hydrocarbon diluents, with the solubility decreasing in the order: aromatic diluent > cyclic diluent > aliphatic diluent. Third phase research has, therefore, been preoccupied with efforts to establish the stoichiometry of the species responsible for the limited solubility. In contrast, relatively little effort has been devoted to investigations focusing on the phase behavior of the relevant systems and on the molecular structure of the heavy organic extract. This paper departs from the previous approaches by promoting the view that the solvent extraction third phase corresponds to the middle phase in a microemulsion fluid system. Using tri-n-butylphosphate (TBP) as a model extractant, phase evolution and aggregation concepts from microemulsion science are used to develop a general framework for interpreting and predicting the patterns of phase behavior in solvent extraction third-phase-forming systems.

### INTRODUCTION

In an excellent review of third phase formation published in 1967, Kertes [1] described the literature as consisting of “fairly abundant but essentially fragmentary data”. In the intervening thirty-five years more papers on third phase formation have appeared [1-6]. However, the data remain fragmentary and a comprehensive theory of third phase formation is yet to be developed. The purpose of this paper is to offer some ideas [5, 6] that can help fill this gap in our knowledge.

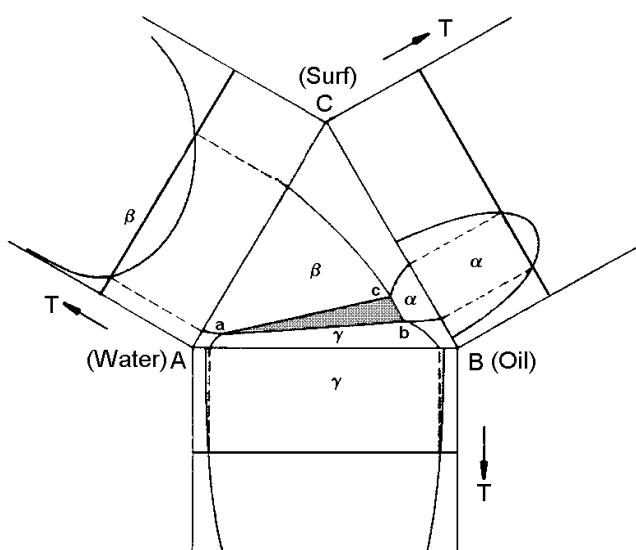

Third phase formation, the separation of the organic phase into two liquids, has a detrimental effect on solvent extraction separations. Fluid mixing is complicated by the presence of two organic liquids. Also, the fact that phase splitting tends to be associated with relatively concentrated organic extracts puts severe restrictions on the highest metal loadings that can be tolerated.

The available reports on third phase formation typically involve basic reagents, such as organophosphorus esters, ethers, and amines [1, 2]. Extraction systems based on tri-n-butyl phosphate (TBP;  $(C_4H_9O)_3P=O$ ) are among those most vulnerable towards organic phase splitting [1, 2]. Recognition that phase separation is related to the limited solubility of the extracted complexes in hydrocarbon diluents has led to research programs that emphasize a search for the stoichiometry of the poorly soluble species. In contrast, investigations that focus on phase behavior have received little attention.

The experimental evidence indicating the presence of molecular aggregates in TBP extracts was critically reviewed in a previous publication from this laboratory [6]. For highly acidic aqueous solutions and highly concentrated metal salt solutions, the extracted species tend to be in the form of ion-pairs. These species are expected to exhibit surfactant-like behavior since they possess both hydrophobic (*i.e.*, the trialkyl radicals) and hydrophilic (*i.e.*,  $P=O(H_2O)_xM^{z+}$ ,  $P=O(H_2O)_yH^+$ ) groups. Thus, as with classical surfactants [7-10], extracted TBP complexes can self-organize into reverse micelles in nonpolar organic solvents. The polar regions of reverse micelles can solubilize water molecules to form water-in-oil (w/o) microemulsions. The earlier paper [6] emphasized the role of aggregation in the extraction of acids and metal ions by TBP. However, the relationship between aggregation and third phase formation was briefly examined and it was postulated that "The solvent extraction third phase corresponds to the middle phase in a microemulsion fluid system". Using TBP as a model extractant, the present paper further examines this claim and elaborates on how microemulsion science provides the missing framework needed to develop a thoroughgoing understanding of third phase formation in solvent extraction systems.

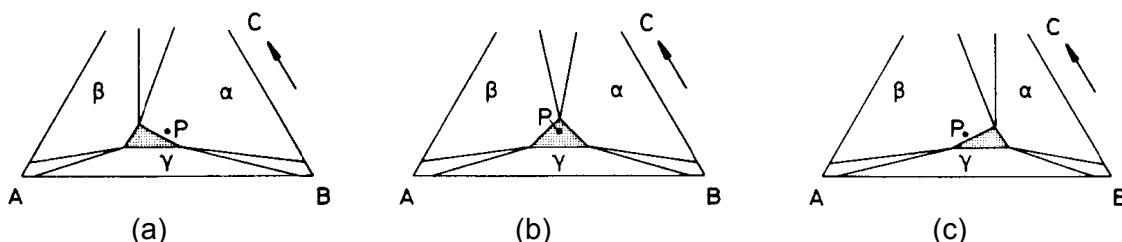

### MICROEMULSION PHASE BEHAVIOR

A microemulsion contains three essential ingredients: water, oil, and surfactant [7-10]. In many practical systems one or more electrolytes (*e.g.*, metal salts and/or mineral acids) and a cosurfactant (*e.g.*, a medium-chain alcohol) may also be present. Kahlweit and coworkers [11-13] have shown that the patterns of phase behavior in microemulsion systems can be effectively visualized and systematized with the aid of phase diagrams. Following their approach [11], Figure 1 presents a schematic ternary phase diagram for a hypothetical water (A)-oil (B)-surfactant (C) system. The area delineated by a, b, and c represents a three-phase triangle; mixtures with compositions within this region will split into three phases, *i.e.*, (a), (b), and (c). On the other hand, regions  $\alpha$ ,  $\beta$ , and  $\gamma$  represent two-phase domains. In region  $\alpha$  phase (b) is in equilibrium with (c), in region  $\beta$  phases (a) and (c) are in mutual equilibrium, while in region  $\gamma$  phase (a) is in equilibrium with phase (b).

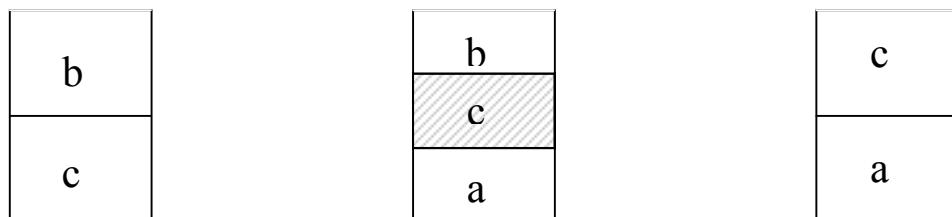

*Figure 1. A schematic ternary phase diagram for a hypothetical water (A)-oil (B)-surfactant (C) system (after Kahlweit et al. [11]).*

As temperature, surfactant, or oil is altered, the shape and size of the three-phase region also varies. This change will reflect changes in the corresponding binary phase equilibria. Thus, Figure 1 is only valid for a particular temperature ( $T_1$ ), and as the temperature is raised, the miscibility gap ( $\beta$ ) in the A-C diagram grows while the corresponding gap ( $\alpha$ ) for the B-C diagram becomes smaller. These effects translate into elongation of side ac of the three-phase triangle and shrinking of side bc. Accordingly, as illustrated in Figure 2, as the temperature is raised, point c moves clockwise relative to a mixture composition at point P. The corresponding test-tube profiles are shown in Figure 3.

*Figure 2. Schematic illustration of the effect of temperature on the three-phase triangle (after Kahlweit et al. [11]). Temperature increases in the direction (a) → (b) → (c).*

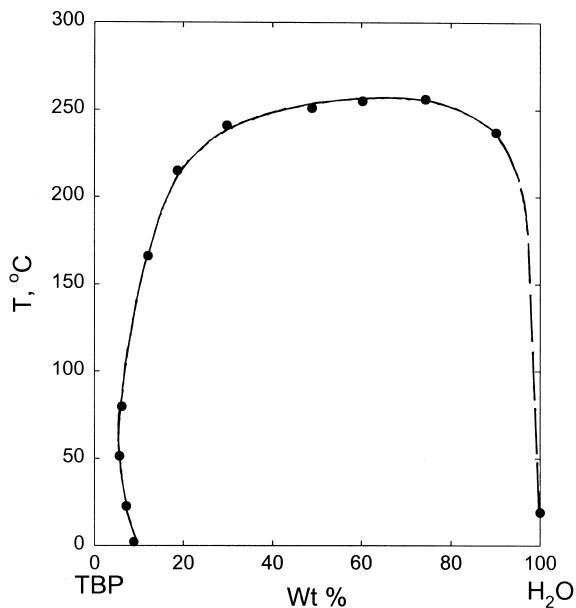

*Figure 3. Test-tube profiles corresponding to the temperature changes in Figure 2.*

The effects of surfactant, oil, and electrolyte on microemulsion phase behavior can also be visualized by considering the corresponding effects on the binary phase diagrams. Consider oils  $B_1$ ,  $B_2$ ,  $B_3$ , and  $B_4$ , where the hydrophobicity decreases in the order  $B_1 > B_2 > B_3 > B_4$ . Furthermore, let the surfactant be completely miscible with the least hydrophobic oil,  $B_4$ . Then, as the oil is changed from  $B_4$  to  $B_1$ , the oil-surfactant (B-C) miscibility gap is expected to decrease in the order  $(B_1-C) > (B_2-C) > (B_3-C) > (B_4-C)$ . Thus, the miscibility gap should be highest for the most hydrophobic oil, i.e.,  $B_1$ . Accordingly, as the hydrophobicity of the oil increases (e.g., by going from an aromatic to an aliphatic hydrocarbon), the three phase interval should become enlarged.

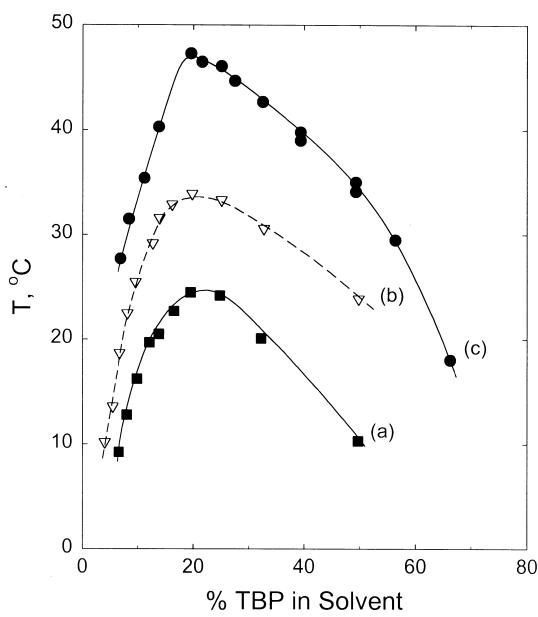

## PHASE DIAGRAMS FOR TBP SYSTEMS

In general solvent extraction diluents and the related aqueous solutions have very little mutual solubility and, therefore, the corresponding water-diluent binary phase diagram should exhibit a very wide miscibility gap, as depicted for the binary A-B diagram in Figure 1. It is apparent, therefore, that if one could justify making the following correspondence: aqueous solution:water (A), diluent:oil (B), and TBP:surfactant (C), then Figure 1 can be taken to represent a pseudoternary phase diagram for a hypothetical TBP-diluent-water-electrolyte system. Access to such diagrams for a specific TBP-diluent-water-acid-metal salt system would permit one to readily assess how process variables, such as TBP, diluent,  $H_2O$ , acid, and metal content, as well as temperature influence third phase formation.

Unfortunately such ternary phase diagrams are not available for most of the relevant solvent extraction systems. In the case of TBP, a few binary phase diagrams are available and some of these are used below to illustrate the utility and power of the microemulsion model of third phase formation.

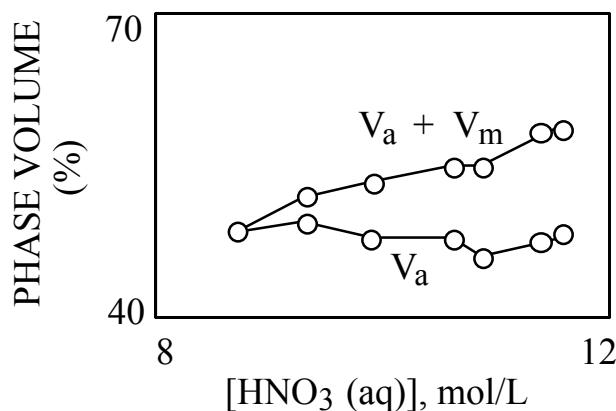

*Figure 4. Binary phase diagram for the TBP-H<sub>2</sub>O system (after Rozen et al. [14].)*

*Figure 5. Pseudobinary phase diagram for the system TBP-kerosene-H<sub>2</sub>O-HNO<sub>3</sub>-Th(NO<sub>3</sub>)<sub>4</sub> (after Healy and McKay [15]). Concentrations in the initial aqueous solutions: (a) 0.69 M Th(NO<sub>3</sub>)<sub>4</sub>, (b) 0.69 M Th(NO<sub>3</sub>)<sub>4</sub> + 0.96 M HNO<sub>3</sub>, (c) 0.86 M Th(NO<sub>3</sub>)<sub>4</sub>.*

Figure 4 presents the binary phase diagram for the TBP-H<sub>2</sub>O system [14]. It can be seen that there is a large miscibility gap up to approximately 225 °C. An upper critical temperature is observed at about 250 °C, above which water and TBP become mutually soluble. If TBP is taken to represent a surfactant (C), then it can be seen that the miscibility gap in Figure 4 matches the trend shown in Figure 1 for the binary A-C diagram of an arbitrary water-surfactant system. A pseudobinary phase diagram for the system TBP-kerosene-H<sub>2</sub>O-HNO<sub>3</sub>-Th(NO<sub>3</sub>)<sub>4</sub> [15] is shown in Figure 5. Below each curve is a two-phase region where a diluent-rich solution (left-hand side) is in equilibrium with a TBP-rich phase (right-hand side). It can also be seen that mutual solubility is enhanced by increase in temperature and that there is an upper critical temperature above which the TBP-rich and the diluent-rich phases become mutually soluble. If the diluent represents oil (B), then referring again to Figure 1, it can be seen that Figure 5 follows the trend depicted in the binary B-C phase diagram.

Figure 5 further shows that in the absence of HNO<sub>3</sub> the miscibility gap increases with Th(NO<sub>3</sub>)<sub>4</sub> concentration (curves a and c). Also, for a given metal concentration, increasing the nitric acid concentration extends the miscibility gap (curves a and b). An expansion of the miscibility gap in the binary B-C phase diagram signals enhanced third phase formation. This effect is illustrated in Figure 6 for the TBP-kerosene-H<sub>2</sub>O-HNO<sub>3</sub>-UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub> system [16]. It can be seen that raising the acid concentration increases the volume of the third phase.

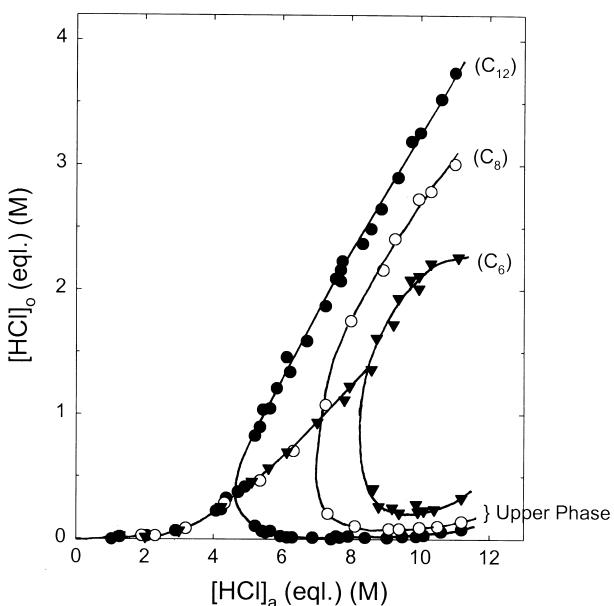

*Figure 6. Effect of HNO<sub>3</sub> concentration on third phase formation in the system TBP-kerosene-water-UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>-HNO<sub>3</sub> (data from Solovkin et al. [16]). Volumes after third phase formation: V<sub>a</sub> = volume of the aqueous phase, V<sub>m</sub> = volume of the middle (third) phase.*

Third phase formation is also affected by the nature of the aliphatic diluent. Figure 7 shows a comparison of the HCl extraction isotherms for 50% TBP solutions in n-hexane, n-octane, and n-dodecane [17]. It can be seen that the aqueous acidity marking the onset of third phase formation follows the order: hexane > octane > dodecane. It can also be seen that the concentration of HCl in the lower organic phase increases from n-hexane to n-dodecane; the opposite trend is observed for the upper organic phase. These effects are consistent with the above discussion on microemulsion phase behavior. The longer chain hydrocarbons are more hydrophobic and are, therefore, expected to be more sensitive to third phase formation.

## AGGREGATION AND THIRD PHASE FORMATION

It is well established that ion-pairs of the type  $(TBP)_x(H_2O)_yH^+ \cdot A^-$ ,  $(TBP)_x(H_2O)_yH^+ \cdot MA_n^-$ , and  $(TBP)_x(H_2O)_yM^{z+} \cdot zA^-$  form in TBP extraction systems [1, 6]. It has been suggested that anhydrous ion-pairs, e.g.,  $TBPH^+ \cdot ClO_4^-$ , also occur in some systems [18]. This latter complex is reminiscent of alkylammonium salts which are recognized surfactants capable of forming reverse micelles. Evidence for the presence of reverse micelles and microemulsions in TBP solvent extraction systems include the observed abrupt increases in viscosity with increase in acid and metal uptake, dramatic electrical conductivity changes, and the co-extraction of water molecules (as reflected, for example, in volumetric changes of the organic phase) [6].

*Figure 7. HCl extraction isotherms for 50% TBP solutions in n-hexane ( $C_6$ ), n-octane ( $C_8$ ), and n-dodecane ( $C_{12}$ ) (after Kopacz and Jezowska-Trzebiatowska [17]).*

Reverse micelles present in an oil interact with each other through a variety of forces, including van der Waals interactions between the solubilized water droplets, and steric interactions between the hydrophobic surfactant chains [3, 4, 19, 20]. If these interactions are sufficiently attractive, the reverse micelles begin to aggregate, squeezing out the oil molecules. Eventually phase separation (a kind of precipitation or flocculation) occurs, resulting in a heavier micelle-rich phase below a lighter micelle-depleted phase. If in fact reverse micelles occur in TBP solvent extraction systems, then it is reasonable to suppose that a similar micellar interaction is responsible for third phase formation. Indeed recent work by Erlinger *et al.* [3, 4], based on investigations of aggregation phenomena in a quaternary malonoamide extractant system, strongly support the original proposal [6] forwarded in 1991 that: "The solvent extraction third phase corresponds to the middle phase in a microemulsion fluid system".

## PREDICTION OF DIFFUSIVITIES IN LIQUID ASSOCIATING SYSTEMS

D. Bosse and H.-J. Bart

Institute of Thermal Process Engineering, University of Kaiserslautern,  
Kaiserslautern, Germany

A model for the prediction of Fick diffusion coefficients in binary associating systems has been developed. Due to association reactions between solute molecules such systems can be regarded as multicomponent systems. Therefore, the proposed model is based on a multicomponent approach for the Maxwell-Stefan diffusivities combined with an extension of the commonly used UNIFAC model which takes association reactions explicitly into account.

### INTRODUCTION

Diffusion plays an important role in all kinds of separation processes, e.g., distillation, extraction, membrane processes, etc. Since the increasing use of nonequilibrium stage modelling [1] a deeper insight into mass transfer has become more important in order to allow accurate and reliable predictions in any kind of equipment. Due to their slowness, diffusional processes are often the rate determining step in reactive liquid systems [2], e.g., extraction with a solvent of much higher viscosity than the solute. A further complexity is that the liquid state cannot be as properly described as the gas phase. Thermodynamic non-idealities - caused by different sizes, shapes, and interaction energies as well as association and solvation of molecules – strongly influence the diffusional behaviour of the different species. These effects usually result in large deviations between experimental data and predicted values.

Diffusion problems are tackled with Fick's law or the Maxwell-Stefan (MS) equation. The relation between the two has been given by Taylor and Krishna [3]. For a binary mixture this yields:

$$D = \Gamma D \quad (1)$$

As can be seen from this equation the Fick diffusivities,  $D$ , equals the MS diffusion coefficients,  $D$ , times the thermodynamic correction factor,  $\Gamma$ . The main difference between both descriptions is that the MS-approach separates diffusional processes from thermodynamic non-idealities while the Fick diffusion coefficients must also account for the non-idealities in the mixture, therefore, the MS-description is preferred throughout this work.

This work deals with diffusional mass transfer in binary associating systems. On first sight, only two constituents are present in such mixtures, namely the monomer molecules of a solute, e.g., alcohol, aldehyde, etc., and a solvent. In reality we are dealing with a multicomponent mixture due to association effects between solute molecules which lead to cluster formation. Hence, the binary diffusivity measured in such systems equals an effective diffusivity that accounts for these effects. Modelling systems with associating constituents as binary mixtures is not straightforward, since reality is not properly reflected. Therefore, the

main goal of this work is to present a new approach for the prediction of diffusivities in liquid associating systems. For this purpose a diffusivity model derived on the basis of the MS-equation has been applied in conjunction with an extension of the well-known UNIFAC model. The solute associates formed in the mixture are treated as separate constituents. A transformation from the multicomponent mixture to the 'pseudo-binary' mixture is also presented. Hence, it is possible to compute binary diffusivities of solute – solvent mixtures on a multicomponent basis.

## THEORY

### Mixture Composition and Formation of Associates

In binary systems with a solute (A) and an inert solvent (B) self-association reactions between solute molecules can occur according to the reaction:

In the following the species in the mixture are indicated by the subscripts '1' for A, '2' for  $A_2$ , ..., ' $n-1$ ' for  $A_{n-1}$ , and 'n' for B. The equilibrium constant of the  $i$ th reaction is defined by:

$$K_i = \frac{(\gamma_i x_i)}{(\gamma_1 x_1)^i} \quad (3)$$

Here  $\gamma_i$  refers to the activity coefficient and  $x_i$  to the mole fraction of the species considered. The relation between the overall binary mole fractions of A and B, indicated by  $\tilde{x}_1$  and  $\tilde{x}_n$ , and the multicomponent mole fractions is given by:

$$\tilde{x}_1 = \frac{\sum_{i=1}^{n-1} i x_i}{\sum_{i=1}^{n-1} i x_i + x_n} \quad (4)$$

$$\tilde{x}_n = \frac{x_n}{\sum_{i=1}^{n-1} i x_i + x_n} \quad (5)$$

For given equilibrium constants these equations yield the real mixture composition. How these constants are determined is shown below.

### Maxwell-Stefan Diffusivities

On the basis of the Maxwell-Stefan equation Rutten [4] has derived an expression that allows computation of the MS-diffusivities of a pseudo-binary mixture with polymerization, i.e., association, on the basis of a multicomponent approach.

$$\tilde{D} = \frac{1}{x_{sum}} \sum_{i=1}^{n-1} \sum_{j=1}^{n-1} \left[ \frac{i x_n + x_{sum}}{x_n + x_{sum}} \right] j A_{ij} x_j \quad (6)$$

In this equation  $x_{sum}$  is defined as

$$x_{sum} = \sum_{i=1}^{n-1} i x_i \quad (7)$$

and  $A_{ij}$  is an element of the inverse matrix of  $[B]$  with dimension  $(n-1)$  whose elements are given by:

$$B_{ii} = \frac{x_i}{D_{in}} + \sum_{k=1, k \neq i}^n \frac{x_k}{D_{ik}} \quad (8)$$

$$B_{ij} = -x_i \left( \frac{1}{D_{ij}} - \frac{1}{D_{in}} \right) \quad (9)$$

The diffusivities given in equations (8-9) are the MS-diffusivities of the multicomponent mixture. At infinite dilution equation (6) reduces to the following expressions in which the left hand sides can be determined from experimental diffusivity data at infinite dilution or from an appropriate model, e.g., Wilke-Chang [5]:

$$X_1 \rightarrow 0 \quad \tilde{D} = D_{1n} = D_{AB} \quad (10)$$

$$X_n \rightarrow 0 \quad \tilde{D} = \left[ \sum \frac{x_i}{D_{in}} \right]^{-1} \quad (11)$$

In order to estimate values for the multicomponent diffusivities, these diffusivities have been related to the monomer pair diffusivity using van der Waals radii,  $R_{vdW}$ .

$$D_{in} = \frac{R_{vdW,1}}{R_{vdW,i}} D_{1n} \approx i^{-1/3} D_{1n} \quad (12)$$

$$D_{ij} = \frac{R_{vdW,1} R_{vdW,n}}{R_{vdW,i} R_{vdW,j}} D_{1n} \approx i^{-1/3} j^{-1/3} \frac{R_{vdW,n}}{R_{vdW,1}} D_{1n} \quad (13)$$

The van der Waals radius in turn is defined by

$$R_{vdW} = \left( \frac{3V_{vdW}}{4\pi N_A} \right)^{1/3} \quad (14)$$

whereas the van der Waals volumes,  $V_{vdW}$ , of the associates are taken as multiples of the volume of the monomer solute. Values for the van der Waals volumes have been listed by Edward [6] and Bondi [7].

The monomer pair diffusivity may now be computed as follows. Equation (10) yields the diffusivity at infinite dilution in pure solvent which is equal to the binary experimental value. In order to obtain the infinite dilution diffusivity in pure solute the equations (11-13) must be combined, which yields a value depending on the mixture composition, i.e. equilibrium constants. At intermediate composition the multicomponent diffusion coefficient of the monomer pair is computed from the infinite dilution diffusivities using a mixing rule, e.g., Vignes [8]. Once these diffusivities have been calculated, the computation of the binary diffusivity given in equation (6) is straightforward.

### Calculation of Equilibrium Constants with the UNIFAC Association Model

In 1999 Asprion extended the commonly used UNIFAC model to account also for association effects [9]. In his work, binary and ternary mixtures of alcohols in both inert and solvating solvents were investigated by spectroscopic analysis in respect to the structure of the associates and solvates formed. Associates can be regarded as molecular clusters of a single species, while solvates are molecular clusters of different components. In addition to the structure analysis, phase equilibrium measurements were conducted in order to obtain new sets of interaction parameters for the UNIFAC model. The resulting UNIFAC association model has been shown to be superior to the commonly used versions of UNIQUAC and UNIFAC. In the following the derivation of this model with respect to systems in which only association reactions occur, i.e., an alcohol as solute in an inert solvent, will be presented.

In this model, associates are regarded as separate chemical species with reaction equilibria defined by equations (2-3). The required equilibrium constants were determined from independent FT-IR measurements. For correlation purposes the number of associates considered in the model was reduced by assuming that, besides dimer association, only one higher associated species had been formed. This higher oligomer can be seen as a representative for all higher associates occurring in the mixture. For the calculation of the equilibrium constant the following relation is favoured

$$\ln K_k = -\frac{\Delta_R h_k^{\text{Ref.}}}{RT} + \frac{\Delta_R s_k^{\text{Ref.}}}{R} \quad k = Di, Po \quad (15)$$

whereas the reaction enthalpy and reaction entropy for the dimer reaction are given by:

$$\Delta_R h_{Di}^{\text{Ref.}} = \frac{\Delta_R h_{Po}^{\text{Ref.}}}{n-1} - \Delta h_{Di} \quad (16)$$

$$\Delta_R s_{Di}^{\text{Ref.}} = \frac{\Delta_R s_{Po}^{\text{Ref.}}}{n-1} - \Delta s_{Di} \quad (17)$$

$n$  refers to the number of solute molecules in an associate. The values for the dimer reaction enthalpy and entropy for the alcohol-inert solvent systems investigated are as follows:

$$\Delta h_{Di} = -12.023 \text{ kJ/mol} \quad (18)$$

$$\Delta s_{Di} = -30.031 \text{ J/(mol K)} \quad (19)$$

Example values for the reaction enthalpy and reaction entropy, which are assumed to be independent of temperature and pressure, of higher oligomers can be found in Table 1.

*Table 1. Reaction enthalpies and entropies for solvents n-hexane and cyclohexane.*

Component	$n$	$-\frac{\Delta_R h_{Po}^{\text{Ref.}}}{n-1}$	$-\frac{\Delta_R s_{Po}^{\text{Ref.}}}{n-1}$
		[kJ/mol]	[J/(mol K)]
Methanol	5	27.524	51.174
Ethanol	5	27.524	54.162
1-Propanol	5	27.524	56.690

Since association has been considered in terms of chemical reactions the UNIFAC parameters for the OH-group have been adapted accordingly. The resulting parameters are given in Tables 2-3, values of the other groups have been adopted from [10].

*Table 2. Parameters  $R_k$  and  $Q_k$  for OH-group.*

Group	Main group	$R_k$	$Q_k$
OH	OH	0.530	0.584

*Table 3. Interaction parameters for the OH-main group with the CH<sub>3</sub>-main group.*

$a_{mn}$	CH <sub>3</sub>	OH
CH <sub>3</sub>	0	578.9
OH	107.5	0

On the basis of this information it is possible to compute multicomponent activity coefficients and together with the information given in [3] the multicomponent thermodynamic correction factor are also accessible.

### Thermodynamic Correction Factor

As can be seen from the definition of the thermodynamic correction factor (here given only for the binary case) the second derivative of a  $g^E$ -model is required.

$$\Gamma = 1 + x_1 \left. \frac{\partial \ln \gamma_1}{\partial x_1} \right|_{T, P, \Sigma} \quad (20)$$

The symbol  $\Sigma$  indicates that the differentiation is to be carried out using the restriction that  $\tilde{x}_1 + \tilde{x}_2 = 1$ . The solution of equation (20) for the UNIQUAC model which has been used to compute  $\Gamma$  has been presented in [3].

## RESULTS

For the binary system ethanol-cyclohexane MS-diffusivities and Fick diffusivities have been calculated with the approach proposed here (model 1) and with a combination of the Vignes equation and the UNIQUAC model (model 2). In order to minimise prediction errors the diffusivity at infinite dilution,  $D^0$ , for cyclohexane in ethanol has been adopted from the experimental data, while the Wilke-Chang equation has been applied to compute  $D^0$  for ethanol in cyclohexane. In Figure 1 the results of these calculations are presented together with data acquired from diaphragm cell experiments [11]. These data have also been transformed to MS-diffusivities by means of the UNIQUAC model (calc.).

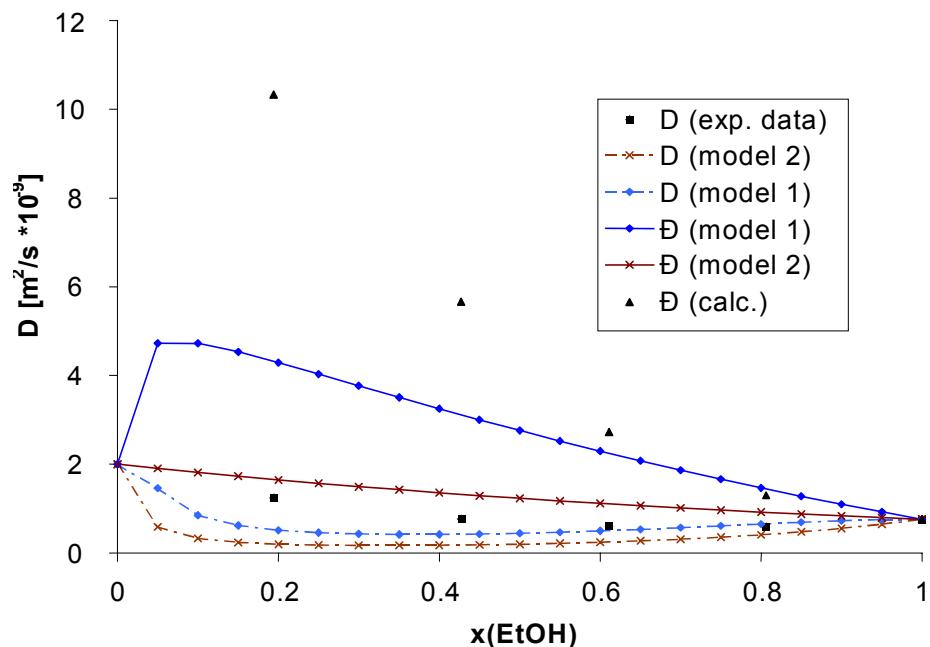

Figure 1. Comparison of experimental data and simulation for system ethanol-cyclohexane.

At lower alcohol concentrations the MS data points show a strong increase in value. The model 1 proposed here qualitatively follows this trend, while the Vignes equation used in model 2 can only predict ideal behaviour. The larger deviations between the data points and the association model can be explained with difficulties in describing the thermodynamic correction factor properly. At lower concentrations of alcohol, i.e., up to  $\tilde{x}(\text{EtOH}) \approx 0.3 - 0.4$ ,  $\Gamma$

falls rapidly from  $\Gamma=1$  in pure benzene to values around 0-0.2. Rutten assumed an inaccuracy in the MS-diffusivities in this region of 50% [4]. Consideration of these deviations would lead to a good agreement between model 1 and the experimental MS-diffusivities. The success of the model proposed here can also be seen in a comparison of the Fick diffusivities. The association model is superior to model 2. Nevertheless, deviations between the experimental data and model 1 can be seen at lower alcohol concentrations. An explanation for these differences is that the commonly used UNIQUAC equation has also been used in the association model to compute  $\Gamma$ .

## CONCLUSIONS

In this work a new model for the prediction of diffusivities in binary associating systems has been presented. Binary Fick diffusivities are computed on the basis of a multicomponent approach for the MS-diffusivities combined with an extension of the commonly used UNIFAC equation. Within this model the associates formed are regarded as separate species.

A first assessment of the association model has been carried out in a comparison of this model with a combination of the Vignes equation and the UNIQUAC model. The results show that the approach proposed here is superior to the other model in describing experimental Fick diffusivities. MS-diffusivities calculated from the literature data can only be qualitatively recalculated because of inaccuracies in  $\Gamma$  at lower alcohol concentrations.

In order to improve the prediction quality of the association model proposed here the thermodynamic correction factor will be calculated using the extended version of the UNIFAC model which has been shown to predict activity coefficients of associating mixtures with high accuracy [9]. Additionally, more experimental data of associating solutes in an inert solvent need to be measured for further model verification.

## STUDY OF THE INTERACTION OF TRIBUTYLPHOSPHATE, NON-IONIC SURFACTANT AND WATER BY FOURIER-TRANSFORM INFRARED SPECTROSCOPY

Zhi-Dong Chang, Xiao-Fang Wei, Jing Wang, Hui-Zhou Liu and Jia-Yong Chen

Young Scientist Laboratory of Separation Science & Engineering,  
State Key Laboratory of Biochemical Engineering, Institute of Chemical Metallurgy,  
Chinese Academy of Sciences, Beijing, China

The interaction of tributylphosphate, the non-ionic surfactant, Tween80, and water has been investigated using Fourier Transform infrared spectroscopy. Results show that if water molecules are present, molecules of tributylphosphate can form a reversed micelle structure. Molecules of tributylphosphate and Tween80 can coalesce through a water bridge. The interaction points between  $\text{H}_2\text{O}$  and tributylphosphate can be  $\text{P}=\text{O}$  or  $\text{P}-\text{O}-\text{C}$ .

### INTRODUCTION

Tributylphosphate (TBP) has been used in recent research as a co-extractant to extract proteins in reversed micelles extraction systems and predispersed extraction systems [1]. The interaction of TBP, surfactant and water is a very important factor in the extraction. Although the interaction of TBP with the water molecule has been reported [2], few papers have been published on the interaction of TBP, water and surfactant molecules. The work reported in this paper focuses on the interaction of TBP, water and non-ionic surfactant, Tween80, molecules.

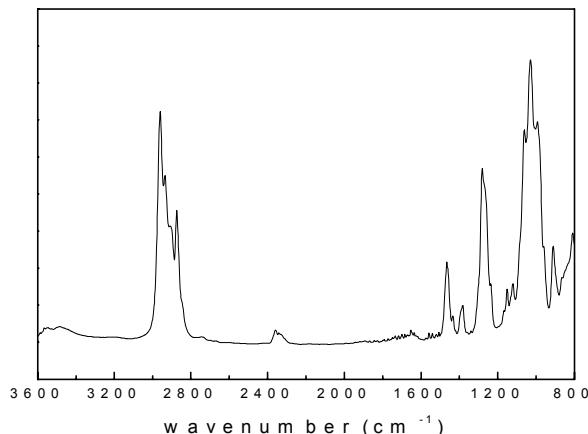

### EXPERIMENTAL

TBP of analytical grade and Tween80 of chemical grade were obtained from Beijing Chemical Reagent Company. Distilled water was used in all experiments.

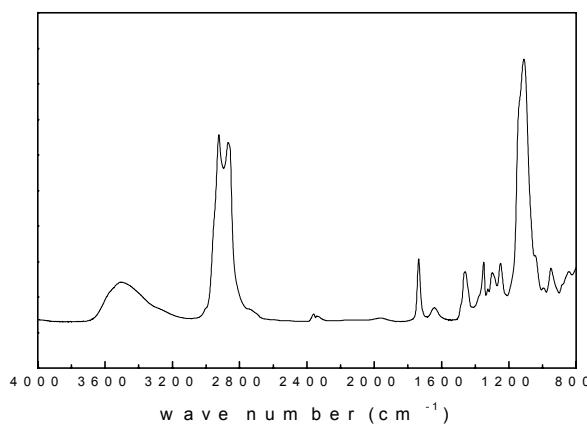

TBP, Tween80 and water were mixed together in various proportions using a WH-90A mini-mixer made by Yarong Biochemical Instruments (Shanghai, China). The mixture was analyzed using a Vector22 Fourier Transform Infrared (FTIR) spectrometer made by Bruker Optik (Germany). The FTIR scan time used was 32 and the resolution,  $2 \text{ cm}^{-1}$ .

### RESULTS AND DISCUSSION

An infrared spectrum for TBP is shown in Figure 1. The typical absorption bands for TBP are due to the presence of C-H,  $\text{P}=\text{O}$  and  $\text{P}-\text{O}-\text{C}$  groups. Bands at  $2800\text{--}3000 \text{ cm}^{-1}$  are due to symmetry and asymmetry stretching of methyl and methylene C-H absorption [3]. Absorption bands at  $1200\text{--}1500 \text{ cm}^{-1}$  are due to bending, twisting, wagging and scissoring of methyl and methylene C-H [2]. Bands at  $1280 \text{ cm}^{-1}$  and  $950\text{--}1100 \text{ cm}^{-1}$  bands are due to  $\text{P}=\text{O}$  stretching and  $\text{P}-\text{O}-\text{C}$  stretching respectively [4]. The spectrum for Tween80 is shown in Figure 2.

*Figure 1. The infrared spectrum for TBP.*

*Figure 2. The infrared spectrum for Tween80.*

When the TBP/Tween80 mixture ratio was 1:4.1, it was observed that the 2800~3000 cm<sup>-1</sup> CH stretching band changed with an increase of water content. The four absorption peaks in this region are due to C-H asymmetric stretching of CH<sub>3</sub> (2958 cm<sup>-1</sup>), C-H asymmetric stretching of -CH<sub>2</sub>- (2924 cm<sup>-1</sup>), C-H symmetric stretching of CH<sub>3</sub> (2872 cm<sup>-1</sup>) and C-H symmetric stretching of -CH<sub>2</sub>- (2853 cm<sup>-1</sup>). Using Gauss functions to fit the curves, it was found that the area of each peak and the peak positions changed with the water content. The area percentage of each peak after normalization and the peak positions are shown in Figures 3 to 6. The results show that when the mole percentage of water in solution exceeded 75%, the peak position and peak area percentage changed sharply. The position of C-H asymmetric stretching of methyl at 2962 cm<sup>-1</sup> shifted to 2945 cm<sup>-1</sup> and the area percentage rose from 1.6% to 41%. The position of C-H asymmetric stretching of methylene nearby 2921 cm<sup>-1</sup> shifted to 2926 cm<sup>-1</sup>, and the area percentage decreased from 40% to 13%. The position of C-H symmetric stretching of methyl at 2864 cm<sup>-1</sup> first shifted to 2898 cm<sup>-1</sup> then to 2880 cm<sup>-1</sup>. The area percentage rose from 25% to 60% and then fell to 40%. The position of C-H symmetric stretching of methylene at 2942 cm<sup>-1</sup> shifted to 2865 cm<sup>-1</sup> with the increase in water content. When the water content exceeded 75%, the peak position shifted to 2853 cm<sup>-1</sup> and the area percentage dropped from 25% to 2%. An explanation for these phenomena follows. In pure solutions, the wave number of C-H symmetric and asymmetric stretching of methyl for TBP is higher than that for Tween80. When blended together, the peak positions shift but no other absorption peaks appear. This result suggests that when Tween80 mixes with TBP, the environment in the solution is suitable to both of them. Their hydrocarbon chains can stretch

out easily and coalesce together. When water is added, hydrogen bonds are formed between water molecules and oxygen molecules of the polyethylene oxide chain of Tween80, causing polyethylene oxide chain bending and overlapping. Thus the C-H stretching of methylene is restrained and the absorption position shifts to a higher wave number. The area percentage of methylene decreases since bending and overlapping of polyethylene oxide chains affect the absorption. Since the supposed molecule structure arrangement is that the hydrophilic portion points inwards with the hydrophobic portion pointing outwards, the hydrophobic chain can stretch out completely and thus enhance the absorption of infrared light.

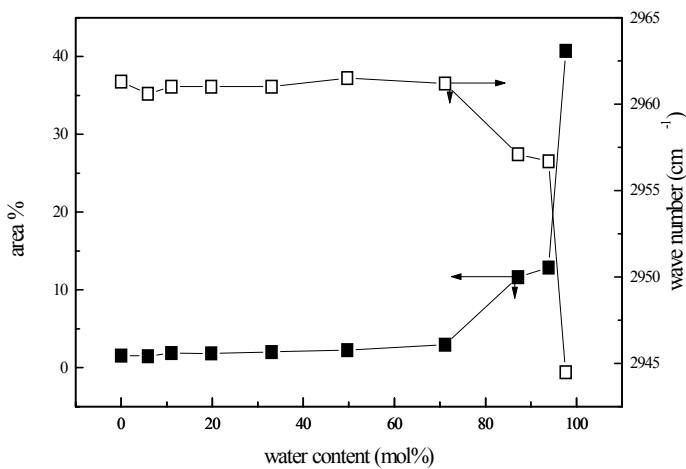

Figure 3. Relation of peak position and area ratio with water content at  $2960\text{ cm}^{-1}$ .

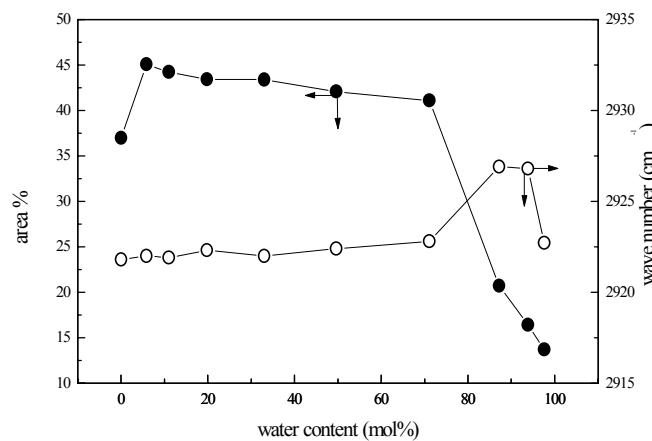

Figure 4. Relation of peak position and area ratio with water content at  $2934\text{ cm}^{-1}$ .

Peaks at  $1487$ ,  $1468$ ,  $1458$  and  $1451\text{ cm}^{-1}$  represent bending of  $-\text{CH}_2-$ , scissoring of  $-\text{CH}_2-$ , asymmetric bending of  $-\text{CH}_3$  and deforming of C-H respectively [5]. The effect of water content on the area percentage of each peak is shown in Figure 7. Although no obvious shift in the positions of the four peaks occurred the absorption intensities of these peaks were observed to change. The area percentages at  $1487$  and  $1468\text{ cm}^{-1}$ , which are associated with the vibration of methylene, decreased. These results reflect that the peaks may be due to the vibration of the methylene of polyethylene oxide. On the other hand, the polyethelene oxide chain coalesces tightly, affecting the absorption of infrared light. The increase of area percentages at  $1458$  and  $1450\text{ cm}^{-1}$  from  $8.2\%$  and  $61\%$  to  $15\%$  and  $68.5\%$ , respectively, demonstrated that the methyl group was exposed on the outside of the molecular aggregation. In addition it was

inferred that the absorption peak at  $1450\text{ cm}^{-1}$  was due to the vibration of methyl. The peak at  $1324\text{ cm}^{-1}$  is assigned twisting of  $-\text{CH}_2-$ . Figure 8 shows that an increase in the water content caused a gradual shift of the peak position to  $1328\text{ cm}^{-1}$ .

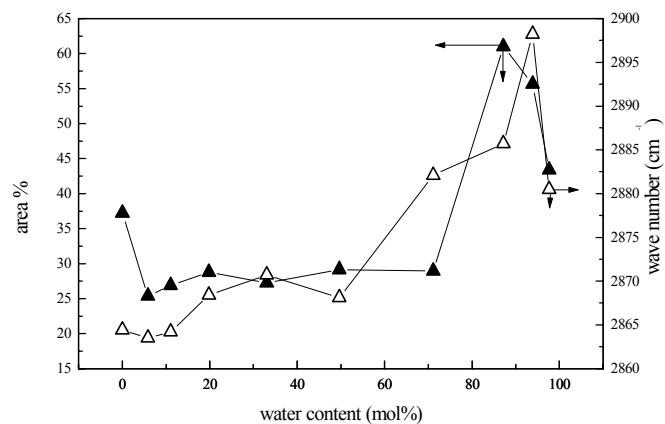

Figure 5. Relation of peak position and area ratio with water content at  $2874\text{ cm}^{-1}$ .

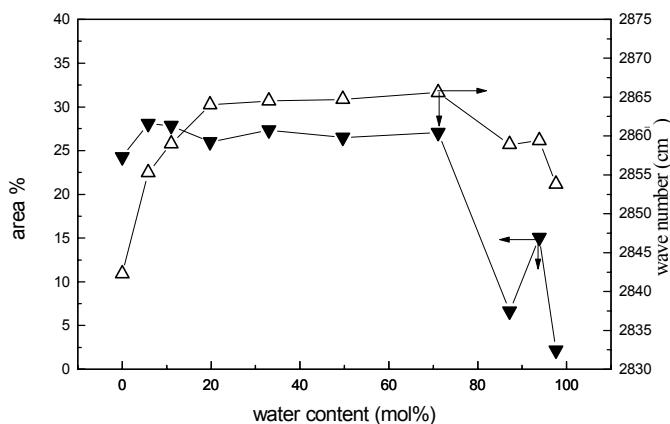

Figure 6. Relation of peak position and area ratio with water content at  $2853\text{ cm}^{-1}$ .

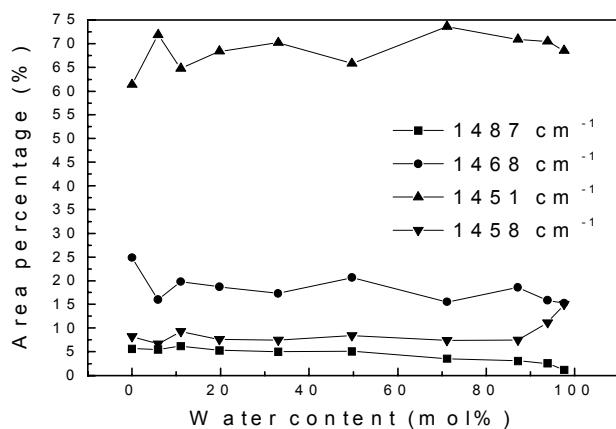

Figure 7. Relation of peak position with water content.

This indicates that the large space obstruction caused by the bulky chain of polyethylene oxide, results in higher energy requirements for the bending of methylene. Peaks at 1146, 1120 and 1100  $\text{cm}^{-1}$  are assigned stretching of C-O of Tween80. Peak positions and area percentages changing with water contents are shown from Figures 9 to 11. The observed decrease in peak positions at 3~6  $\text{cm}^{-1}$  indicates that a hydrogen bond was formed between a water molecule and the O of C-O-C group. This would reduce the interaction of C-O.

## CONCLUSIONS

It was deduced from the results of a FTIR spectroscopic analysis that a reversed micelle structure was formed when water was added to the TBP and Tween80 mixed system. The interaction points between  $\text{H}_2\text{O}$  and TBP can be P=O or P-O-C. Water and TBP can form hydrogen bond at P=O and C-O-P. Molecules of TBP and Tween80 can coalesce through a water bridge.

# ANALYSIS OF AMINE-BASED EXTRACTION SYSTEMS CONTAINING MORE THAN ONE ORGANIC PHASE: INVARIANCE AND IMPLICATIONS FOR EXTRACTION EFFICIENCY AND SELECTIVITY

Aharon M. Eyal, Betty Hazan, Riki Canari, Asher Vitner, and Tali Reuveny

Casali Institute of Applied Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

Single organic-phase extraction systems were formed while extracting acrylic acid by tricaprylylamine (TCA) (no diluent), TCA in kerosene, or TCA in kerosene with 2% octanol. In contrast, two organic phases were formed on extracting maleic acid, and on extracting maleic and acrylic acid from their mixed solution using TCA in kerosene. The preference of maleic acid for the heavy phase over the light one is 80- to 1.6-fold larger than that of acrylic acid (it increases with the increase of the maleic-to-amine molar ratio). These results are explained by extraction mechanisms and the phase rule. Formation of two organic phases can be used successfully for selective separation between a product acid and other acids that preferably distribute into the second organic phase.

## INTRODUCTION

In some cases of using amine-based extractants for extracting mineral acids [1], carboxylic acids [2,3], or metals (like uranium [4]), the organic phase splits into two phases - heavy and light. This phenomenon is undesired in many cases, but could be beneficial in others, e.g., enhancing enrichment in extraction [2,3]. A second organic phase can be of particular interest for selective extraction in a number of industrial systems, e.g., extraction from an aqueous solution containing a mixture of two carboxylic acids.

The present paper analyses the third phase formation based on the Gibbs phase rule determining the general relationship between the degrees of freedom of the system, the number of phases, and the number of components. The effect of diluent properties is discussed and, for the case of extraction from solutions containing maleic and acrylic acids, distribution between the two organic phases and selectivity are analyzed, based on the extraction mechanism.

## THEORY

### Gibbs Phase Rule

The extraction in a three-phase system can be analyzed based on the Gibbs phase rule. This rule determines the general relationship between the degrees of freedom of the system, the number of phases, and the number of components [5,6].

Consider a system containing C number of distinct chemical species (components a, b, c, etc.) and P phases ( $\alpha$ ,  $\beta$ ,  $\gamma$ ), where all the species distribute between the phases and none enters into reaction. The state of each phase is defined by the temperature, T, the pressure, p, and the activity of each of the species in that phase. In other words, the number of the variables for each phase is:

2 (temperature and pressure) + C – 1 (the concentration of one of the component is determined by the sum of the others) = C + 1

Thus, the total number of the variables in all the phases is:

$$P(C+1) = \text{the total number of variables in all the phases} \quad (1)$$

(It should be noted that these variables specify the state of the phases, but not their size). Phases which are in equilibrium must have the same temperature, pressure, and chemical potential,  $\mu$ , for each of the species. Thus, assuming three phases ( $\alpha$ ,  $\beta$ ,  $\gamma$ ) and two species (a, b), there are the following equations between the variables:

$$T_\alpha = T_\beta \quad (2a) \qquad T_\beta = T_\gamma \quad (2b)$$

$$p_\alpha = p_\beta \quad (2c) \qquad p_\beta = p_\gamma \quad (2d)$$

$$\mu_{\alpha,a} = \mu_{\beta,a} \quad (2e) \qquad \mu_{\beta,a} = \mu_{\gamma,a} \quad (2f)$$

$$\mu_{\alpha,b} = \mu_{\beta,b} \quad (2g) \qquad \mu_{\beta,b} = \mu_{\gamma,b} \quad (2h)$$

The total number of equations is: (P-1) temperature equations + (P-1) pressure equations + (P-1) equations of  $\mu$  for species a + (P-1) equations of  $\mu$  for species b, or:

$$(P-1)^* (C+2) = \text{the total number of equations} \quad (3)$$

The number of variables of which their values may be freely chosen by the experimentalist is defined as the degrees of freedom of the system F. According to the Gibbs phase rule, the degrees of freedom can be calculated by subtracting the total number of equations (Equation (3)) from the total number of the variables in all the phases (Equation (1)), hence:

$$F = P(C+1) - (P-1)^* (C+2) \quad (4a)$$

$$\text{or} \quad F = C + 2 - P \quad (4b)$$

Equation (4b) defines the Gibbs phase rule.

## MATERIALS AND METHODS

### Materials

The amine used was tricaprylyl amine (TCA), supplied as Alamine 336 (A-336) by Cognis (MW~391, 95%). The diluents were a low-aromatic kerosene, Isopar K (Exxon), and 1-octanol (Merck, 99%). The acids were maleic acid (MW = 116, BDH, 99%-100.5%) and acrylic acid (MW = 72, Aldrich, 99%).

### Methods

In the single-acid extraction systems, 4 g aliquots of the organic phase were mixed at 25°C for 30 min with 1g aliquots of aqueous phases containing various concentrations of maleic acid. In two-acid extraction systems, 3 g aliquots of the organic phase loaded with the two acids were mixed at 25°C for 30 min with 1 g aliquots of aqueous phases. In some of the

experiments, the various phases (two or three) were separated by centrifugation. The organic phases were washed with 1 N NaOH solution. The wash solutions were analyzed by high performance liquid chromatography (HPLC) (where the temperature was 42°C, the column was Polyspher<sup>R</sup> OA KC (Merck), the mobile phase was 0.01 N H<sub>2</sub>SO<sub>4</sub>, and the flow rate was 0.4 ml/min).

## RESULTS

### Single-acid Extraction System

Table 1 shows that three-phase extraction systems were formed while extracting maleic acid by A-336 (no diluent), A-336 in kerosene, or A-336 in kerosene + 2% octanol (where the initial amine:acid molar ratios were in the range between 1 and 4.5). In contrast, two-phase extraction systems were formed while extracting acrylic acid by A-336 (no diluent), A-336 in kerosene, A-336 in kerosene + 2% octanol, or A-336 in kerosene + 10% octanol. Two-phase extraction systems were also formed while extracting maleic acid by A-336 in kerosene + 10% octanol.

*Table 1. Number of phases formed in extraction systems containing a single acid.*

Extractant	Maleic 0.1-0.45 mol/kg	Acrylic 0.1-0.45 mol/kg
A-336 (no diluent)	+++	---
0.45 mol/kg A-336 in kerosene	+++	---
0.45 mol/kg A-336+ 2% octanol in kerosene	+++	---
0.45 mol/kg A-336+10% octanol in kerosene	---	---

+++ Three-phase extraction system; --- Two-phase extraction system.

Table 2 presents the extraction of maleic acid by A-336 with no diluent. The final maleic acid concentration for all these experiments was 0.014 mol/kg in the aqueous phase, and 0.012 and 1.71 mol/kg in the light and the heavy organic phases, respectively.

*Table 2. Maleic acid extraction systems containing three components and three phases.*

Initial composition (g)			Final composition (g)		
Water	Maleic	A-336	Light organic phase	Heavy organic phase	Aqueous phase
1.54	0.47	2.01	0.33	2.30	1.49
1.70	0.35	2.01	0.8	1.75	1.5
2.04	0.24	2.00	1.3	1.2	1.76
1.93	0.11	2.02	1.76	0.5	1.81

Figure 1 presents results for the extraction of maleic acid by 0.45 mol/kg A-336 in kerosene. The concentration of the acid in the light and the heavy organic phases, and the volume ratio between the organic phases are presented as a function of the acid concentration in the aqueous phase. Figure 1 shows that the acid concentrations in the heavy and the light phase are almost independent of the acid concentration in the aqueous phase. Those concentrations are about 1.5 and 0.01 mol/kg for the heavy and the light phase, respectively. In addition, the ratio between the heavy organic and the light organic phases increases linearly with increasing acid concentration in the aqueous phase.

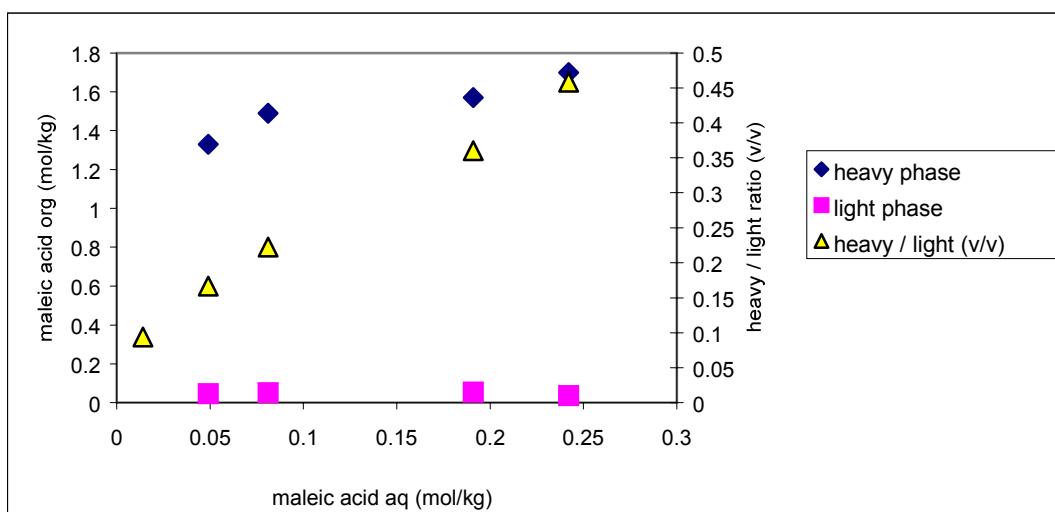

Figure 1. Extraction of maleic acid by 0.45 mol/kg Alamine 336 in kerosene.

### Two-acid Extraction System

Table 3 describes the extraction of maleic and acrylic acid from an aqueous solution by 0.45 mol/kg A-336 in kerosene. It shows the volume ratio between the organic phases (heavy/light), the acid concentrations in the two organic phases, the calculated molar ratio between the acids in each organic phase (e.g.,  $\text{light}_{\text{maleic}/\text{acrylic}}$ ), the preference of each acid for the heavy phase over the light phase (e.g.,  $P_{(\text{H/L})\text{maleic}}$ ), and the ratio between the organic phase preference for the maleic acid and that for acrylic acid ( $R = P_{(\text{H/L})\text{maleic}} / P_{(\text{H/L})\text{acrylic}}$ ).

Table 3. Extraction from solutions containing both maleic and acrylic acid by 0.45 mol/kg A- 336 in kerosene.

Amine/Maleic/ Acrylic	Heavy/ Light	Maleic		Acrylic		Acrylic/Maleic		P (Heavy/Light)		R Maleic/Acrylic
Initial molar ratio	(v/v)	Heavy mol/kg	Light mol/kg	Heavy mol/kg	Light mol/kg	Light	Heavy	Maleic	Acrylic	P/P
0.45:0.1:0.1	0.08	0.142	0.0012	0.088	0.058	49.5	0.62	121	1.5	79.7
0.45:0.1:0.2	0.08	0.144	0.0021	0.197	0.15	7.1	1.4	67	1.3	52.1
0.45:0.1:0.6	0.23	0.305	0.028	1.360	0.28	10.0	4.5	11	4.9	2.2
0.45:0.2:0.1	0.22	0.353	0.013	0.293	0.048	3.7	0.83	28	6.1	4.5
0.45:0.2:0.2	0.22	0.642	0.014	0.592	0.072	5.3	0.92	47	8.2	5.8
0.45:0.2:0.4	0.23		0.019		0.148	7.9				
0.45:0.2:0.5	0.29	0.652	0.023	0.954	0.21	9.2	1.5	28	4.5	6.3
0.45:0.3:0.1	0.24	0.35	0.0075	0.214	0.020	2.7	0.62	46	10.6	4.3
0.45:0.3:0.2	0.29		0.013	0.509	0.050	3.8			10.2	
0.45:0.3:0.3	0.33	0.82	0.016	0.751	0.074	4.7	0.92	52	10.1	5.1
0.45:0.45:0.1	0.40	0.704	0.014	0.250	0.015	1.1	0.35	51	16.7	3.0
0.45:0.45:0.2	0.47	0.409	0.012	0.406	0.032	2.8	0.99	35	12.5	2.8
0.45:0.7:0.1	0.56	0.841	0.0033	0.127	too low			255		
0.45:0.7:0.2	0.56	0.519	0.0066	0.329	0.0067	1.0	0.64	78	49.4	1.6

Table 3 shows that:

1. Although one organic phase was observed in the extraction of acrylic acid by 0.45 mol/kg A-336 in kerosene (Table 1), two organic phases were formed in all the systems containing both maleic and acrylic acid.
2. The ratio between the heavy-to-light organic phase decreases from 0.56 to 0.08 on decreasing the molar ratio between the total acids (maleic + acrylic) to amine in the system from 0.9/0.45 to 0.2/0.45.
3. The preference values of acrylic acid for the heavy phase over the light ( $P_{(H/L)\text{acrylic}}$ ) are higher than unity, but lower than those for maleic acid. The value of the acrylic preference  $P_{(H/L)\text{acrylic}}$  increases on increasing maleic acid concentrations in the system.
4. The ratio between the organic phase preference for the maleic acid and that for acrylic acid ( $R = P_{(H/L)\text{maleic}} / P_{(H/L)\text{acrylic}}$ ) is very sensitive to the maleic acid concentration. It decreases from about 80 to 1.6 on increasing the maleic acid to amine molar ratio in the system from 0.1/0.45 to 0.7/0.45.

## DISCUSSION

### Gibbs Phase Rule

Let us analyze the number of the degrees of freedom in the systems described above based on Gibbs phase rule. In all of the systems, the temperature (T) and pressure (P) are determined (25°C and atmospheric, respectively).

### Acid - amine - water system

In the system containing acrylic acid, amine and water (Table 1), the number of components, C, is 3 and the number of phases is 2. There are three degrees of freedom ( $F = C + 2 - P = 3$ ), but since T and P are determined, there is only one degree of freedom left. One may control the concentration of the acid in the aqueous phase, which determines that in the organic phase. In contrast, in a system containing maleic acid, amine and water (Table 2), the number of components is also 3, but the number of phases is 3. In such a case there are 2 degrees of freedom, but since T and P are determined, no degree of freedom is left and the system becomes invariant (as long as there are 3 phases). At the given T and P, the concentrations of the maleic acid in the light and the heavy organic phases and that in the aqueous phase were fixed: 0.012, 1.71, and 0.014 mol/kg, respectively.

### Acid - amine - diluent - water system

Figure 1 shows that in a system containing maleic acid, amine, kerosene, and water, three phases were formed as in the previous case. However, unlike in that case, there are 4 components, which increases the number of degrees of freedom from zero to 1. Hence, here, as in the case of amine-water-acrylic acid with two phases, one may control the concentration of the acid in one of the phases (which is the degree of freedom) which determines the concentration in the other.

### Two acids - amine - diluent - water system

In the case of extraction systems containing both acrylic and maleic acid (Table 3), two organic phases were also formed. With five components, 3 phases and fixed P and T, the numbers of degrees of freedom in this system is two. Indeed, controlling the concentration of the two acids in the aqueous phase determines their concentration in each of the organic phases).

## **Formation of Three Phases, Extraction Mechanisms, and Practical Aspects**

### **Single-acid extraction system**

In the system containing maleic acid, amine, and water (no diluent), the polarity of the ion pairs  $R_3NH^+ - OOC-C=C-COOH$  is high. Therefore, the mutual solubility between the free amine ( $R_3N$ ) molecules and those of the ion pairs is low. As a result, two organic phases were formed in this case. The solubility of the non-polar diluent (kerosene) in the maleic ion-pairs medium is very low too. Thus, two organic phases were also observed in the system containing maleic acid, amine, kerosene, and water. Being a more polar diluent, octanol acts as a co-solvent and increases the mutual solubility of free amine and amine-maleic acid ion pairs. Hence, the organic phase does not split into two in the case of the extraction system with high octanol content.

Acrylic acid ( $pK_{a,Acrylic} = 4.24$ ) extraction is different from that of the maleic acid ( $pK_{a,1, Maleic} = 1.83$ ). The ion pairs of the weaker acid (acrylic acid) are less polar than those of the maleic and the mutual solubility between the free amine molecules and the ion pairs is higher. As a result, a single organic phase was formed in all the acrylic acid extraction systems.

Hartl and Marr [2,3] suggest improving separation and enrichment in extraction of certain carboxylic acids by choosing conditions where three phases (an aqueous and two organics) are formed.

### **Extraction system containing two acids**

In the extraction of both acrylic and maleic acid from their mixture solutions, the solubility of the maleic acid ion pairs in the light organic phase is low. That is still true when that light phase contains acrylic acid ion pairs. As a result, the organic phase splits in two. Once a heavy, more polar phase forms, the acrylic acid ion pairs prefer it over the light phase, which is less polar ( $P_{(H/L)Acrylic}$  are higher than unity). The polarity of the heavy phase increases with increasing concentration of maleic acid ion pairs. Therefore,  $P_{(H/L)Acrylic}$  increases with increasing maleic acid concentration in the system. Since ion pairs of both acids prefer the heavy phase, the volume of this phase increases with increasing the total concentration of ion pairs (acrylic or/and maleic acid) in the system.

The high affinity of the organic base (the amine) for the acids enables selectivity for extracting the acid over the nonacidic components in the mixture [7]. But the most difficult impurities from which to separate the carboxylic acid in a fermentation broth, are other carboxylic acids. Thus, the selectivity in extraction of carboxylic acids from aqueous solutions containing their mixtures is an important issue. The three-phase systems can be used successfully for selective separation between a product acid and other carboxylic acids that preferably distribute into the second organic phase, in addition to the selective separation of carboxylic acids from non-acidic compounds (like sugars) that preferably distribute into the aqueous phase.

## COMPUTATIONAL TIME SAVING IN THE MONTE CARLO SIMULATION OF LIQUID-LIQUID DISPERSIONS

Zaki El Hassan and E. Susana Perez de Ortiz\*

Department of Chemistry & Chemical Engineering, University of Paisley, Paisley, UK

\*Department of Chemical Engineering, Imperial College, London, UK

This work examines the Monte Carlo models for the simulation of liquid-liquid dispersions proposed in the literature and discusses the implications of their simplifying assumptions on the dynamics of the simulated dispersion and the transfer processes that may take place in it. Following an analysis of the computational load caused by the calculation of the different events taking place in the dispersion, a time saving approximation is proposed for the overall coalescence frequency that preserves the accuracy of the simulation while achieving significant reductions in the computational time. The proposed algorithm allows the implementation of sophisticated interaction models for drops breakage and coalescence as well as other deterministic processes.

### INTRODUCTION

Design of liquid-liquid extractors or mixing equipments relies heavily on laboratory or pilot-plant scale tests. Most of the design depends on experience and trial and error rather than a well-established theoretical basis. This may be attributed to the complexity of the mixing systems' hydrodynamics. The interactions between mass transfer, heat transfer, reaction kinetics and flow structure make it a difficult task to model and design extraction contactors from fundamentals. The existence of regions of substantially different turbulence structure inside the tank requires a rigorous description of the local turbulence features and of the boundary conditions where the regions meet. Two main approaches are found in the literature for modelling such systems. One is to use non-interacting models that ignore the micromixing effects and use averages for the system properties such as the surface area. They include the effective interfacial area models and drop size and residence time distribution models.

The second approach is based on the use of the interaction models that incorporate both microscale and macroscale processes. They provide a vehicle for treating drop breakage and coalescence and account for their effect on the overall process. The importance of micromixing has been illustrated by Curl [1] who showed that for chemically reacting systems, any reaction of order other than one is sensitive to micromixing. Stochastic systems that involve random motions of particles or lumps of fluid that require an statistical treatment are best treated by using the population balance equations (PBE), stochastic simulation methods or Monte Carlo simulation techniques.

The PBEs originated in the treatment of microbial growth. The first time the framework of PBEs appeared in the chemical engineering literature was by Hulbert and Katz [2]. Randolph and Larson [3] discussed the application of PBEs in crystallization. Ramkrishna and coworkers [4-6] studied PBEs in connection with small populations in which random fluctuations would be important. They also discussed the general features of population balances with regard to their applicability in chemical engineering problems [4,6-8]. Valentas and coworkers [9,10], Jeon and Lee [11], Sovova [12], and Shah *et al.* [13] used PBEs to simulate liquid-liquid dispersions but at the expense of accuracy as simplifications were introduced. Normally, when the different rate expressions are incorporated in PBEs, mixed integro-differential equations result that render PBEs of limited use except for simplified cases.

The difficulties associated with PBEs when rate processes were included in the models led to the search for other methods that could be used to analyse realistic situations. The development of digital computers made it possible to overcome most of the PBE's limitations encountered when dealing with complicated equations by using Monte Carlo simulations. Monte Carlo methods may prove more convenient for the following reasons:

1. Techniques are flexible, powerful, and free of convergence problems.
2. They eliminate the need for solving complicated integro-differential equations that result when transfer processes modelling is added to the simulation.
3. The simulation gives information about fluctuations of mean population characteristics as well as their individual entities around the average values, a feature not always possible with PBEs.
4. They allow for easy implementation of the basic expressions for mass and heat transfer rates without unnecessary simplification that may cause significant differences between experimental and simulation results.

The use of Monte Carlo techniques in particulate systems description was pioneered by Spielman and Levenspiel [14] then followed by Zeitlin and Tavlarides [15], Shah *et al.* [16], Bapat *et al.* [17], Hsia and Tavlarides [18], and Okufi [19], among others. This research refers to liquid-liquid and solid-liquid dispersions. Ramkrishna [6] established the connection between PBEs and Monte Carlo simulation techniques by using the method of the interval of quiescence (IQ).

## MODELS AND ASSUMPTIONS

Application of the Monte Carlo simulation techniques requires *a priori* knowledge of the processes at the microscale level which, in case of dispersion splitting and coagulation, are the mechanisms of breakage and coalescence. The development of an adequate algorithm can make it possible to handle mass transfer, heat transfer, as well as complex chemical reactions taking place in the dispersion.

The accuracy of the simulation of liquid-liquid dispersions depends on both the drop interaction models used and the robustness of the simulation algorithm. The approximations made vary from the assumption of interactions between identical drops to more sophisticated ones that use the dispersion characteristics to effect reasonable approximations. They are normally dictated by the computational resources available.

Most Monte Carlo models start by creating a digitised drop size sample according to a predetermined distribution, depending on the nature of the process and the underlying assumptions. In cases where a solute and mass transfer are involved, a trivariate distribution is normally created. In general, the initial time is considered to be zero and the solute is uniformly distributed. In cases where stages are involved, then each drop may have an initial age and a concentration different from the others. Using appropriate phenomenological

models, breakage and coalescence frequencies are assigned. A suitable technique for time management is then selected and the simulation started. The system properties are examined during the assigned time interval then the type(s) of stochastic event(s) taking place are determined and executed. Methods used to execute deterministic events vary according to the models chosen and level of accuracy required. The simulation is continued until a predetermined criterion is achieved. This may be steady state in population size distribution, a predetermined number of events, or a specific population size.

The most fundamental work done in the simulation of liquid-liquid dispersion was carried out by Bapat *et al.* [17] where a fully fledged Monte Carlo model was implemented using the phenomenological models developed earlier by Coualaglou and Tavlarides [20]. The interactions between drops were simulated without introducing any simplifying assumptions that can reduce accuracy or render the results of limited value. No restrictions were made on the sizes of drops coalescing or the daughter droplets resulting from breakage. Their model allowed the implementation of other processes such as mass transfer with relative ease. The penalty for such rigorous approach was a fast increase in computational resources as the sample size was increased and following drops splitting. El Hassan [21] analysed this increase and found it to be proportional to the square of population size.

Several researchers used different approaches to deal with the simulation time problems in their quest to reduce the computational resources required. Laso *et al.* [22, 23] developed a model that significantly reduced computational load with the following assumptions:

1. Drops are assigned to classes with representative sizes.
2. Only breakage into equally sized drops was allowed.
3. Only coalescence between two equally sized drops was allowed.

Das [24] studied only breakage but used similar restrictions regarding daughter droplets sizes. Skelland and Kanel [25] considered mass transfer in agitated systems using similar assumptions for coalescence and breakage as those used by Laso *et al.* [22, 23] but added the effect of drops circulation and rebounding to their model. Balmelli and Steiner [26] used an approach similar to Bapat *et al.* [17] but used representative drop sizes to describe the properties of drops within a certain category. A similar approach was used by Mousa and de Ven [27]. Ribeiro *et al.* [28-30] produced an efficient algorithm that does not restrict interactions to similar drops categories but used representative drop sizes increased algorithmically.

## NEW MODEL

In this paper we present the first step in a new approach [21] to dispersion simulation intended to reduce the computational load while preserving accuracy. This is achieved by minimising the number of assumptions made and by restricting the simplifications.

An examination of the computational load due to the different events was made using a Monte Carlo simulation of a dispersion of 2000 drops in the size range 0.0-0.5 mm and performed using the phenomenological models of Coualaglou and Tavlarides [20] and a full spectrum of drop sizes.

The breakage frequency  $g(a)$  of a drop of diameter  $a$  is given by:

$$g(a) = k_1 \frac{\overline{u^2(a)}^{1/2}}{a} \exp \left[ -k_2 \frac{\sigma}{\rho_d a \overline{u^2(a)}} \right]$$

and the corresponding equation for coalescence frequency  $f(a,a')$  between two drops of diameters  $a$  and  $a'$  is:

$$f(a, a') = k_3 (a + a')^2 \left( \overline{u^2(a)} + \overline{u^2(a')} \right)^{1/2} \exp \left[ k_4 \frac{\mu_c \rho_d}{\sigma^2} \frac{\left( \overline{u^2(a+a')} \right)^{3/2}}{a + a'} \left( \frac{aa'}{a + a'} \right)^4 \right]$$

where  $k_1, k_2, k_3, k_4$  are constants,  $\sigma$  is the interfacial tension,  $\rho$  the density,  $\mu$  is the viscosity,  $u$  the fluctuation velocity across drop diameter, and the subscripts  $c$  and  $d$  refer to the continuous and dispersed phases, respectively.

The algorithm is similar to that developed by Bapat *et al.* [17]. An analysis of the time taken to update the state of the dispersion after each of the different events showed that the main computational load was due to the calculation of the population coalescence frequencies. The model uses a full spectrum of drop sizes, thus avoiding the use of representative drop sizes to simulate the population, where the only approximation made is that of the population coalescence frequencies. This was therefore identified as the section of the simulation with potential for computational time saving. An analysis of the variation with drop size of the overall coalescence frequency of that drop with the rest of the drop population revealed that that the sensitivity is low and smooth, unlike the abrupt changes observed in the breakage frequencies after events are executed. Thus if the drop population is divided into categories of small diameter increments, and the mean size within each category is used in the calculations instead of the spectrum of sizes, the error introduced is small provided that the actual number of drops in the dispersion is used. This is shown in Table 1 for different numbers of categories.

*Table 1. Percentage error in population coalescence frequency.*

Number of Categories	Coalescence Frequency % error
50	0.036
120	0.0059
180	0.0018

Therefore the proposed model uses representative drop sizes only to update coalescence frequencies while keeping the actual drop sizes, ages, and other properties unchanged. Although two drops in one category may have the same coalescence frequencies, their breakage, coalescence, circulation, and rebound probabilities remain distinct. Therefore this approach introduces a minimum of simplifications and does not affect population behaviour in any significant manner.

The model also shifts the emphasis from repetitive CPU operations to the proper utilisation of the storage capacity of the random access memory.

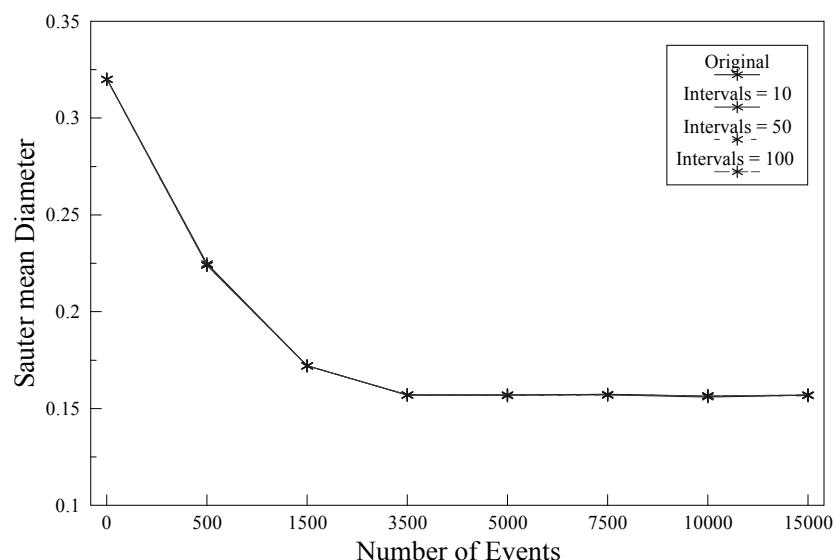

The resulting computational time savings in comparison with a non-simplified algorithm exceeds 97% for any significant number of events as shown in Table 2.

As can be seen, this approach resulted in a very significant reduction in computing load. As the only approximation was in the method by which the coalescence frequency was calculated, it is necessary to show that there was no degradation in the quality of properties used in the simulation and this is shown in Table 2 for a population sample of 2000 drops. All the percentages used in comparison are calculated using a rigorous algorithm similar to that developed by Bapat *et al.* [17].

*Table 2. The new algorithm - computer time saving.*

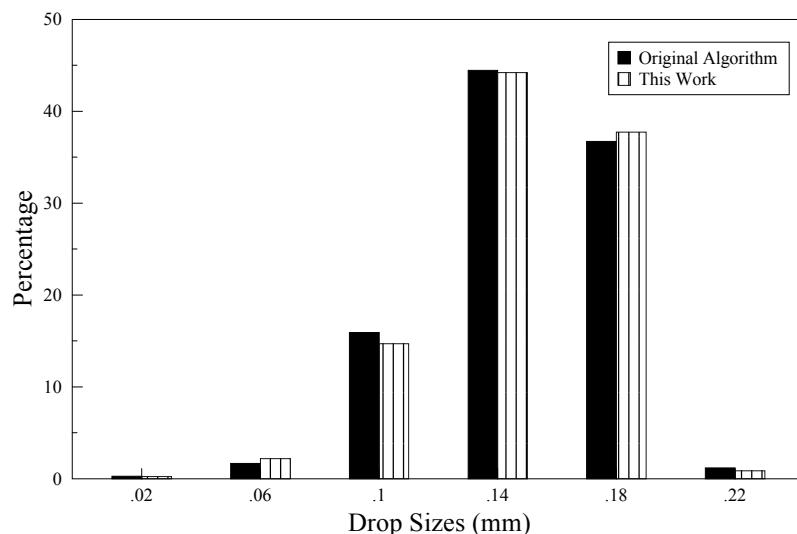

Events	Computer Time Saving (%)		
	10 Intervals	50 Intervals	100 Intervals
500	88.7	88.1	87.1
1500	96.4	96.1	95.8
3500	97.4	97.3	97.1
5000	97.3	97.2	97.1
7500	97.2	96.8	97.1
10000	97.2	97.1	97.1
15000	97.1	97.1	97.0

Figure 1 shows that the evolution of the population Sauter mean diameter obtained with the new model is similar to that resulting from the use of the more rigorous simulation algorithm.

*Figure 1. Evolution of Sauter mean diameter.*

A comparison of the drop size distributions calculated with the two algorithms after 5000 events is shown in Figure 2. It can be seen that the results are quite similar.

*Figure 2. Comparison of drop size distributions.*

## CONCLUSIONS

A computer time-saving Monte Carlo algorithm for the simulation of liquid-liquid dispersions in stirred tanks is presented. The only simplification with respect to more rigorous algorithms is in the calculation of overall coalescence frequency for which the drop size spectrum in each category has been substituted by a mean drop size while retaining the total number of drops in the dispersion. Dispersion updating after all other events is calculated using the entire drop spectrum and unsimplified phenomenological equations. The reductions achieved in the computational load are above 85%.

## AN EXPRESSION OF EQUILIBRIUM CONSTANTS IN SYNERGISTIC EXTRACTION

Yuko Hasegawa, Izuru Matsubayashi, and Akiko Inagaki

Department of Chemistry, Faculty of Science, Science University of Tokyo, Tokyo, Japan

To examine the effect of water molecules dissolved in the organic phase on the magnitude of synergistic extraction, the water solubility, the residual hydration number of the central metal in the chelates and the adducts, the extraction constants of the chelates, and the formation constants of the phen adducts to the chelate have been determined. Using the data obtained from the extraction of europium(III) and zinc(II) with pivaloyltrifluoroacetone (PTA) and/or 1,10-phenanthroline into chloroform, benzene, carbon tetrachloride, and hexane, the adduct formation constants introduced the term of water concentration in the organic phase were calculated. The difference of the constants among the solvents is much smaller than that defined conventionally. It has been concluded that the water content in organic phases, and the hydration and dehydration of the relevant species are the important factors controlling the magnitude of synergistic effects, because water molecules in the organic phases compete with a Lewis base in adduct formation.

### INTRODUCTION

The magnitude of the synergistic extraction of metal ions with a  $\beta$ -diketone and a Lewis base, depends on the nature of the solvents [1]. The solvent effects have been discussed on the basis of the dielectric constants [2] and solubility parameter of organic solvents [3-5]. However, less attention has been paid to the effect of the water in organic phases on the synergistic effects, although the organic phase is always saturated with water in solvent extraction system, and the content in the organic phase is largely different among organic solvents.

The present study has been aimed to examine the effect of water molecules dissolved in the organic phase on the magnitude of synergistic extraction. Since europium(III) is a typical hard acid and zinc(II) is in a middle of hard and soft acids, and their surface charge density should be similar to each other, they have been chosen to compare the involvement of water in organic phase to the adduct formation.

## EXPERIMENTAL

Most experiments were performed in a thermostated room at 298 K.

### Stability Constants of Metal Complexes with Phen in 0.1 M Ionic Medium

Chloroform solution containing various amounts of phen ( $(0.5\text{--}1.0)\times10^{-4}\text{ M}$ : 1 M = 1 mol·dm<sup>-3</sup>) was shaken with zinc(II) ( $1.5\times10^{-2}\text{ M}$  at maximum) aqueous solution at  $\text{pC}_\text{H}$  2 – 3 ( $\text{pC}_\text{H} = -\log[\text{H}^+]$ ) for an hour, where phen is 1,10-phenanthroline and was purchased as monohydrate. Similarly  $\text{CCl}_4$  containing phen was shaken with europium(III) (0.03 M at maximum) perchlorate aqueous solutions at  $\text{pC}_\text{H}$  3.5 - 5.5. The concentration of phen in the organic phases was determined from the absorbance at 265.8 nm.

### Adduct Formation Constants of PTA-Chelates with Phen in Organic Solvents

The procedure was performed in a similar way to that described elsewhere [6]. The aqueous solution containing europium(III) ( $(0.2\text{--}1.2)\times10^{-3}\text{ M}$ ) or zinc(II) ( $1.1\times10^{-4}\text{ M}$ ) adjusted the total ion concentration to 0.1 M with sodium perchlorate, 8.0 mL, was shaken with the identical volume of an organic solution containing PTA (0.05 - 0.2 M) and/or phen ( $< 5.0\times10^{-3}\text{ M}$ ). The hydrogen ion concentration was measured potentiometrically using  $1.00\times10^{-2}\text{ M}$  perchloric acid at 0.1 M ( $\text{H, NaClO}_4$ ) as a standard of  $\text{pC}_\text{H}$  2.00. The europium(III) concentration in the organic phase was determined by ICP-AES (inductively coupled plasma atomic emission spectrometry; HITACHI P-4000) after back extraction into 0.1 M perchloric acid. The concentration of europium(III) in aqueous phases was calculated by subtracting the concentration of europium(III) transferred into the organic phase from the initial concentration in the vial. The zinc(II) concentration in the organic phase was measured after the back extraction by atomic absorption spectrophotometer (HITACHI Z-6000). The zinc(II) concentration in the aqueous phase was also measured.

### Hydration Number of the PTA-Chelates and their Adducts with Phen

The PTA-chelate solutions were prepared by shaking europium(III) or zinc(II) perchlorate solution at  $\text{pC}_\text{H}$  5 - 6 with an organic solution of PTA at a given concentration. The adduct of europium(III) chelate with phen was prepared by extracting europium(III) with PTA and phen into an organic solvent. A portion of the organic phase was transferred into another tube and the water concentration was measured by coulometric Karl-Fischer titration (Hiranuma Sangyo Model AQ-7, Ibaraki, Japan), using HYDRANAL Coulomat AK as the anolyte, serving as a generator of  $\text{I}_2$ , and HYDRANAL Coulomat CG-K as catholyte were obtained from Riedel-de Haën (Seelze, Germany).

## RESULTS AND DISCUSSION

### Stability Constants of Metal Complexes with Phen in 0.1 M Ionic Medium

Since neither  $\text{Zn}^{II}$  nor  $\text{Eu}^{III}$  was extracted, the distribution ratio of phen accompanied with the formation of aqueous complexes with metal ion ( $\text{M}^{m+}$ ) can be represented as follows,

$$D_\text{B} = \frac{[\text{B}]_\text{o}}{[\text{B}] + [\text{HB}^+] + [\text{MB}^{m+}] + \Lambda} = \frac{K_{d,\text{B}}}{(1 + [\text{H}^+]/K_{a,\text{B}}) + \sum n \beta_n [\text{M}^{m+}] [\text{B}]^{n-1}} \quad (1)$$

where,  $\beta_n = [\text{MB}_n^{m+}] [\text{M}^{m+}]^{-1} [\text{B}]^{-n}$ . Assuming the formation of only the first complex, Eq. (1) can be represented as,

$$\log D_\text{B} + \log \left( 1 + \frac{[\text{H}^+]}{K_{a,\text{B}}} \right) = \log K_{d,\text{B}} - \log \left( 1 + \frac{\beta_1 [\text{M}^{m+}]}{1 + [\text{H}^+]/K_{a,\text{B}}} \right) \quad (2)$$

Figure 1 shows the relation of Eq. (2) when phen distributes between a given organic solvent and 0.1 M NaClO<sub>4</sub> in the presence of zinc(II) and europium(III). The values on Y-axis in the flat lines to X-axis agreed with  $\log K_{d,B}$ , i.e., 2.72 (CHCl<sub>3</sub>) and 0.11 (CCl<sub>4</sub>). When the data in Figure 1 were analyzed using  $pK_{a,B}$  4.77,  $5.98 \pm 0.07$  for Zn<sup>II</sup> complex was obtained as  $\log \bar{\beta}_1$ , while it was less than 1.8 for Eu<sup>III</sup> complex. The different stability of the complex for Eu<sup>III</sup> from that for Zn<sup>II</sup> may reflect the different affinity of these metal ions to oxygen atom in H<sub>2</sub>O and nitrogen atom in phen.

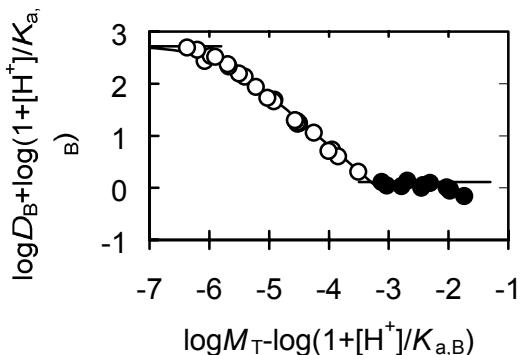

Figure 1. Correlation between  $\log D_B + \log(1+[H^+]/K_{a,B})$  and  $\log M_T - \log(1+[H^+]/K_{a,B})$ .  
aq : 0.1 M NaClO<sub>4</sub>, ○ Zn<sup>II</sup> org : CHCl<sub>3</sub>, ● Eu<sup>III</sup> org : CCl<sub>4</sub>.

### Synergistic Extraction of Europium(III) and Zinc(II) with PTA and Phen

When the distribution ratio ( $D$ ) of europium(III) or zinc(II) between 0.1 M NaClO<sub>4</sub> and an organic solution at a given concentration of PTA,  $\log D$ , was plotted as a function of pC<sub>H</sub> (Eu<sup>III</sup>: 3.1 - 4.3, Zn<sup>II</sup>: 3.5 - 5.8), straight lines having slope of +m were obtained. Accordingly, under the present experimental condition, the formation of the ionic chelates such as EuA<sup>2+</sup> and ZnA<sup>+</sup> can be ignored. When Eu<sup>III</sup> was extracted with PTA of several concentration (0.05 - 0.2 M) at a given pC<sub>H</sub>, the plot of  $\log D$  vs.  $\log [HA]_o$  also gave a straight line having a slope of +3. Using  $pK_a$  (7.01) and the distribution constant of PTA ( $\log K_d$  : 2.51 (CHCl<sub>3</sub>), 2.15 (C<sub>6</sub>H<sub>6</sub>), 2.15 (CCl<sub>4</sub>), 1.87 (C<sub>6</sub>H<sub>14</sub>)) [7], the extraction constants denoted as  $K_{exm0} = [MA_m]_o[M^{m+}]^{-1}[A^-]^{-m}$  were calculated. The values of  $K_{exm0}$  obtained are summarized in Table 1.

Table 1. The extraction constants of PTA-chelate, the adduct formation constants with phen, and the saturated solubility of water in pure organic solvents at 298 K.

	Eu <sup>III</sup>		Zn <sup>II</sup>		Water solubility in organic solvents /M
	$\log K_{ex30}$	$\log \bar{\beta}_1$	$\log K_{ex20}$	$\log \bar{\beta}_1$	
CHCl <sub>3</sub>	$18.1_3 \pm 0.0_5$	$7.6_1 \pm 0.0_6$	$9.6_5 \pm 0.0_5$	$8.5_6 \pm 0.0_6$	$(7.2 \pm 0.2) \times 10^{-2}$
C <sub>6</sub> H <sub>6</sub>	$18.2_9 \pm 0.0_7$	$9.4_0 \pm 0.0_9$	$9.3_0 \pm 0.0_5$	$10.7_7 \pm 0.0_8$	$(3.8 \pm 0.1) \times 10^{-2}$
CCl <sub>4</sub>	$17.5_8 \pm 0.1_2$	$10.1_4 \pm 0.1_5$	$8.9_7 \pm 0.0_4$	$10.3_9 \pm 0.0_4$	$(8.5 \pm 0.3) \times 10^{-3}$
C <sub>6</sub> H <sub>14</sub>	$16.7_4 \pm 0.1_4$	$11.1_2 \pm 0.2_0$	$8.2_7 \pm 0.0_4$	$11.0_1 \pm 0.0_3$	$(3.5 \pm 0.4) \times 10^{-3}$

Figure 2 shows the enhancement of the distribution ratio of europium(III) (a) and zinc(II) (b) in the presence of phen. Since the plot gives a straight line with a slope of 1, the stoichiometry between  $\beta$ -diketonato chelate and phen can be regarded as 1:1, and the total metal concentration in the organic phase,  $M_{o,T}$ , can be regarded as  $[MA_m]_o[B]_o$ . Accordingly the total concentration of phen in the vial,  $B_T$ , can be represented by Eq. (3).

$$B_T = [B] + [BH^+] + [MB^{m+}] + [B]_o + M_{o,T} \\ = [B]_o \{1 + (1 + [H^+]/K_{a,B} + \beta_1[M^{m+}])/K_{d,B}\} + M_{o,T}. \quad (3)$$

where  $\log K_{d,B}$  is 0.76 for  $C_6H_6$  and -1.24 for  $C_6H_{14}$ .

When metal ion is extracted with  $\beta$ -diketone and phen, the distribution ratio of the metal ion can be generally represented as

$$D = \frac{[MA_m]_o + [MA_m \cdot B]_o + \Lambda}{[M^{m+}] + [MA^{m-}] + \Lambda + [MB^{m+}] + [MB_2^{m+}] + \Lambda} \quad (4)$$

Then the net enhancement of the distribution ratio of the metal (II or III) in the presence of phen can be represented as

$$\log(D[A]^{-m} K_{exm0}^{-1}) + \log(1 + \beta_1[B]) = \log \bar{\beta}_1 + \log[B]_o \quad (5)$$

where  $\bar{\beta}_1 = [MA_m \cdot B]_o / [MA_m]_o [B]_o^{-1}$  (6)

and  $[A^-]$  is calculated from the following equation;

$$A_T = [HA] + [A^-] + [HA]_o + m[MA_m \cdot B]_o \\ = [A^-] \{1 + [H^+](1 + K_d)/K_a\} + m M_{o,T} \quad (7)$$

The values of  $\bar{\beta}_1$  were determined using the data in Fig. 2. The adduct formation constants obtained are also listed in Table 1. As seen from Table 1, the adduct formation constants are similar between zinc(II) and europium(III). Although the reason can not be explained easily, plausibly it may reflect the different hydration tendency and the different coordination numbers.

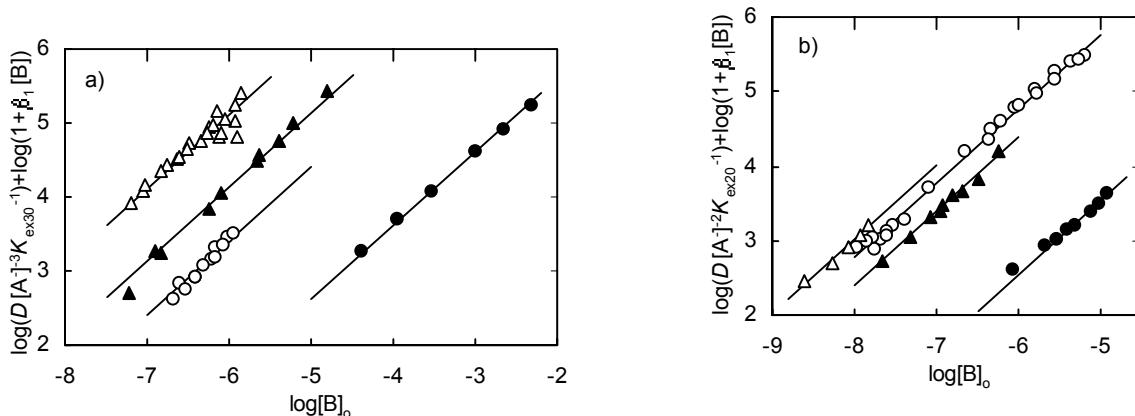

Figure 2. The change in the distribution ratio ( $D$ ) of a) europium(III) or b) zinc(II) containing PTA as a function of phen concentration at equilibrium

●:  $CHCl_3$ , ○:  $C_6H_6$ , ▲:  $CCl_4$ , Δ:  $C_6H_{14}$ .

### Hydration Number of the PTA-Chelates and their Adducts with Phen

When the water concentration in the benzene, carbon tetrachloride and hexane was measured in the extraction of  $Eu^{III}$  with PTA, the concentration of water in the organic solvents increased linearly with increasing the concentration of the  $Eu^{III}$  extracted, as similarly as reported in chloroform [8]. The value at the intercept agreed with water solubility in the pure organic solvents. Then the residual hydration numbers ( $n_0$ ) of  $Eu^{III}$  are obtained from dividing the increment of water content,  $[H_2O]_{o,T} - [H_2O]_{solv}$ , by the concentration of  $[Eu(pta)_3]$  in the organic phase;  $2.4 \pm 0.0$  in  $CHCl_3$ ,  $2.5 \pm 0.1$  in  $C_6H_6$ ,  $2.2 \pm 0.0$  in  $CCl_4$ , and  $2.1 \pm 0.1$  in  $C_6H_{14}$ . The order

of the residual hydration numbers of central metal in the PTA chelates among organic solvents is similar to that of the water solubility. The residual hydration numbers of  $[Zn(pta)_2]$  and  $[Eu(pta)_3 \cdot phen]$  ( $n_1$ ) were determined in a similar way. In the all organic solutions studied, the hydration numbers of  $[Eu(pta)_3 \cdot phen]$  were almost zero. This may suggest that almost all hydrated molecules would be released from europium(III) on the formation of the adducts. The number in the PTA chelate of zinc(II) was  $1.1 \pm 0.1$  in  $CHCl_3$ ,  $1.4 \pm 0.2$  in  $C_6H_6$ ,  $0.8 \pm 0.1$  in  $CCl_4$ , and  $0.8 \pm 0.1$  in  $C_6H_{14}$ , although it was expected to be 2.0 assigning 6 to the coordination number of zinc(II). The reason for the much smaller values than expected can be not explained at present. The coordination number of zinc(II) in the PTA chelate extracted may be a mixture between 4 and 6. In the worst case it may suggest that water content can not be determined exactly in the presence of zinc(II) by Karl-Fischer titration. The detailed discussion must wait until more data are accumulated.

### A Novel Definition for the Equilibrium Constants in Organic Solvents Saturated with Water.

In general, the term of water is excluded from the equilibrium constant in complexation in organic solutions as represented by Eq. (6), because the involvement of water molecules in organic solvents has not been treated in the complexation in the organic phases.

However, the formation constants of the adducts can be represented as,

Then the adduct formation constant should be written as

$$K_1 = [MA_m \cdot B]_o [H_2O]_o^n [MA_m \cdot nH_2O]_o^{-1} [B]_o^{-1} \quad (9)$$

The equilibrium constant,  $K_1$ , may be related to the adduct formation constant,  $\bar{\beta}_1$ :

$$K_1 = \bar{\beta}_1 [H_2O]_o^n \quad (10)$$

where we can use the saturated water solubility in the organic solvent as the concentration of water. The values of  $K_1$  are calculated from the adduct formation constant according to the conventional definition, the hydration number, and the water solubility. As listed in Table 2, the numbers are similar among the solvents studied, although in  $CHCl_3$  the value is a little smaller than others. Accordingly, the difference of the magnitude of the synergistic extraction among organic solvents can be explained by the difference of water concentration in the organic phases as seen from Eq. (10).

*Table 2. Formation constants of phen adduct to  $\beta$ -diketonato chelate according to proposed definition ( $\log K_1$ ).*

	$CHCl_3$	$C_6H_6$	$CCl_4$	$C_6H_{14}$
$Eu^{III}$	$4.9 \pm 0.1$	$5.9 \pm 0.1$	$5.6 \pm 0.2$	$6.1 \pm 0.2$
$Zn^{II}$	$7.4 \pm 0.1$	$8.8 \pm 0.2$	$8.7 \pm 0.1$	$9.1 \pm 0.1$

From the present study it has been concluded that the involvement of water in organic solvents should be treated, whenever the extraction is compared among organic solvents. As the expression of the magnitude of the synergistic extraction of metal ions with  $\beta$ -diketone and a Lewis base, in other words, as the expression of the adduct formation equilibrium, we would like to offer Eq. (8), and as the equilibrium constant, Eq. (9) instead of Eq. (6).

## ACKNOWLEDGEMENTS

The authors are grateful to Messrs. K. Nakaya and T. Saito, Science University of Tokyo, for their experimental aid. This research was partially supported by a Grant-in-Aid for Scientific Research (C), No. 11640614 for the Ministry of Education, Science and Culture, Japan.

## SOME FUNDAMENTAL ASPECTS OF THE CLOUD POINT PHENOMENON AND APPLICATION TO THE EXTRACTION OF PHENOL FROM AQUEOUS STREAMS

Katarzyna Materna, Gerard Cote\* and Jan Szymanowski

Poznan University of Technology, ICTE, Poznan, Poland

\*Ecole Nationale Supérieure de Chimie de Paris, Paris, France

This paper shows the influence of various parameters on the cloud point of a series of new oxyethylated methyl dodecanoates and an oxyethylated alcohol. In particular, the salting-out effect (decrease of the cloud point) arising from the presence of NaCl or NaHCO<sub>3</sub> is explained by the existence of a hydration shell with enhanced water structure as well as a zone with decreased salt concentration (*i.e.*, with excess water molecules) around the -(OCH<sub>2</sub>CH<sub>2</sub>)<sub>n</sub>- chain, as compared with the bulk. On the opposite, the salting-in effect (increase of the cloud point) is explained by depletion of water around the -(OCH<sub>2</sub>CH<sub>2</sub>)<sub>n</sub>- chain. Extraction data are also reported for phenol chosen as a model pollutant.

### INTRODUCTION

The concern to protect the environment becomes everyday stronger and despite major progresses achieved over the last three decades in the field of separation techniques, the removal of pollutants from aqueous industrial streams and wastewaters remains an important challenge. Indeed, well-established techniques such as liquid-liquid extraction exhibit important restrictions and drawbacks. For instance, the diluents and extractants constituting the organic solvents are partly lost in the aqueous phases by solubility and mechanical dispersion as fine droplets and, therefore may be the source of an induced pollution. Furthermore, the use of large volumes of hydrocarbons as diluents may be hazardous. As a result, new separation methods based on innovative concepts are currently being investigated. Thus, the cloud-point extraction technique, which does not use any organic diluent, attracts an increasing attention [1-5].

Cloud-point separations use aqueous micellar solutions of nonionic surfactants that undergo a phase separation (cloud-point phenomenon) upon appropriate temperature increase. From a physical point of view, the increase of temperature provokes the dehydration of the hydrophilic groups of the surfactant molecules, an increase of the aggregation number and the swelling of the micelles until the micellar solution becomes turbid and the separation of a surfactant-rich phase takes place. Such a phase separation leads to a surfactant-rich phase (the extract) in which the solutes are transferred and an almost micelle-free dilute solution of the nonionic surfactants (the raffinate). The phase separation is reversible, and on cooling the mixture to a temperature below the cloud point, the two phases merge to form once again a clear solution.

In its principle, the cloud point extraction technique is highly attractive, but despite many fundamental studies few data are available in the literature for evaluating its applicability in environmental cleanup engineering, as for instance the decontamination of industrial aqueous streams or polluted soils.

Earlier works were based on the use of oxyethylated alkylphenols as non-ionic surfactants, but it is obvious that such compounds are not acceptable in the aimed application because they are toxic and resistant to biodegradation. On the other hand, nonionics such as the new narrow-range oxyethylated methyl dodecanoates [ $C_{11}H_{23}CO(OCH_2CH_2)_nOCH_3$ ] recently synthesized from inexpensive materials avoid such a difficulty, as they hydrolyse easily and give non-toxic and non-surface active moieties [5-7].

Another concern is the consumption of energy to heat the aqueous solutions above their cloud points (*i.e.*, the temperature denoted hereafter CP at which a given micellar solution splits into two liquid phases). Indeed, a simple calculation shows that about 1.2 kWh is needed to increase the temperature of 1 m<sup>3</sup> of water by 1 °C. As a result, the consumption of energy to cause the splitting of the micellar phase is rather high, especially because an overheating ( $\Delta T = T_{set.} - CP$ , where  $T_{set.}$  denotes the settling temperature) of at least 10°C is essential to obtain less hydrophilic surfactant-rich phases and higher distribution coefficients for pollutants such as phenols [5]. However, the overheating  $\Delta T$  should not be too high as the distribution coefficients and yields of extraction of solutes (*e.g.*, phenol) first increase with overheating, then reach a maximum and finally decrease at high values of  $\Delta T$  and/or  $T_{set.}$ . Thus, it is of high importance to control the cloud point to optimise both the efficiency of extraction and consumption of energy.

In the present paper, the influence of various parameters on the cloud point of aqueous solutions of nonionics, including various oxyethylated methyl dodecanoates and an oxyethylated alcohol, is reported and discussed. Extraction data for phenol, a model pollutant, are also presented.

## EXPERIMENTAL

The various oxyethylated methyl dodecanoates [ $C_{11}H_{23}CO(OCH_2CH_2)_nOCH_3$ ] used were kindly provided by the Institute of Heavy Organic Synthesis, Kedzierzyn-Kozle (Poland) and are denoted hereafter as OMD-n, where n refers to the average degree of oxyethylation. The surfactants effectively tested exhibited average degrees of oxyethylation equal to 6, 8, 10 and 12 and their compositions determined by GC and HPLC were reported in previous papers [5-7]. Simulsol OX 1006L [ $C_{10}H_{21}(OCH_2CH_2)_6OH$ ] from Seppic (France) was also used in some experiments. Sodium chloride [NaCl], sodium hydrogenocarbonate [NaHCO<sub>3</sub>], potassium thiocyanate [KSCN] and phenol of reagent grade were from PROLABO (France) and used as delivered. Finally, deionised water was used for the preparation of all the aqueous solutions.

The cloud points were determined in a classical way by heating the micellar solutions above their CP and then by leaving their temperature to slowly decrease under intensive mixing, until the instant of complete disappearance of the turbidity (the temperatures at which the solutions became transparent were assumed to be the cloud points). The determination was repeated at least three times for each solution and the error on the average values of CP did not exceed 1°C.

The concentration of phenol in aqueous solutions was determined spectrophotometrically at 270 nm by using a SECOMAM S.750 spectrophotometer (France).

## RESULTS AND DISCUSSION

### Effects of Various Parameters on the Cloud Point of Non-Ionic Surfactant Solutions

#### **Surfactant concentration**

The cloud point of nonionics is influenced by the concentration of the latter and exhibits a minimum [3,8]. However, in a limited range of concentration, the cloud point is rather insensitive to the concentration of the nonionic surfactant used. Thus, the cloud points of aqueous solutions of oxyethylated methyl dodecanoates are fairly constant between 10 and 50 g.L<sup>-1</sup> [5]. As all our experiments were performed within this range, the effect of surfactant concentration is no longer considered below.

#### **Surfactant hydrophile-lipophile balance**

The appearance of cloudiness is greatly dependent on the structure of the non-ionic surfactant used. Such a dependence can be understood by considering the packing ratio  $P = \upsilon/a_0 l_c$  where  $a_0$  is the cross-sectional area of the hydrophilic group of the surfactant, and  $\upsilon$  and  $l_c$  are the volume and effective length of the hydrophobic tail, respectively [9,10].  $P$  provides a measure of the hydrophile-lipophile balance (HLB). Schott sought a universal relationship between the HLB value and the cloud point of nonionic surfactants [11]. In fact, examination of the cloud points of 165 nonionic surfactants showed that there is no universal relationship between calculated HLB and experimental CP (a graph plotting CP vs HLB consists not of a line but of a band), but that within a homologous series of surfactants having the same hydrophobic moiety and varying degrees of oxyethylation, Eq. (1) applies rather well [11]:

$$CP (\text{ }^{\circ}\text{C}) = a + b \text{ HLB} + c (\text{HLB})^2 \quad (1)$$

In many cases, the term in  $(\text{HLB})^2$  can be ignored and a linear relationship gives the best fit. For instance, in the absence of electrolyte, the following equation was found for the cloud point of the series of oxyethylated methyl dodecanoates of interest here [ $C_{11}\text{H}_{23}\text{CO(OCH}_2\text{CH}_2)_n\text{OCH}_3$ , with  $n = 5$  to 14] [5] :

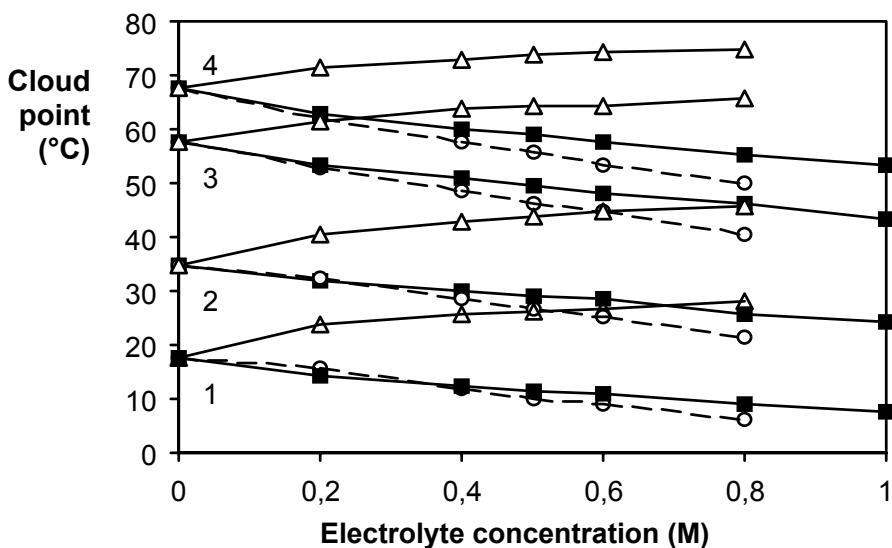

$$CP (\text{ }^{\circ}\text{C}) = -245.8 + 20.27 \times (\text{HLB})^G \quad (2)$$

where  $(\text{HLB})^G$  represents the hydrophile-lipophile balance in Griffin's scale (*i.e.*,  $(\text{HLB})^G = 20M_H/M_S$  where  $M_H$  and  $M_S$  denote the molecular weight of the hydrophilic groups and the molecular weight of the surfactant, respectively; [for OMD-n,  $M_H = 44(n+1)$ ]).

#### **Electrolyte concentration**

The cloud point of a solution of nonionic surfactant can be deeply altered by the presence of various materials including electrolytes, cosurfactants and organic solutes [1,12]. The influence of electrolytes is usually explained in terms of salting-out and salting-in effects, but the formation of complexes between the polyoxyethylene groups of the nonionic surfactants and the metal cations of the electrolyte, including alkali-metal cations (*e.g.*,  $K^+$ ), may also contribute to alter the cloud point [9,13].

The influence of various electrolytes on the cloud point of different narrow-range oxyethylated methyl dodecanoates (OMD-n) is considered in Figure 1. Examination of this figure shows that the cloud point corresponding to a given oxyethylated methyl dodecanoate decreases with the concentration of  $\text{NaCl}$  and that of  $\text{NaHCO}_3$ , but increases with the concentration of  $\text{KSCN}$ . This exemplifies the salting-out and salting-in effects, respectively, and can be interpreted in terms of water structure. Indeed, generally, ions that are water structure formers (*e.g.*,  $\text{Cl}^-$ ) lower the cloud points, whereas ions that are water structure breakers (*e.g.*,  $\text{SCN}^-$  and  $\text{I}^-$ ) increase the cloud points [8,13].

Florin *et al.* have developed a model for the cloud point of high-molecular-weight poly(ethylene oxide), PEO, in aqueous salt solution [14,15]. The basic feature of this model is the existence of a hydration shell with enhanced water structure as well as a zone with decreased salt concentration (*i.e.*, with excess water molecules) around the PEO chain, as compared with the bulk. When the temperature is increased, water molecules are forced back into the bulk solution from the salt-deficient regions, which allows the overlap of the latter and finally the splitting of the solution.

Florin *et al.* have established that the observed change in the cloud points due the presence of an electrolyte arises from the difference  $w - w_o$  given by Eq. (3) :

$$w - w_o = b (\mu_1 - \mu_1^\circ) + \lambda \quad (3)$$

where  $w$  and  $w_o$  are the molar-free-energy contributions from PEO chain - PEO chain interactions and overlaps of hydration shells and salt-deficient zones (if any), in the presence and absence of salt, respectively,  $b$  is the sum of transferred water molecules per  $-\text{O}-\text{CH}_2-\text{CH}_2-$  monomer unit,  $\mu_1$  and  $\mu_1^\circ$  refer to the chemical potential of water in the bulk and in the standard state, respectively, and  $\lambda$  includes all the remaining salt effects. Florin *et al.* found that  $b$  greatly varies from one salt to another. For instance, for PEO solutions at 90°C,  $b$  is close to 3 for NaCl, but only to 0.3 for KI. A negative value of  $b$  is even obtained at 96°C, which indicates depletion of water near the PEO chains, instead of excess as described above.

The difference  $w - w_o$  varies almost linearly with absolute temperature in the case of PEO solutions :

$$w - w_o = \alpha - \beta \quad (\alpha = 15.47 \text{ J.K}^{-1}.\text{mol}^{-1}; \beta = 5682 \text{ J.mol}^{-1}; R^2 = 0.9994) \quad (4)$$

If Eq. (3) and Eq. (4) are identified,  $(\mu_1 - \mu_1^\circ)$  is replaced by  $RT\ln a_w$  and T is identified to the cloud point, one obtains:

$$1/CP = (\alpha / [\beta + \lambda]) - (bR / [\beta + \lambda]) \ln a_w \quad (5)$$

where R and  $a_w$  denote the gas constant and the water activity (at CP), respectively. If Eq. (5) is assumed to be applicable to the aqueous solutions of oxyethylated methyl dodecanoates considered in the present work and if CP° refers to the cloud point in the absence of electrolyte, Eq. (5) can be rewritten as:

$$CP^\circ/CP = 1 - (bR/\alpha) \ln a_w \quad (6)$$

By using the water activity data available in the literature [16], the experimental results given in Figure 1 have been replotted under the form of a CP°/CP vs.  $\ln a_w$  graph, which leads to a series of straight lines as expected from Eq. (6) [for instance, for OMD-10 in the presence of NaHCO<sub>3</sub> : CP°/CP = 0,9999 - 2,1091  $\ln a_w$  with  $R^2 = 0,9993$ ]. From the slopes of these straight lines the following values of b were derived : 1.8 ± 0.2, 3.6 ± 0.5 and - 1.9 ± 0.3 for NaCl, NaHCO<sub>3</sub> and KSCN, respectively. The value of 1.8 ± 0.2 found for NaCl with OMD-n is slightly lower than that previously reported with PEO ( $b \approx 3$ ) [15], but nevertheless clearly illustrates the process of dehydration. On the other hand, the negative value obtained for KSCN suggests that this salt creates a depletion of water around the -(OCH<sub>2</sub>CH<sub>2</sub>)<sub>n</sub>- chain (*i.e.*, a zone with increased concentration of salt), as compared with the bulk, as already observed with KI. However, the extent of the phenomenon is surprisingly large here.

### **Phenol concentration**

The presence of organic solutes is known to have a great effect on the cloud points via the phenomenon of micellar extraction. In general, long-chain nonpolar solutes, such as saturated aliphatic hydrocarbons, which are solubilized in the inner core of the micelles, appear to cause an increase in the cloud point of the solutions, whereas polar and polarizable compounds, such as fatty acids and alcohols of moderate chain length, phenol, benzene, etc., which are solubilized in the outer regions of the micelles, depress it [1,12].

It was observed here that the presence of phenol decreases the cloud point of aqueous solutions of Simulsol OX 1006L in 1 M NaCl according to Eq. (7) (Table 1):

$$CP(^{\circ}C) = -622.5[\text{Phenol}] + 34.95 \quad ([\text{Phenol}] \text{ in M}; R^2 = 0.9979) \quad (7)$$

which shows that the phenol depresses the cloud point much more effectively ( $\Delta CP/\Delta[\text{Phenol}] \approx -622 \text{ } ^{\circ}\text{C.M}^{-1}$ ) than electrolytes such as NaCl ( $\Delta CP/\Delta[\text{NaCl}] \approx -9 \text{ } ^{\circ}\text{C.M}^{-1}$ ). However, if the cloud point extraction method is applied for the removal of low concentrations of phenol [or other organic pollutant] (*e.g.*, < 10<sup>-3</sup> M), the cloud point should be rather constant along the process line.

### **Characteristics of the Surfactant-rich Phase and Extraction Data for Phenol**

In our previous work performed with oxyethylated methyl dodecanoates [5], it was shown that the volume of the surfactant-rich phase and, as a result, the volume phase ratio ( $V_s/V_w$ ) sharply decreases with increasing overheating ( $\Delta T = T_{\text{set.}} - CP$ ) and/or settling temperature  $T_{\text{set.}}$  [ $\Delta T$  and  $T_{\text{set.}}$  were varied simultaneously]. The results obtained in the present study with Simulsol OX 1006L at constant settling temperature (*i.e.*,  $T_{\text{set.}} = 50^{\circ}\text{C}$ ) and reported in Table 1 show that an increase of  $\Delta T$  caused by an increase of the initial concentration of phenol, at constant  $T_{\text{set.}}$ , effectively decreases the ratio  $V_s/V_w$ . As expected, it is also observed that the distribution coefficient of phenol,  $D_{\text{Phenol}}$  increases as the surfactant-rich phase becomes less hydrophilic (*i.e.*, as  $V_s/V_w$  decreases). However, due to the combination of the increase of  $D_{\text{Phenol}}$  and the decrease of  $V_s/V_w$ , the yield of phenol extraction remains remarkably constant. Finally, it should be noticed that with  $[\text{Phenol}]_{\text{initial}} = 49.4 \text{ mM}$ , the system is already turbid at room temperature, but that the efficiency of phenol extraction is as good as in the other experiments. This suggests that it could be more efficient to perform all the extraction procedure above CP (*i.e.*, as in classical liquid-liquid extraction, but without organic diluent), which is possible as the dispersion of the surfactant is easy here. Indeed, this would avoid consumption of much energy to make the solution turbid, without loss of extraction performance.

**Table 1.** Extraction data for phenol and physical characteristics of the extraction system.  
 [Simulsol OX 1006L] = 40 g.L<sup>-1</sup>; phenol variable in 1 M NaCl (pH ≈ 3); T<sub>set.</sub> = 50°C.

Solvent extraction studies of cobalt and nickel have been carried out using a phosphinic acid. The percentage extraction of metal ions increased with increasing equilibrium pH. Cobalt was preferentially extracted over nickel. The equilibria data were correlated with a stoichiometry of 1:4 for cobalt and 1:6 for nickel using activity coefficient corrections. The complex stoichiometry of the system has been confirmed using FT-IR spectroscopy. The models used for calculating activity coefficients were the Pitzer model for the aqueous phase and the regular solution theory of Hildebrand and Scott for the organic phase.

### INTRODUCTION

The separation of cobalt and nickel solutions into pure components is difficult, because of their similar physico-chemical properties. Solvent extraction has proven to be an efficient tool [1, 2]. To provide a model for equilibria and kinetics which is consistent for a broad concentration range non-idealities of both phases have to be taken into account [3]. This can be done using activity coefficients which are partial molar quantities of the Gibbs excess enthalpy. The Gibbs excess enthalpy can be calculated using suitable models such as the Pitzer model for electrolyte solutions [4] and the regular solution theory of Hildebrand and Scott [5] for organic species. The Pitzer model contains several parameters which can be regressed from the experimental data. To be exact in the models, the stoichiometry of the metal complex has to be known. Complex stoichiometry which can be found in the literature are mostly derived from slope analysis at low concentrations. For consistent modeling, it is desirable to know if there is a concentration dependency of the organic metal complex structure. FT-IR analysis is a useful tool in this respect [6].

### EXPERIMENTAL

The phosphinic acid was diluted with solvent. Three different stock solutions were prepared by dissolving cobalt salt in water. Solution I contains 34 g/l cobalt and 2.6 g/l nickel. Solution III contains 10 % of the concentration from solution I, solution II 50 % of the concentration of solution I. The two phases were contacted in a shaker machine for 20 h to reach thermodynamic equilibrium. The equilibrium data are shown in Figure 1. Cobalt is preferably extracted over nickel at low pH-values. At high pH values it was possible to extract the total amount of cobalt and nickel from the aqueous phase.

Atomic absorption spectrophotometry, AAS, (Hitachi Z 8100) was used for the analysis of metal concentration in both phases. Direct organic phase analysis was found to be less accurate than re-extracting the organic phase with acid. The error in the metal mass balance was up to 10 % for direct organic AAS analysis and less than 5 % for the stripped organic solution.

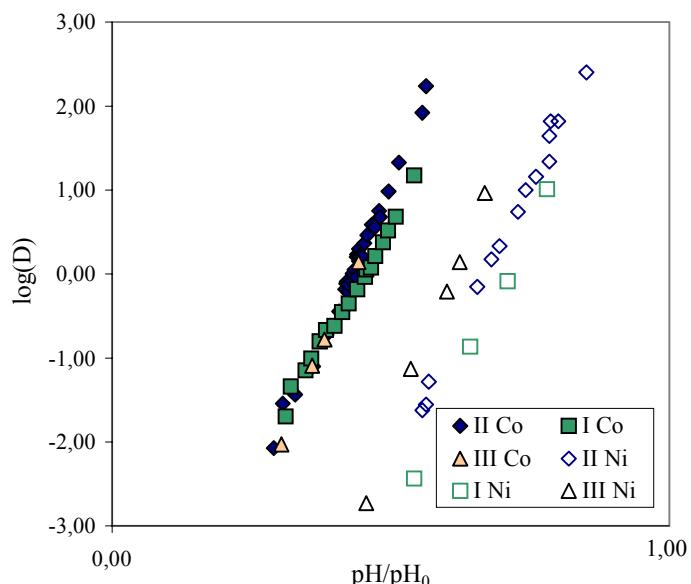

Figure 1. Equilibrium data of Co/Ni/phosphinic acid.

### ORGANIC-PHASE FT-IR SPECTROSCOPY

The predominant metal complex for phosphinic acid in the organic phase according to literature is 1:4 for cobalt ( $\text{CoR}_2(\text{RH})_2$ ) and 1:6 for nickel ( $\text{NiR}_2(\text{RH})_4$ ) [7-11]. The authors did not mention, however, the concentration range valid for those complexes. Most of the information was derived from slope analysis, which is only valid for low concentrations. FT-IR measurements were carried out to investigate directly the structure in the organic phase. Resonances of IR-active groups can be identified in an IR-spectrum. The valence oscillation of the P=O double binding is identified in the range of  $1240\text{-}1180\text{ cm}^{-1}$  [12]. Phosphinic and phosphoric acids can be identified by characteristic vibrational bands in that area. Sainz-Diaz *et al.* [6] investigated the Zn-D2EHPA system by FT-IR measurements. Two distinct bands were identified at  $1234\text{ cm}^{-1}$  and  $1206\text{ cm}^{-1}$  for the phosphoric acid. The band at  $1234\text{ cm}^{-1}$  decreases for increasing metal loading on the ion exchanger, whereas the other band increased. Thus a correlation to the unloaded ion exchanger molecule and one for the metal loaded dimer is possible. The same behavior was observed for Ni-D2EHPA.

FT-IR spectrophotometric analysis were carried out with a Nicolet FT-IR Avatar 320 using KBr-windows. The reproducibility of FT-IR measurements was determined to be within 8 %. Figure 2 shows the FT-IR spectrum for the phosphinic acid dissolved in solvent. With increasing cobalt loading, two diminishing bands can be identified and one increasing band can be identified, respectively.

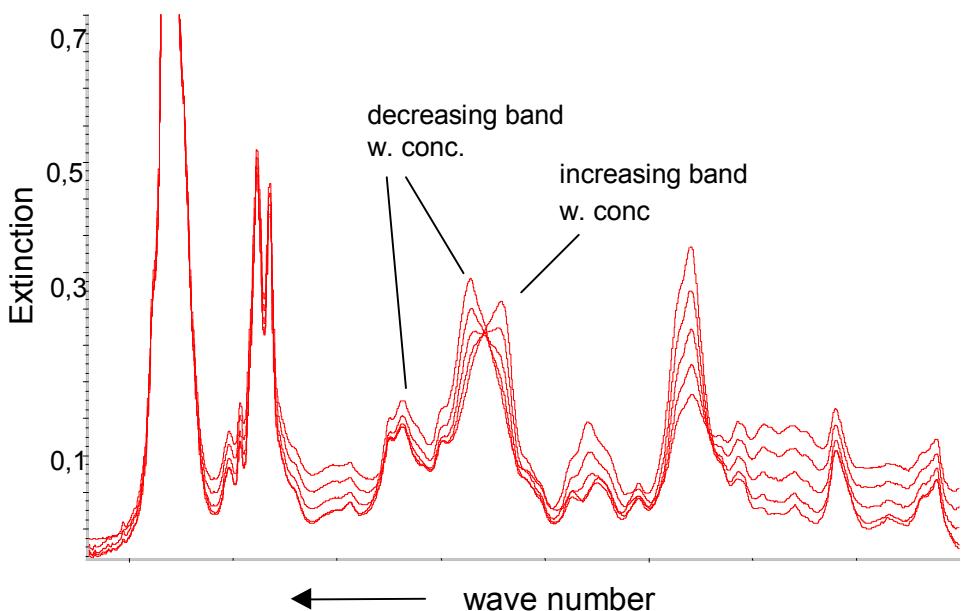

Figure 2. FT-IR-spectrum of Co loaded phosphinic acid.

In Figure 3, FT-IR measurements of the phosphinic acid with different cobalt loadings are plotted over the diminishing band height. Here a linear relationship between metal loading and band height is observed. This strongly indicates that the complex in the organic phase does not vary with concentration. The same observations were made for nickel. A calibration curve was determined by measuring the unloaded ion exchanger at different dilutions in an aliphatic solvent. Figure 4 shows a linear relationship between ion exchanger concentration and band height. Now it is possible to actually assign a concentration of free ion exchanger in loaded organic phases. To determine the actual cobalt complex one has to determine the actual sodium concentration which remained in the organic phase resulting from pre-neutralization. A similar procedure for nickel yields the Ni-complex behavior in the organic phase.

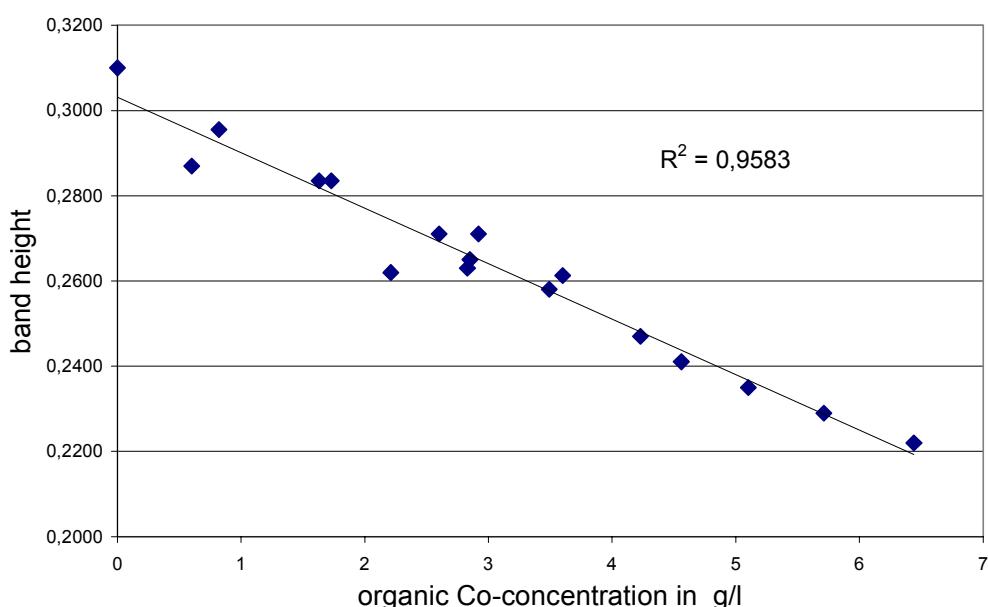

Figure 3. Reducing band for cobalt loaded phosphinic acid.

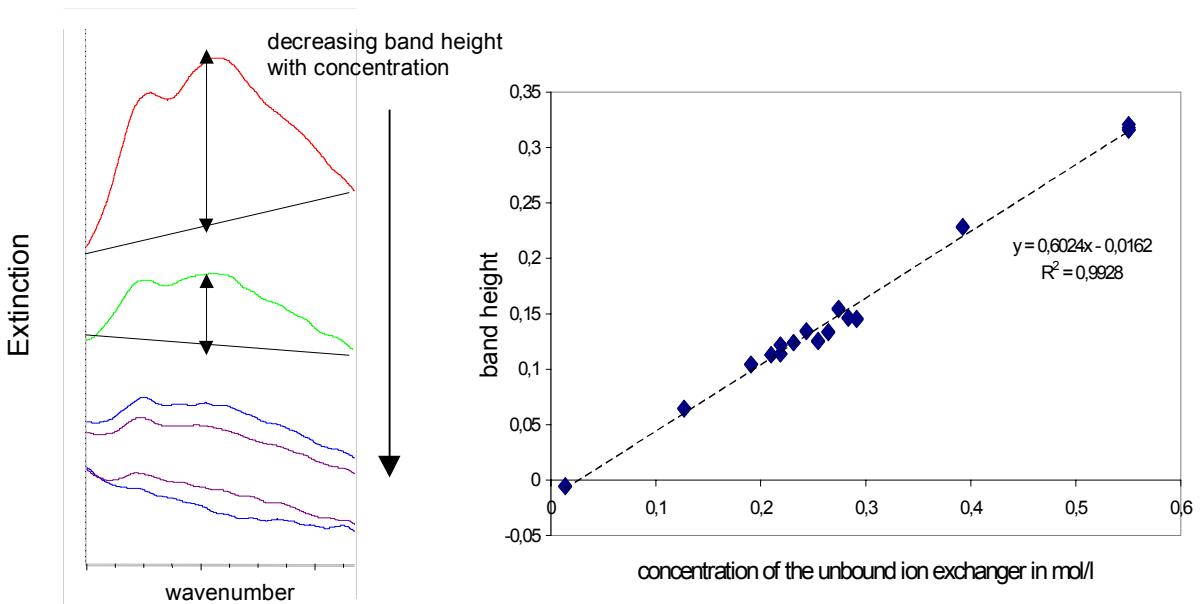

Figure 4. Calibration curve with different phosphinic acid concentration.

The present evaluation of the FT-IR measurements could not confirm the complexes proposed in the literature. The evaluation rather indicates a 1:2 complex for cobalt ( $\text{CoR}_2$ ) and nickel ( $\text{NiR}_2$ ). Further experiments are crucial to show whether this observation holds for lower metal loadings, which would be more compatible to the literature cited. However, no dependency or a change of the stoichiometry of the metal complex with concentration, in the concentration range studied, was found for the cobalt and nickel complexes.

### EQUILIBRIA MODELLING WITH $\text{g}^\text{E}$ -MODELS

Phosphorus-based ion exchangers exist as dimers in kerosene like diluents [13, 14]. With the stoichiometry given in the literature the equilibrium reaction can therefore be written as:

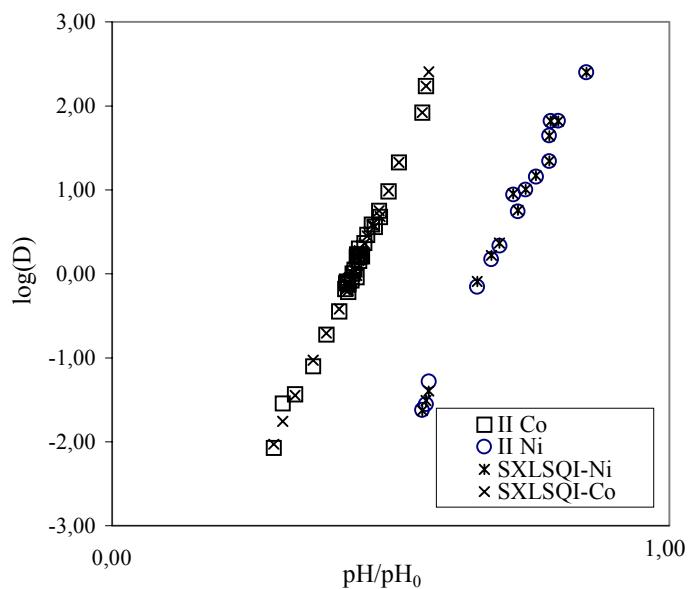

The mass action law then reads as:

$$K_{\text{Co}} = \frac{\overline{\text{CoR}_2(\text{RH})_2} \cdot [\text{H}^+]^2}{\overline{(\text{RH})_2}^2 \cdot [\text{Co}^{2+}]} \cdot \frac{\gamma_{\text{CoR}_2(\text{RH})_2} \cdot \gamma_{\text{H}^+}^2}{\gamma_{(\text{RH})_2}^2 \cdot \gamma_{\text{Co}^{2+}}} \quad (3)$$

$$K_{\text{Ni}} = \frac{\overline{\text{NiR}_2(\text{RH})_4} \cdot [\text{H}^+]^2}{\overline{(\text{RH})_2}^3 \cdot [\text{Ni}^{2+}]} \cdot \frac{\gamma_{\text{NiR}_2(\text{RH})_4} \cdot \gamma_{\text{H}^+}^2}{\gamma_{(\text{RH})_2}^3 \cdot \gamma_{\text{Ni}^{2+}}} \quad (4)$$

To calculate the activity coefficients,  $\gamma_i$ , the Pitzer model[4] is used for the aqueous phase and the Hildebrand-Scott [5] solubility parameter is used for the organic species. Pitzer parameters, Masson parameters and solubility parameters were taken from the literature [15]-[17]. The freely available computer program SXLSQI of Baes *et al.* [18] is used to correlate the experimental data by regressing free parameters of the  $\text{g}^\text{E}$ -models. Figure 5 shows good correspondence of the model with correlated parameters and the experimental equilibrium data.

*Figure 5. Correlated equilibria data using activity coefficients.*

## CONCLUSIONS

The extraction equilibria for reactive extraction of divalent cobalt and nickel from acid solutions using a commercial phosphinic acid as extractant were studied. The percentage extraction of metal ions increased with increasing equilibrium pH. Cobalt was preferentially extracted over nickel. The correlated data using activity coefficients leads to higher model depth. Predictions over the concentration range measured are thus possible. The  $\log D$  over  $pH$  plot yields linear relationships. In order to model the equilibrium data and reaction kinetics, the predominant metal complex in the organic phase has to be known. The stoichiometry of the slope analysis is only valid for low concentrations, therefore the organic phase was investigated by FT-IR spectroscopy analysis over a wide concentration range. Characteristic bands were attributed to the loaded and unloaded ion exchanger. Linear relationships of the characteristic bands with concentration show that the stoichiometry of the metal complex is no function of concentration. With this, FT-IR analysis has proven to be a suitable tool to determine the organic metal complex under extreme conditions.

## ACKNOWLEDGEMENTS

The authors wish to thank Bayer AG and H.C. Starck for their support of this work. Melanie Schmidt is thanked for conducting the FT-IR experiments.

# ESTIMATION OF ACTIVITIES IN THE EXTRACTION OF IRON(III) WITH TRI-N-BUTYL PHOSPHATE AND OF COBALT(II) WITH ALIQUAT 336 FROM MAGNESIUM CHLORIDE MEDIA

Ali Azimi and Nevill M. Rice\*

National Iranian Copper Industries Co. (NICICO), Tehran, Iran

\*Department of Mining and Mineral Engineering, School of Process, Environmental and Materials Engineering, University of Leeds, Leeds, U.K.

Activities in both phases in the extraction of iron(III) from chloride media, containing  $\text{FeCl}_3$ ,  $\text{MgCl}_2$  and HCl by tri-*n*-butyl phosphate (TBP) were estimated. The activity of water in the  $\text{H}_2\text{O}-\text{FeCl}_3$  system was calculated from freezing point data in the literature for  $\text{FeCl}_3$  concentrations up to 1.3 molal and the corresponding  $\text{FeCl}_3$  activity estimated using the Gibbs-Duhem equation. The activity of TBP in the  $\text{FeCl}_3-\text{H}_2\text{O}-\text{TBP}$  system was estimated by application of a multi-component Gibbs-Duhem equation to the distribution and water content data for the extraction of iron by TBP at 25°C but the technique could not be applied to extraction from  $\text{FeCl}_3 - \text{MgCl}_2$  mixtures due to lack of activity coefficient data in mixed electrolytes. The composition of the extracted complex was confirmed as  $\text{FeCl}_3 \cdot 3\text{TBP}$  by slope analysis. An attempt to obtain thermodynamic data for modelling of the extraction of cobalt(II) chloro-complexes from  $\text{MgCl}_2$  media by Aliquat 336 in xylene using vapour pressure osmometry was unsuccessful because the system failed to come to equilibrium due to slow aggregation and the presence of impurities and other components.

## INTRODUCTION

The extraction of iron with several different reagents was studied as part of the development of methods for separation and recovery of metals leached from lateritic nickel ores by HCl [1-10]. Iron(III) can be extracted from chloride media, including HCl,  $\text{MgCl}_2$  and HCl -  $\text{MgCl}_2$  mixtures, by several solvating, cation or anion exchange type extractants [6,8,10,11]. Tri-*n*-butyl phosphate (TBP) has been used in a pilot plant for removing Fe(III) from  $\text{NiCl}_2$  leach liquors in the Falconbridge Matte Leach Process [12,13] when only three loading stages were required as a result of the high  $\text{NiCl}_2$  tenor. An attempt to replicate this at low  $\text{NiCl}_2$  concentration in 6 M HCl with ~5 g/L  $\text{Ni}^{2+}$  required many more stages [14]. Hayman [6] confirmed the improvement in Fe(III) extraction at high concentrations of  $\text{NiCl}_2$  or  $\text{MgCl}_2$  due to the increased aqueous ionic activity of  $\text{FeCl}_3$  at high ionic strength. The extraction of Fe(III) by neutral extractants is well-documented [15-19]. High  $\text{Cl}^-$  concentration is important for stabilising  $\text{FeCl}_3$  complexes though protonated  $\text{HFeCl}_4$  may also be extracted at high acidity. After removing iron from the liquor, Co may be recovered by extracting anionic Co(II) chloro-complexes with alkyl-amines including Aliquat 336 [8,20].

## MODEL FOR THE EXTRACTION OF IRON WITH TBP

For the extraction of the  $\text{FeCl}_3$  complex, the extraction equilibrium can be written as:

from which the thermodynamic extraction equilibrium constant,  $K_{(\text{ex})}$ , may be defined:

$$K_{(\text{ex})} = a_{\text{FeCl}_3 \cdot 3\text{TBP}} / a_{\text{FeCl}_3} a^3_{\text{TBP}} \quad (2)$$

$$\text{whence: } \log D_{\text{Fe}} = \log K' + \log \alpha_3 + 3 \log m_{\text{TBP}} + 3 \log a_{\text{Cl}^-} \quad (3)$$

$D_{\text{Fe}}$  is the distribution ratio of iron(III),  $\alpha_3$  the fraction of aqueous iron as the  $\text{FeCl}_3$  complex,  $m_{\text{TBP}}$  the molality of free TBP,  $a_{\text{Cl}^-}$  the chloride ion activity and  $K'$  a composite term given by

$$K' = K_{(\text{ex})} \beta_3 (\gamma_{\pm} \gamma_{\text{TBP}} / \gamma_0) \quad (4)$$

$\beta_3$  is the overall stability constant of  $\text{FeCl}_3$  complexes;  $\gamma_{\pm}$ , the mean aqueous ionic activity coefficient of  $\text{FeCl}_3$ ,  $\gamma_{\text{TBP}}$  and  $\gamma_0$  are the activity coefficients of the organic TBP and iron species.  $\gamma_{\pm}$  should be constant at constant ionic strength and  $\gamma_0$  is assumed to be constant for constant TBP concentration. To apply this model the parameters in equations (3) and (4) should be known. Data for stability constants are available in the literature [21,22] to enable calculation of  $\alpha_3$  but the organic phase activity coefficients need to be determined from data for the activity of water in the relevant electrolyte solutions. Activities of TBP during solvent extraction have been reported in connection with nuclear fuel processing [23-25] and for the extraction of  $\text{ZnCl}_2$  [26] using the Gibbs-Duhem equation [27] to determine  $\text{H}_2\text{O}$  activity in the organic phase. The formation of  $\text{TBP} \cdot \text{H}_2\text{O}$  in the organic phase is generally agreed [23-25]. Mean ionic activity coefficients for several aqueous metal chloride solutions have been reported [28-34] but only freezing point data were available for  $\text{FeCl}_3$  (for concentrations up to 1.3 molal [35]).

### Gibbs-Duhem Equation

For a two-component system at constant temperature and pressure where  $N$  represents the number of moles of each component, A and B, and  $a$  the corresponding activity the Gibbs-Duhem equation is:

$$N_A d \ln a_A + N_B d \ln a_B = 0 \quad (5)$$

Integration and rearrangement leads to:

$$-\ln a_A = \int_1^{AB} (N_B / N_A) d \ln a_B \quad (6)$$

Therefore if  $N_A$ ,  $N_B$  (or their respective mole fraction,  $X$ , or molality,  $m$ ) and  $a_B$  are known,  $a_A$  may be evaluated by graphical or numerical integration of a plot of  $N_B / N_A$  against  $\ln a_B$  between the appropriate limits. For evaluation of the activity coefficient of  $\text{FeCl}_3$  from freezing point data [9] the equation can be transformed to:

$$-\ln \gamma_{\pm} = j + \int_0^m j d \ln m_{\text{Fe}} - \frac{\Delta \theta}{\lambda} \int_0^{\Delta \theta} (1-j) d \Delta \theta \quad (7)$$

$$\text{for } j = 1 - (\Delta \theta / v m \lambda) \quad (8)$$

where  $\Delta \theta$  is the depression of the freezing point,  $\lambda$  the freezing point depression constant of  $\text{H}_2\text{O}$  (= 1.860 at  $0^\circ\text{C}$ ),  $\$$  for  $\text{H}_2\text{O} = 5.4 \times 10^{-4}$  and  $v$ , the number of ions = 4 for  $\text{FeCl}_3$ . The activity of water,  $a_w$ , may be calculated [31,32] from the osmotic coefficient,  $\Phi$ , in electrolytes of molality,  $m$ , using:

$$-\ln a_w = v m \lambda \Phi / 1000 \quad (9)$$

The activity of TBP was estimated by application of a multi-component Gibbs-Duhem equation

$$\int d \ln a_A = - \int (N_B / N_A a_B) da_B - \int (N_C / N_A a_C) da_C \quad (10)$$

to the distribution data and water content data for the extraction of iron from  $\text{FeCl}_3$  solutions with TBP at  $25^\circ\text{C}$  [8]. (Note that  $a_w$  is equal in each phase at equilibrium).

## EXPERIMENTAL METHOD

The distribution of Mg and Fe(III) between water and TBP (BDH, A.R grade) or TBP in Shellsol A (Shell Chemicals Ltd) was measured by contacting equal volumes of each phase in sealed containers for two hours at 298 K in a shaking thermostat bath. The phases were separated after standing in the bath for several hours. Organic phases were stripped with water and the metal content of both phases determined by atomic absorption spectrophotometry using a Varian Techtron AA-775 double beam instrument and standard addition method (to compensate for matrix effects). Co(II) extraction with Aliquat 336 (tri-n-octylmethylammonium chloride, Henkel) in xylene or Shellsol A was measured similarly. H<sub>2</sub>O in the organic phase was measured by Karl Fischer titration using a conductimetric end point and calibrated against weighed samples of water. The effect of Fe(III), which lowered the apparent concentration of water, was compensated by titration against the H<sub>2</sub>O content of methanol solutions of FeCl<sub>3</sub>.9.3H<sub>2</sub>O (BDH) (1 mg Fe(III) ≡ 0.9 mg H<sub>2</sub>O). Densities were measured using a density bottle calibrated with distilled water [35].

## RESULTS AND DISCUSSION

### TBP- MgCl<sub>2</sub>-H<sub>2</sub>O System

For concentrations up to 3 mol/L Mg the value of D<sub>Mg</sub> is <10<sup>-3</sup>[8] so that Mg extraction may be ignored. The aqueous activity of water in MgCl<sub>2</sub> was calculated from the osmotic coefficient [28,29] using (9), and the activities of H<sub>2</sub>O and TBP in the organic phase were estimated using (6). Figure 1 shows the Gibbs-Duhem plot and Figure 2 the organic activities of water, a<sub>w</sub> and TBP, a<sub>TBP</sub>, as a function of their respective mole fractions, X. Henry's law a = k<sub>H</sub>X, was obeyed by both TBP and water with a<sub>TBP</sub> = 0.7 X<sub>TBP</sub> and a<sub>w</sub> = 1.5 X<sub>w</sub>, using slopes from the "trend lines".

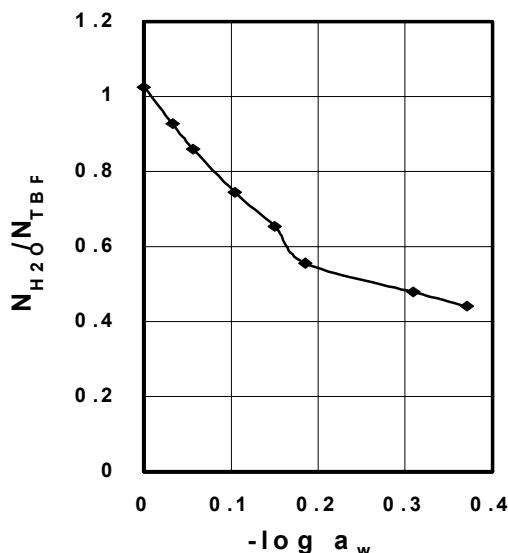

Figure 1. Gibbs-Duhem plot for the TBP-MgCl<sub>2</sub>-H<sub>2</sub>O system.

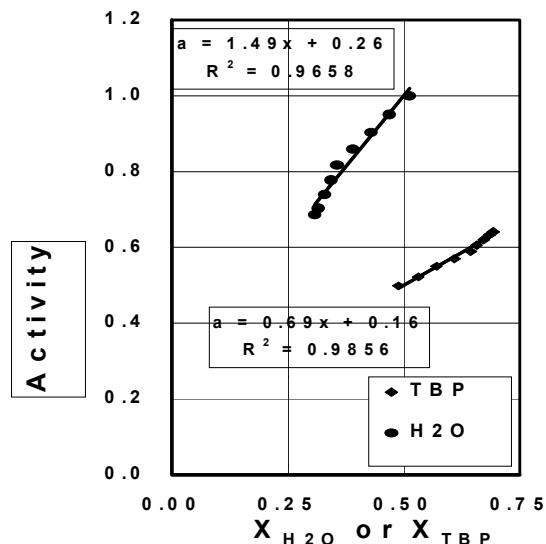

Figure 2. Organic phase activities of TBP and H<sub>2</sub>O in the TBP- MgCl<sub>2</sub>-H<sub>2</sub>O system.

### FeCl<sub>3</sub> - H<sub>2</sub>O System

Table 1 shows  $\gamma_{\pm}$  for FeCl<sub>3</sub>, and also values of a<sub>FeCl<sub>3</sub></sub>, calculated from freezing point data [35] by equation (7) with the integration limits set as described in [8]. (Note: a<sub>FeCl<sub>3</sub></sub> = 27m<sup>4</sup> $\gamma_{\pm}^4$ ).

### $\text{FeCl}_3 - \text{H}_2\text{O} - \text{TBP}$ System

The activity of TBP was evaluated using equation (10) with A  $\equiv$  TBP, B  $\equiv$   $\text{FeCl}_3$  and C  $\equiv$   $\text{H}_2\text{O}$  by separate plotting and integration of  $N_B / N_A a_B$  vs.  $a_B$  and  $N_C / N_A a_C$  vs.  $a_C$ .  $a_{\text{FeCl}_3}$  was obtained by interpolation of the data from Table 1. The first integral was evaluated graphically and the second numerically by curve fitting. The integration limits were taken to be the activity values for water saturated TBP (0.498) and very dilute  $\text{FeCl}_3$  solution with  $a_{\text{FeCl}_3} = 3 \times 10^{-5}$  and  $a_w = 0.998$ . Mole fractions of total and free TBP,  $X_{\text{TBP}}$ , were estimated ( $m_{\text{TBP free}} = m_{\text{TBP tot}} - 3m_{\text{Fe org}}$ ). Results shown in Table 2 display no simple relationship between  $a_{\text{TBP}}$  and  $X_{\text{TBP}}$  and behaviour is far from ideal.

*Table 2. Calculated activity of TBP in the  $\text{FeCl}_3 - \text{H}_2\text{O} - \text{TBP}$  system (TBP = 3.754 mol kg $^{-1}$ ).*

### $\text{FeCl}_3 - \text{MgCl}_2 - \text{H}_2\text{O} - \text{TBP}$ System

The Gibbs-Duhem method could not be extended to this system due to lack of activity coefficient data for mixed aqueous solutions of  $\text{FeCl}_3$  and  $\text{MgCl}_2$ . Although expressions exist to calculate mean ionic coefficients of 1:1/1:1 and 1: 1/1:2 mixtures [29] nothing exists for 1:2/1:3 mixtures so it is necessary to rely on empirical data and empirical or semi-empirical models for such systems.

### Extraction of Fe(III) from MgCl<sub>2</sub> solutions with TBP

Jansz [30] has reported the activities of Cl<sup>-</sup> ions in MgCl<sub>2</sub>/HCl mixtures. His data for a<sub>Cl<sup>-</sup></sub> were used to plot the variation of Fe extraction with a<sub>Cl<sup>-</sup></sub> with undiluted TBP from 0.0196 M (1.1 g/L) Fe(III) in 0.1 M HCl with varying MgCl<sub>2</sub> concentration (Figure 3). The effect of varying TBP concentrations (in Shellsol A) on the extraction of Fe from 1.1 g/L Fe(III) in 4.0 M MgCl<sub>2</sub>/0.1 M HCl is presented in Figure 4. The slopes of both graphs are close to 3, indicating that the model equation (3) is valid and that the extraction proceeds according to reaction (1).

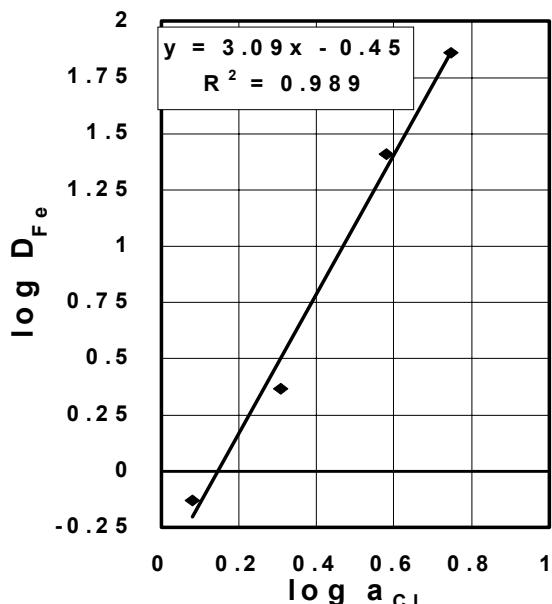

Figure 3. Extraction of Fe(III) from MgCl<sub>2</sub> media with 100 % TB.P

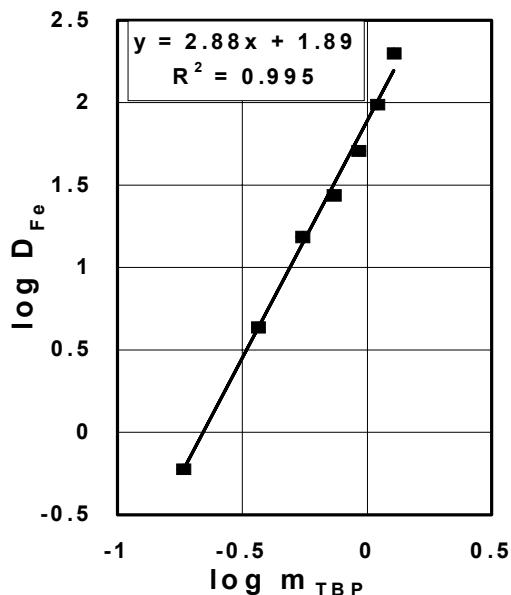

Figure 4. Extraction of Fe(III) from 4.0 M MgCl<sub>2</sub> at varying TBP concentrations in Shellsol A.

### Extraction Of Cobalt(II) With Aliquat 336

Ignoring possible aggregation of the extractant, the extraction of chloro-complexes of Co(II) with Aliquat 336 may be represented by the reaction:

from which:  $\log D_{Co} = \log K' + \log a_n + m \log [R_4NCl]_{(org)} + (2-n) \log a_{Cl^-}$  (13)

From (13) the slope of a plot of log D<sub>Co</sub> vs. log [R<sub>4</sub>NCl]<sub>(org)</sub> = m (14)

and [36] the slope of a plot of log D<sub>Co</sub> vs. log a<sub>Cl<sup>-</sup></sub> should = i<sub>org</sub> - i<sub>aq</sub> = m + 2 - n (15)

Figures 5 and 6 show variation of the extraction of Co(II) by Aliquat 336 from MgCl<sub>2</sub> solutions containing, initially, 1 g/L Co(II) and also 0.05 M HCl with log[R<sub>4</sub>NCl]<sub>(org)</sub> and log a<sub>Cl<sup>-</sup></sub> respectively in order to evaluate m and n from (14) and (15). Figure 5 shows that the value of m increases with increasing aqueous chloride concentration to a maximum of 2 in 6 M Cl<sup>-</sup>, i.e., the organic co-ordination number, i<sub>org</sub> = 4, as expected for tetrahedrally co-ordinated CoCl<sub>4</sub><sup>2-</sup>. However, although the slope in Figure 6 = 3.3 on average, it is closer to 2 at low a<sub>Cl<sup>-</sup></sub> and increasing whereas according to (15) it should fall as a<sub>Cl<sup>-</sup></sub> and hence n increases. This is clearly not true, probably due to aggregation of Aliquat so that the model (13) is inadequate.

### Vapour Pressure Osmometry of Aliquat 336 Solutions in Xylene

In order to allow for aggregation and replace [R<sub>4</sub>NCl]<sub>(org)</sub> by a<sub>R<sub>4</sub>NCl</sub> in the model equation (13) an attempt was made to obtain association data for Aliquat 336 in xylene using vapour pressure osmometry (VPO). Owing to experimental difficulties, i.e., the system failed to reach a constant temperature within a finite time, no useful data could be obtained. The failure of the system to achieve equilibrium can be explained in terms of slow formation of aggregates of Aliquat in the

xylene [37]. A study of tri-*n*-dodecylammonium chloride and nitrate in toluene by VPO has recently reported the formation of dimers of the chloride [38]. It is also probable that the purity of the extractant sample used was insufficient for VPO [37].

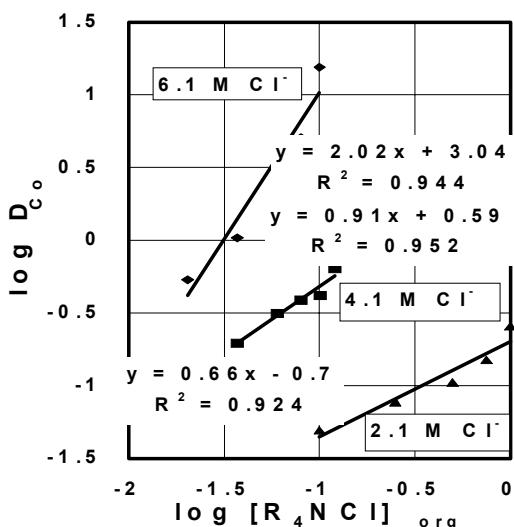

Figure 5. Variation of cobalt(II) extraction by Aliquat 336 concentration from  $MgCl_2$  solutions.

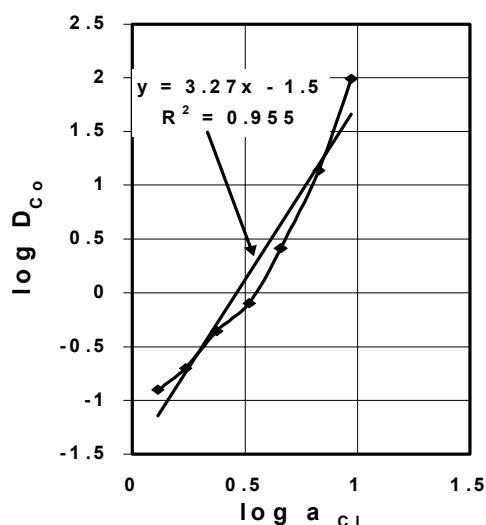

Figure 6. Variation of cobalt(II) extraction by Aliquat 336 (0.625 M) with chloride activity.

## CONCLUSIONS

An attempt to derive a thermodynamic model for the extraction of Fe(II) from  $MgCl_2$  solutions by TBP was partially successful but lack of activity data for mixed ionic media prevented application to the  $FeCl_3 - MgCl_2 - H_2O - TBP$  system and demonstrated the need for empirical data. No useful data could be obtained by VPO for modelling of the extraction of Co(II) with Aliquat 336.

## AQUEOUS TWO-PHASE EQUILIBRIUM DATA FOR POLYETHYLENE GLYCOL, POTASSIUM PHOSPHATE AND BROMELAIN

Albina S. Moreira, Douglas N. Silva, Osvaldo Chiavone-Filho

UFRN, Dept. de Engenharia Química, Natal, Brasil

Liquid-liquid equilibrium data for the aqueous two-phase system with polyethylene glycol (PEG), potassium phosphate and the enzyme bromelain are presented. The project of an analytical cell is described, together with the developed experimental procedure. The concentration of the salt was directly determined for the potassium by atomic absorption spectrophotometry. PEG was quantified with the help of a calibration curve and measures of refractive index. For the determination of the bromelain concentrations in the partition experiments, direct measurements of absorption in the UV range was applied. The method of Lowry was used as reference for the determination of protein content. The dependence of the pH on the partition coefficients was evaluated at a determined tie-line length. The viability of this system for the bromelain extraction was demonstrated.

### INTRODUCTION

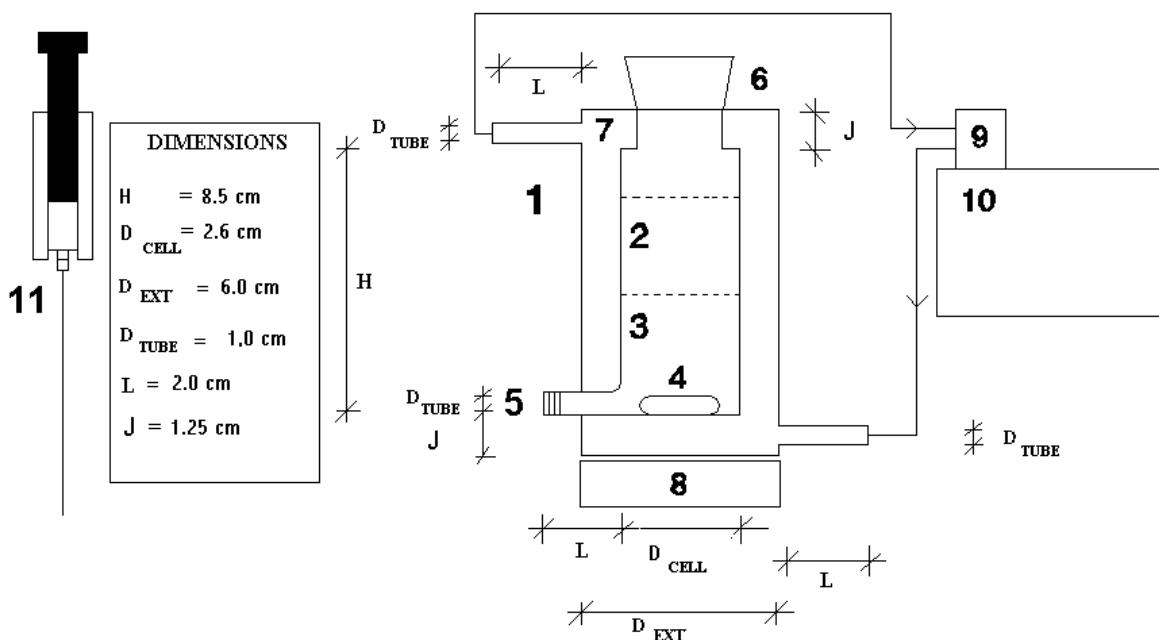

The extraction of natural products is gaining importance due to the increasing demands of the pharmaceutical and food industries. Bromelain is an enzyme extracted from the pineapple and presents a series of applications, *i.e.*, meat tenderizer, enrichment of flours, dehydrated eggs, soy milk, brewery, digestion of worms, treatment of wounds and burns, improvement of the efficiency of X-raying the uterus, minimization of menstrual pains, anti-inflammatory agent, and as an inhibitor of cancerous cells [1].

Liquid-liquid extraction using aqueous systems with polymers and salts has shown to be a feasible technique for the partition and concentration of enzymes [2]. The knowledge of liquid-liquid equilibrium data is fundamental for the design and operation of such unities of extraction.

In this work, liquid-liquid equilibrium data for the system  $\text{H}_2\text{O} + \text{PEG-3350} + \text{KH}_2\text{PO}_4/\text{K}_2\text{HPO}_4$  at 298.15 and 313.15 K are presented. Furthermore, experimental results of the partition coefficient of the bromelain in the aqueous mixtures with PEG3350 and potassium phosphate are also given in a range of pH.

## EXPERIMENTAL SET-UP AND PROCEDURE

The designed analytical cell is described in Figure 1.

*Figure 1. Liquid-liquid equilibrium device: (1) analytical cell with jacket; (2) upper liquid phase; (3) lower liquid phase; (4) magnetic bar; (5) connector and septum for cleaning and sampling of the lower liquid phase; (6) conical join for cleaning, sampling of the upper liquid phase and measurement of the temperature; (7) jacket; (8) magnetic stirrer; (9) temperature controller and pump for circulating thermostatized water; (10) thermostatic bath; (11) syringe.*

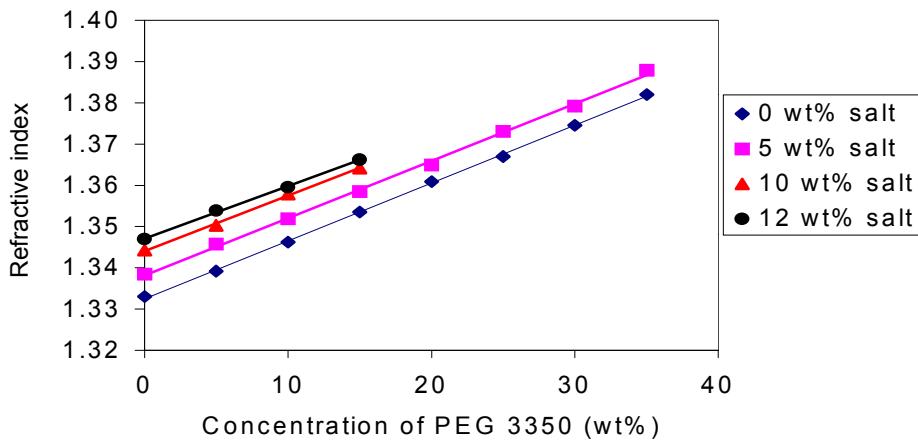

Based on the literature data [2], due to the similarity of the system, and also by trial-and-error, the initial global concentrations to form two liquid phases could be found, in order to start the determination of the phase diagram.

For each tie-line, a mixture of known and appropriate composition inside the two-phase region is poured into the cell. The system is then subjected to mixing for about four hours at constant temperature. The mixture is then left resting for at least twelve hours, usually overnight, for complete separation of the phases in equilibrium. Finally, samples of the top and bottom phases are withdrawn for analysis, in a careful way to avoid disturbance of the system.

### METHODS OF ANALYSIS

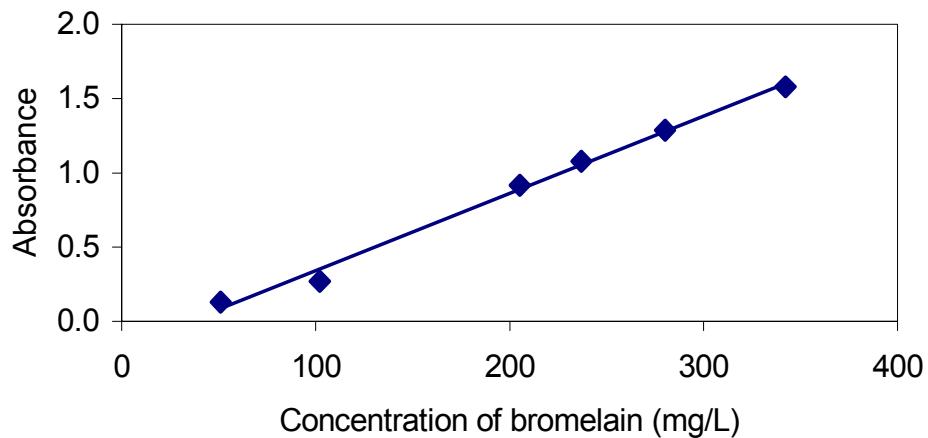

The concentration of salt was directly determined for the potassium by atomic absorption spectrophotometry. PEG was quantified with the help of a calibration curve and measures of refractive index of various synthetic solutions of concentrations determined gravimetrically (see Figure 2). The water content was obtained by difference. It may be observed that the solutions with higher salt content (10 and 12 wt%) presented stable behavior (one liquid phase) up to a limited concentration of PEG.

The method of Lowry [3] was firstly applied, as reference, to determine the protein content present in the bromelain, which was provided by SIGMA. Then a calibration curve was prepared with known enzyme concentrations using direct measurements of absorbance at the recommended wavelength of 280 nm (see calibration curve in Figure 3).

*Figure 2. Calibration curves for the determination of PEG concentration at 298.15 K as a function of the potassium phosphate concentration and refractive index.*

This direct method presented satisfactory reproducibility with the advantage that it is not destructive, requiring no reagent and few dilutions for both phases in the partition experiments. It is noteworthy that partition experiments without enzyme were also carried out in parallel in order to determine the absorption of the other species presented, *i.e.*, PEG and potassium phosphate, and proceed the proper discount [4]. The variation of the pH of the solutions was provided by the combination of the salts mono and di-potassium phosphate mass ratios ( $\text{KH}_2\text{PO}_4/\text{K}_2\text{HPO}_4$ ).

*Figure 3. Calibration curve of absorbance of bromelain in water by the direct method at 280 nm [ $\text{Abs} = 0.0052 (\text{C in mg/L}) - 0.1807$ ].*

## RESULTS AND DISCUSSION

In order to verify the efficiency of the projected equilibrium cell and also the experimental procedure, liquid-liquid equilibrium data for the aqueous system with PEG3350 and potassium phosphate (KPH) were determined at 298.15 and 313.15 K (see Tables 1 and 2).

Based on the data obtained (Figures 4 and 5), the partition experiments for the bromelain were defined in terms of initial concentration, since it is recommended to work with significant tie-line lengths, that produce adequate differences of volume, density and viscosity between the two liquid phases. It is noteworthy that there are two differences between the diagrams presented in Figures 4 and 5, i.e., temperature and pH, resulting a somewhat distinct behavior.

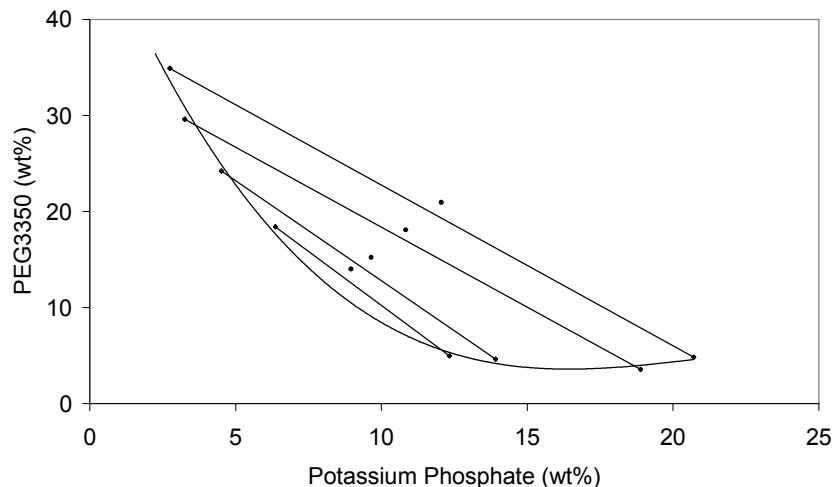

Figure 4. Phase diagram for the aqueous system PEG3350/potassium phosphate at 298.15 K and pH = 7.0.

Table 1. Liquid-liquid equilibrium data for the aqueous\* system PEG3350/potassium phosphate at 298.15 K and pH = 7.0.

Feed		Bottom phase		Top phase	
KHP (wt%)	PEG3350 (wt%)	KHP (wt%)	PEG3350 (wt%)	KHP (wt%)	PEG3350 (wt%)
8.96	14.00	12.33	4.97	6.36	18.40
9.66	15.23	13.92	4.63	4.51	24.21
10.83	18.07	18.89	3.56	3.25	29.61
12.05	20.93	20.71	4.84	2.75	34.92

\*Water content is obtained by difference.

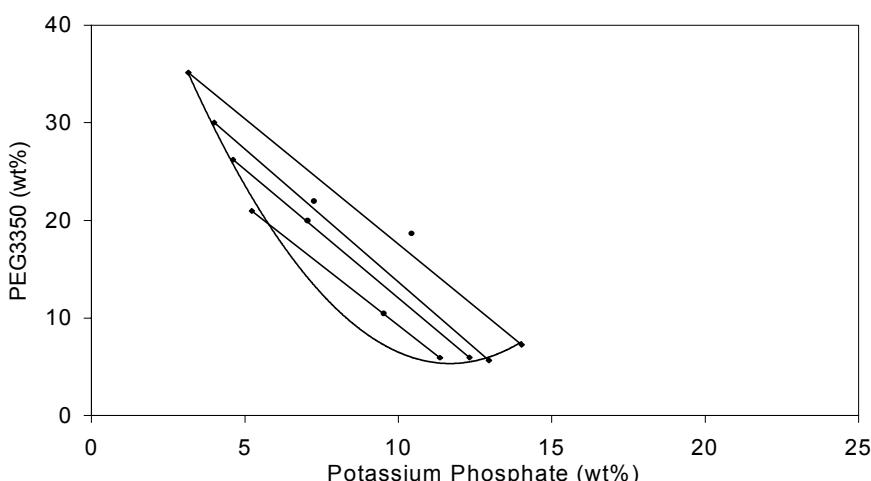

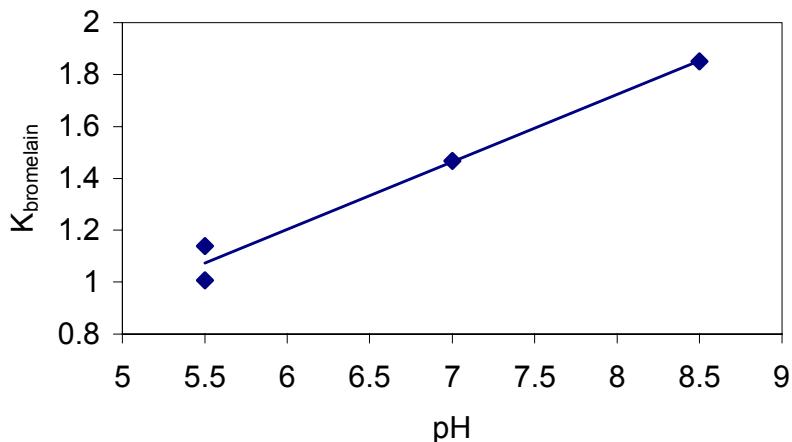

Figure 5. Phase diagram for the aqueous system PEG3350/potassium phosphate at 313.15 K and pH = 4.5.

*Table 2. Liquid-liquid equilibrium data for the aqueous\* system PEG3350/potassium phosphate at 313.15 K and pH = 4.5.*

Feed		Bottom phase		Top phase	
KHP (wt%)	PEG 3350 (wt%)	KHP (wt%)	PEG 3350 (wt%)	KHP (wt%)	PEG 3350 (wt%)
9.53	10.45	11.36	5.93	5.22	20.96
7.05	19.94	12.32	5.94	3.99	30.00
7.25	21.96	12.95	5.65	4.00	30.01
10.43	18.64	14.02	7.25	3.16	35.13

\*Water content is obtained by difference.

Figure 6 shows the partition coefficient of the bromelain as a function of the pH for the aqueous two-phase system with PEG3350 + KH<sub>2</sub>PO<sub>4</sub>/K<sub>2</sub>HPO<sub>4</sub>. It can be observed that the values of the partition coefficient (K) are larger than 1, meaning that the salting-out effect is occurring. Experiments with the same system including dextran and using the salt just as buffer for a range of pH values, revealed the opposite behavior (K < 1) in terms of partition coefficient, i.e., the bromelain was concentrated to the dextran-rich phase, which may be explained by the affinity effect, since dextran and bromelain are macromolecules. However, the results obtained with the PEG/salt system indicate the viability of bromelain separation and it is also more economic than the using dextran.

*Figure 6. Partition coefficient of the bromelain in aqueous PEG3350 + KH<sub>2</sub>PO<sub>4</sub>/K<sub>2</sub>HPO<sub>4</sub> as a function of the pH at 298.15 K and with tie-line length of 30.4 wt%.*

## CONCLUSIONS

The analytical methodology employed for determination of liquid-liquid equilibrium data was demonstrated to be adequate and simple. The results presented satisfactory reproducibility.

One drawback was the determination of the first feed composition adequate for the liquid-liquid experiments. These difficulties were due to the fact that the system is multicomponent and the solubility dependences in terms of temperature and pH were not completely known.

The partition coefficient values obtained for the bromelain in the aqueous system with PEG3350 + potassium phosphate indicated the viability of the concentration and storage of this enzyme with the studied system of separation.

## SELECTIVITY OF METAL EXTRACTION AT THE MICELLAR MECHANISM

Oxana A. Sinegribova and Ol'ga V. Muraviova

D. Mendeleyev University of Chemical Technology of Russia, Moscow, Russia

The present work is devoted to the study of the influence of colloidal particle formation on the selectivity for rare and non-ferrous metal extraction using organophosphorus extractants. The extraction systems containing salts of different metals, neutral and acid organophosphorus extractants (TBP, HDEHP) and various surfactants were the objects of the investigation. It was shown that the selectivity of extraction could be changed due to the surfactant addition. The selectivity of metal extraction depends on the aqueous phase composition, pH, nature and content of added surfactant. The study of the kinetics of extraction indicated that in the presence of surfactant the mass transfer of individual metals took place with the different rates, hence the dynamic separation of metals could be possible.

### INTRODUCTION

Due to the amphiphilic nature of common commercially available metal extractants, they have a tendency to aggregate into micelles, microemulsions and lyotropic liquid crystals under certain conditions. This phenomenon may affect the extraction performance: namely the kinetic and thermodynamic features of metal extraction may be changed due to the formation of colloidal particles depending on their composition and type [1,2].

It was shown earlier that the selective separation of two similar metal ions is performed less efficiently in the micellar system [3]. The addition of TBP and isodecanol to the systems containing acid extractants leads to a dramatic decrease of Co/Ni separation factor [4]. Stoyanov found that the cause of this phenomenon is the formation of micelles. He showed that the presence of modifiers (alcohol, TBP, etc.) increased water content in the organic phase and therefore favoured the formation of mixed micelles [5].

But the extractability and selectivity can be controlled by proper manipulation of the micellar structure [6]. Sometimes the formation of colloidal structures can promote the selectivity of extraction. The structural-mechanical barrier consisting of the aggregated droplets of aqueous phase is a possible reason for the increase of the Pt/Pd separation coefficients in the emulsion extraction systems with tetraoctylammonium di-(2-ethyl)phosphate [7].

Only a few studies have been applied to the problem of selectivity of extraction by the micellar mechanism. The present work is devoted to the study of the influence of colloidal particle formation on the selectivity for rare and non-ferrous metal extraction using organophosphorus extractants. The extraction systems containing salts of different metals, acid or neutral organophosphorus extractants and surfactants were the objects of the investigation. Surfactants with low surfactive properties, which can really increase the metal distribution coefficients [8], were used.

## EXPERIMENTAL

In the present work the following substances have been used: HDEHP(di(2-ethylhexyl) phosphoric acid), TBP (tributylphosphate), TOPO (trioctylphosphinoxide), toluene, aliphatic alcohols (from butanol to decanol); nitrates, sulphates and chlorides of yttrium, lanthanum, zirconium, hafnium with the content of main material not less than 98 %. The concentration of metals was determined by complexometric titration with EDTA.

For the study of the effect of colloidal formation on the dynamic selectivity, the kinetic curves of metal extraction were obtained. The mass transfer was carried out across the flat interface in a horizontal rotating cell (HRC). HRC is a device with a flat interface submitted to weak mechanical action directed into the interfacial field. When the cylindrical cell is placed in horizontal position the interface becomes parallel to the axis of symmetry of the cylinder. At the cylinder wall aqueous, organic phases and wall are brought in contact. During the cell rotating the perimeter of the phase contact slips over the cylinder surface. As a result of the slipping, interfacial perturbations arise providing effective interfacial renewal [9].

## RESULTS AND DISCUSSION

The effect of nature and concentration of added surfactant on the extractability of lanthanide extraction by the solutions of HDEHP in toluene was studied. The values of the ratio of the distribution coefficients for La and Y at the addition of different SAS are presented in Table 1. The concentration of added surfactant corresponds to the maximum of the metal distribution coefficients [10].

The data of Table 1 show that the increase of ratio  $D_Y/D_{La}$  depends on the composition of aqueous phase considerably. The ratio  $D_Y/D_{La}$  increases with decrease of the hydrocarbon length. The higher increase of ratio is observed in the presence of  $\text{CH}_3\text{COOH}$ . TBP and TOPO improve the ratio of the distribution coefficients for La and Y to the same extent.

The dependence of the ratio of the distribution coefficients for La and Y on the concentration of added surfactant is presented in the Table 2.

The ratio of the distribution coefficients  $D_Y/D_{La}$  increases with the increase of the SAS content in the extraction system as compared with the systems without surfactant. The dependence of values of the ratio  $D_Y/D_{La}$  on the concentration of added SAS has a maximum. The ratio depends on the composition of aqueous phase and higher for the extraction from hydrochloric medium.

It was found that the location of yttrium in the lanthanide extractability row by HDEHP (La, Ce, Pr, Nd, Eu, Dy, Er, Yb were used) depends on the process conditions, namely on the composition of the aqueous phase, on the molar ratio between the concentrations of the extractant, metal and the added surfactant. At the certain conditions, for example, at the extraction from hydrochloric medium ( $U = [\text{octanol}]/[\text{HDEHP}] = 0.1$ ), yttrium is outstanding from these lanthanide extractability row:  $\text{La} < \text{Ce} < \text{Pr} < \text{Nd} < \text{Eu} < \text{Dy} < \text{Er} < \text{Yb} < \text{Y}$ .

*Table 1. Comparison of extractability of La and Y in the presence of surfactant.*

TOPO	0.02	2.6	3.4	2.9

Aqueous phase: [Me<sup>3+</sup>] = 0.1 mol/L, pH 2.0. Organic phase: [HDEHP] = 0.2 mol/L in toluene.

*Table 2. Effect of surfactant content on extractability of La and Y.*

[surfactant], mol/L	D <sub>Y/D<sub>La</sub></sub>					
	butanol		octanol		TOPO	
	Extraction from hydrochlor. medium	Extraction from nitric medium	Extraction from hydrochlor. medium	Extraction from nitric medium	Extraction from hydrochlor. medium	Extraction from nitric medium
0.0	2.0	2.6	2.0	2.6	2.0	2.6
0.01	3.6	3.0	2.9	2.9	1.9	2.7
0.02	5.5	4.3	3.4	3.4	2.6	3.3
0.04	6.4	4.5	2.9	3.4	2.1	2.5
0.08	5.9	4.0	2.6	3.6	1.3	1.4

Aqueous phase: [Me<sup>3+</sup>] = 0.1 mol/L, pH 2.0. Organic phase: [HDEHP] = 0.2 mol/L in toluene.

The possibility of the dynamic separation of lanthanides was verified in HRC using octanol as the added surfactant. The extraction of lanthanides (Y, La, Pr, Dy, Er) proceeds with identical rates in the absence of SAS, the kinetic curves coincide practically, and kinetic separation is not possible (Figure 1). But for the addition of octanol to the extraction system, when the micellar mechanism of extraction occurs, the process proceeds with different rate, and the micellar mechanism of extraction occurs, the process proceeds with different rate, and dynamic separation can take place. It should be noted that the presence of octanol causes an increase in the mass transfer rate. For the extracted metals the separation of REE on the yttrium, light and heavy groups can take place.

The influence of surfactant present in the extraction system on the extraction of Zr and Hf by the solutions of HDEHP in toluene from different medium was studied. It was established that the composition of aqueous phase affects the ratio D<sub>Zr</sub>/D<sub>Hf</sub>. For the extraction from nitric and hydrochloric medium, the addition of octanol practically does not affect the separation factor, and the difference between the distribution coefficients for Zr and Hf is low or is absent. For the extraction from sulphuric medium, the ratio D<sub>Zr</sub>/D<sub>Hf</sub> is more considerable. Data of the extractability of zirconium and hafnium in the presence of butanol and octanol

show dependence on the concentration of added alcohol for the extraction from sulphuric medium (Table 4).

The rise of the selectivity of zirconium and hafnium extraction by HDEHP can be obtained at a certain concentration of added alcohol. But at these conditions, a decrease of the distribution coefficients is observed [10].

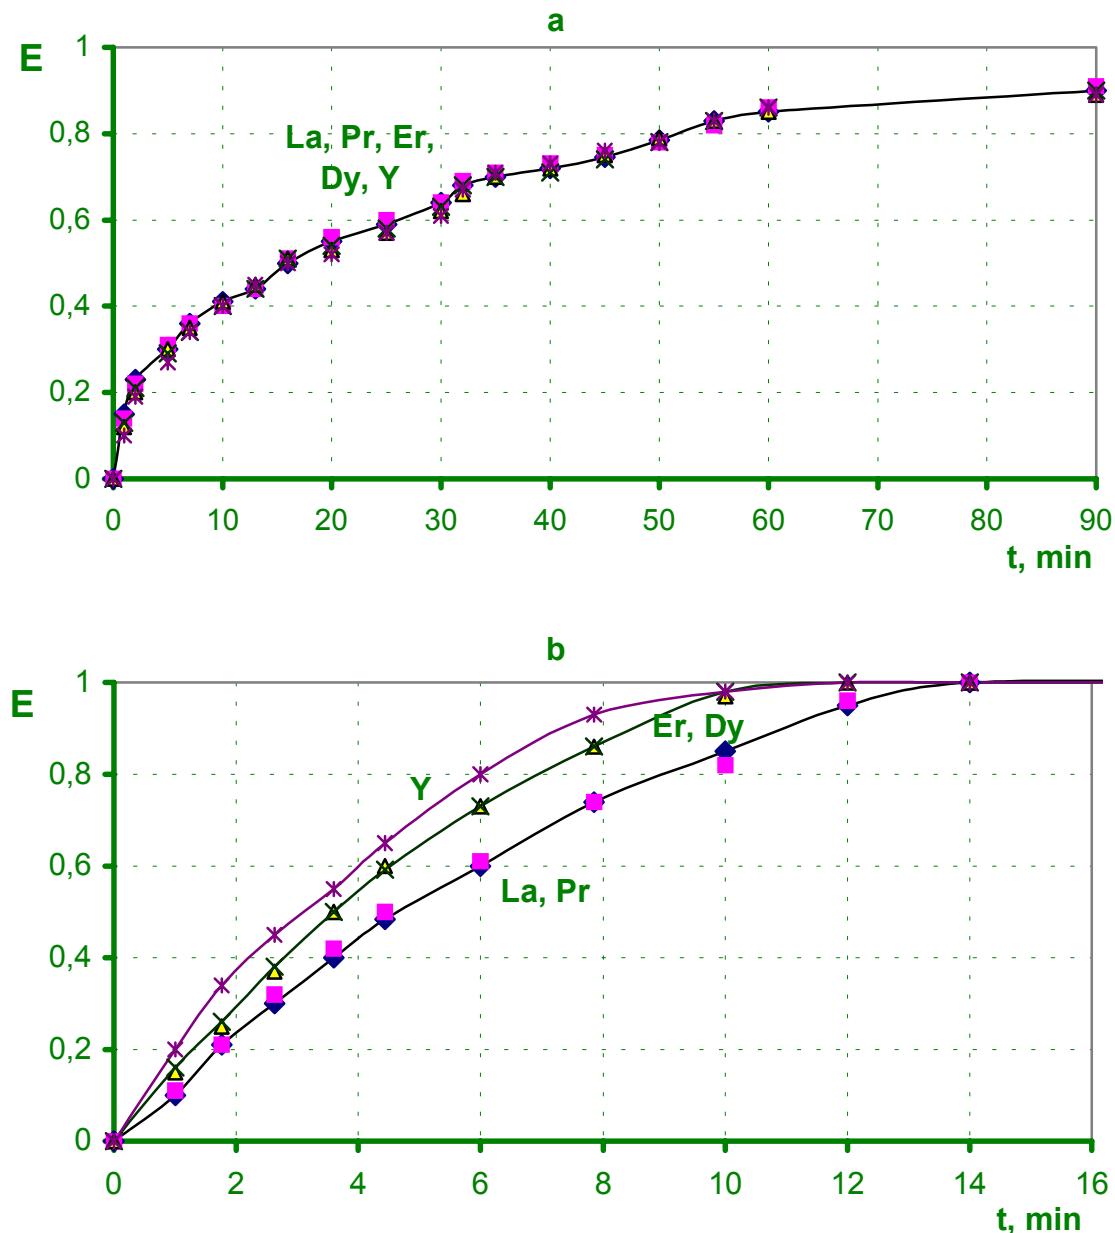

Figure 1. Effect of octanol on kinetics of lanthanides extraction by HDEHP from hydrochloric medium in octanol presence. a - without octanol; b - in the presence of octanol,  $[LnCl_3]=0.1$  mol/L, pH 2;  $[HDEHP]=0.2$  mol/L in toluene.

It should be noted that for the HDEHP extraction of Zr and Hf from different medium, in contrast to lanthanide extraction, the selectivity decrease was not observed, so the surfactant presence can lead to an increase the distribution coefficients of Zr and Hf without the selectivity decreasing.

The relation between the distribution coefficients of zirconium and hafnium in the presence of different SAS (at concentration of added surfactant corresponding to maximum of the metal distribution coefficients) for different media is presented in Table 5.

surfactant	[surfactant], mol/L	D <sub>Zr</sub> /D <sub>Hf</sub>		
		Extraction from hydrochloric medium	Extraction from nitric medium	Extraction from sulphuric medium
-	0	1.04	1.06	1.29
CH <sub>3</sub> COOH	0.08	1.20	1.11	1.52
butanol	0.08	1.13	1.20	1.40
isopentanol	0.08	1.20	1.14	1.87
hexanol	0.08	1.16	1.12	1.68
octanol	0.10	1.13	1.10	1.68
decanol	0.10	1.14	1.11	1.61

Aqueous phase: [Me] = 0.075 mol/L; pH 0.3. Organic phase: [HDEHP] = 0.4 mol/L in toluene.

The ratio D<sub>Zr</sub>/D<sub>Hf</sub> depends on the composition of the aqueous phase and is higher for extraction from sulphuric medium. This phenomenon is probably explained by the processes of complexing, which are more intensive in sulphuric system as compared with the hydrochloric and nitric systems. The dependence of the ratio between the distribution coefficients of zirconium and hafnium from the hydrocarbon length of aliphatic alcohol has a maximum at the extraction from sulphuric medium.

The influence of SAS addition on the extraction of Zr and Hf by solutions of TBP in toluene from different media has also been investigated. Two systems were considered: the system in which zirconium is preferably extracted (extraction from nitric solutions) and the system in which hafnium is preferably extracted (extraction in the presence of NCS<sup>-</sup> anion). The enhancement of extractability in the presence of alcohol is greater for Hf. In the extraction system when zirconium and hafnium are extracted from nitric medium by TBP, the increase of metal distribution coefficients is more obvious for Hf, the selectivity of metal extraction in the presence of alcohol decreases as compared with the systems without surfactant. But the

selectivity of the process can be considerably increased by surfactant addition to the system with the  $\text{NCS}^-$  anion, where Hf is preferably extracted (Table 3).

Analysis of the data of Table 3 shows that the increase of ratio  $D_{\text{Hf}} / D_{\text{Zr}}$  depends on the hydrocarbon length of the added alcohol and on the composition of aqueous phase.

*Table 3. Effect of surfactant additions on the extractability of Zr and Hf by TBP in the presence of  $\text{CNS}^-$  - anions.*

Aqueous phase:  $[\text{Me}] = 0.075 \text{ mol/L}$ ;  $[\text{HCl}] / [\text{MeO}_2] ([\text{H}_2\text{SO}_4] / [\text{MeO}_2]) = 2.0$ ;  $[\text{NH}_4\text{CNS}] = 100 \text{ g/L}$ .

Organic phase: [TBP] = 1.46 mol/L in toluene.

## CONCLUSIONS

The increase in the selectivity of metal extraction in the presence of SAS can be obtained under the definite conditions. The selectivity of metal extraction depends on the aqueous phase composition, pH, nature and content of added surfactant, and on the nature of extracted metals. The study of the kinetics of metal extraction indicated that the mass transfer of individual metals took place at different rates when the micellar mechanism of extraction occurred. So, at these conditions the dynamic separation of metals could be possible.

# MICELLAR MECHANISM PECULIARITIES OF METAL EXTRACTION BY ORGANOPHOSPHORUS EXTRACTANTS IN THE PRESENCE OF SURFACTANT

Oxana A. Sinegribova and Ol'ga V. Muraviova

D. Mendeleyev University of Chemical Technology of Russia, Moscow, Russia

The main focus of the present work is the study of surfactant's influence on the metal loading of the extractant for extraction of different metals by organophosphorus extractants. It was found that the addition of co-surfactant to the extraction system could change the metal loading of the extractant. The isotherms of extraction of calcium, yttrium and zirconium from different medium were obtained using n-butanol or n-octanol as the example of the added surfactant. It was shown that in the presence of surfactant in the extraction system, the metal loading of HDEHP and TBP increased significantly as compared with the extraction process without surfactant. The metal loading of extractant depends on the surfactant amount and on the conditions of the extraction.

## INTRODUCTION

The conception of micellar mechanism, which is due to addition of co-surfactant into the extraction system, is one of intensively developing conceptions of the solvent extraction theory. But in general the investigations in this field were carried out with the aim of increasing the distribution coefficients and mass transfer coefficients of metals.

Most extractants are surfactants, which are able to form different types of colloid structures at certain conditions. Such structures can consist of thermodynamically stable aggregates, like micelles, microemulsions, lyotropic liquid crystals, and thermodynamically unstable particles [1]. The structurisation in extraction systems can take place in the bulk and at the interface. The structures formed in extraction systems can influence the parameters of the extraction process: distribution coefficient, separation coefficient, extraction rate, and phase separation rate. The colloidal structures of different types may take a part in the formation of the viscous interfacial films [2].

The parameters of the extraction process can be improved due to micellar mechanisms of metal extraction. But the main attention has been paid to the enhancement of metal distribution coefficients. Due to the addition of surfactant in the extraction system the distribution coefficients of iron [3,4], aluminium [4], cobalt and nickel [5,6] etc. can increase considerably. It was shown that the colloidal formation by Ca, La, and Zr in the presence of aliphatic alcohol changes the distribution coefficients of these metals [7]. The dependence of distribution coefficient on  $\mathbf{U}$ , the molar ratio between the concentrations of n-octanol and HDEHP (di (2-ethylhexyl) phosphoric acid) ( $\mathbf{U}=[\text{n-octanol}]/[\text{HDEHP}]$ ), has a maximum. The value  $\mathbf{U}_{\text{opt}}$  corresponding to the maximum value of the distribution coefficient depends on the nature of extracted metal, nature and concentration of added alcohol and pH.

The change of extraction parameters due to micellar mechanisms has not been studied systematically. In the present work a lot of attention has been paid to the study of surfactant's influence on the metal loading of the extractant for the extraction of different metals by organophosphorus extractants such as HDEHP and tributylphosphate (TBP). The extraction was carried out from sulphuric, nitric and hydrochloric medium. The micellar mechanism of extraction was realised due to the addition of the co-surfactant with low surfactive activity into the extraction system. Ca, Y, Zr were used as extractable metals.

## EXPERIMENTAL

The following substances have been used: HDEHP, TBP, toluene, aliphatic alcohols (from butanol to decanol); nitrates, sulphates and chlorides of Ca, Y and Zr with the content of main material not less than 98 %. The concentration of metals was determined by complexometric titration with EDTA. The content of water in organic phase was determined by Karl Fisher method.

In order to determine the hydrodynamic radius of colloidal aggregates in the organic phase the methods of photon-correlation spectrometry were used. Photon-correlation spectrometer included He-Ne laser with the operation wavelength of the light 632.8 nm, photometer F-221 and correlator "Unicor SP" with 128 high-speed signal processors. Computing program allowed in the real-time mode to calculate the correlation function, using cumulant method [8].

## RESULTS AND DISCUSSION

Figure 1 presents the isotherms of yttrium extraction from hydrochloric medium into toluene solutions of HDEHP at different content of butanol (different values of  $U$ ). The loading capacity of extractant depends on the amount of added alcohol. The maximum loading capacity is achieved at the concentration of alcohol corresponding to the maximum of distribution coefficients  $U = U_{opt}$  ( $U_{opt} = 0.2$ ). In this case the course of isotherm is steep and the loading capacity of extractant increases significantly as compared with the data obtained in the extraction system without butanol. At following increase of the molar ratio butanol/HDEHP the loading capacity decreases.

The loading capacity of extractant in the presence of 1-octanol (at  $U_{opt}$ ) depends on the composition of aqueous phase (Figure 2). The most loading capacity of extractant was observed for the extraction from hydrochloric medium.

It follows from extraction isotherms presented above that by the realization of micellar mechanism the metal capacity of extractant can be increased. The metal loading capacity of HDEHP depends on the nature of added alcohol (Figures 3 and 4). The enhancement of the loading capacity for calcium extraction is higher than for yttrium.

The addition of butanol or octanol in the extraction system containing TBP,  $HNO_3$  and Zr can influence on the metal loading capacity too (Figure 5).

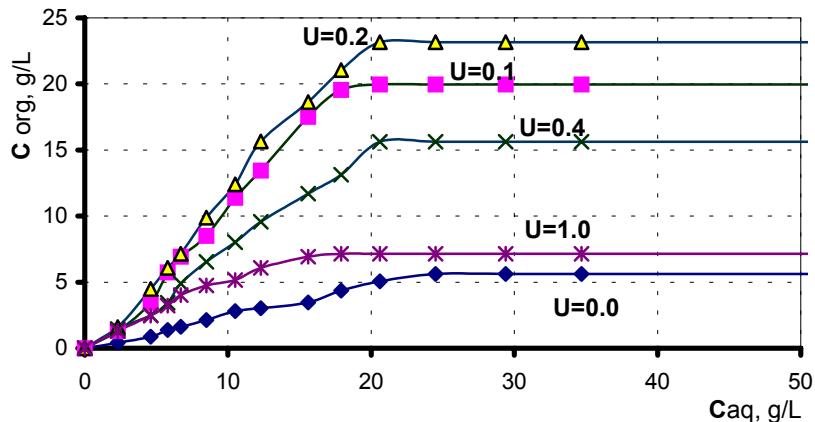

Figure 1. Isotherms of yttrium extraction by HDEHP from hydrochloric medium at the presence of n-butanol. [HDEHP] = 0.2 mol/L in toluene, pH 2.

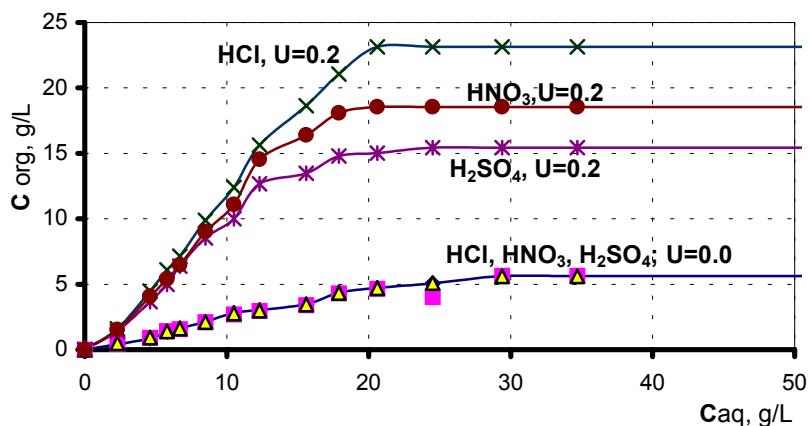

Figure 2. Isotherms of yttrium extraction by HDEHP from different medium at the presence of n-butanol. [HDEHP] = 0.2 mol/L in toluene, pH 2.

The hydrodynamic radius of particles in organic phase was determined for the estimation of the colloidal aggregate size in extraction system  $\text{MeCl}_n/\text{HCl}/\text{HDEHP}/\text{toluene}/\text{n-octanol}$  at the loading of extractant. It was established that in the presence of alcohol the hydrodynamic radius of particles increases considerably as compared with radius of particles without octanol. For example, the value of the hydrodynamic radius for calcium is equal 18.4 nm in the system without alcohol and 159 nm at the concentration of added octanol corresponding to maximum of distribution coefficient of Ca ( $\mathbf{U} = \mathbf{U}_{\text{opt}} = 0.2$ ). The lanthanum radius is equal 23.7 nm without octanol and 223 nm at the concentration of added SAS corresponding to the maximum of distribution coefficient of La ( $\mathbf{U} = \mathbf{U}_{\text{opt}} = 0.1$ ). The measurement of the colloidal particle size in the organic phase indicated that in dependence of added alcohol content the reversed micelles or microemulsion were formed in the organic phase. The obtained data confirmed the supposition about the structural transition in the extraction system containing metal di-2-ethylhexylphosphate and n-octanol [6].

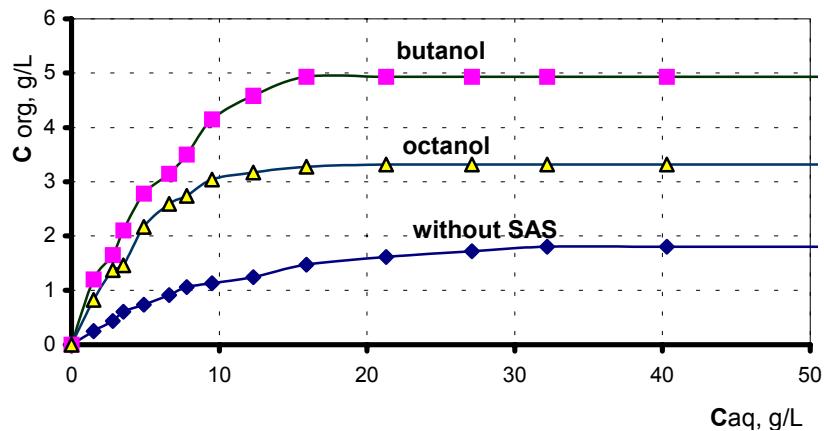

Figure 3. Isotherms of extraction of calcium from hydrochloric medium in the presence of *n*-butanol and *n*-octanol. [HDEHP] = 0.2 mol/L in toluene,  $U = U_{opt}$  (butanol:  $U = 0.3$ ; octanol:  $U = 0.2$ ), pH 2.

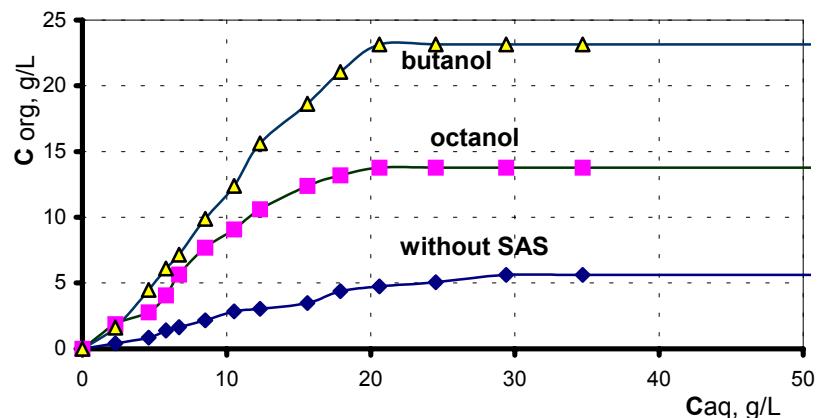

Figure 4. Isotherms of extraction of yttrium from hydrochloric medium in the presence of *n*-butanol and *n*-octanol. [HDEHP] = 0.2 mol/L in toluene,  $U = U_{opt}$  (butanol:  $U = 0.2$ ; octanol:  $U = 0.1$ ), pH 2.

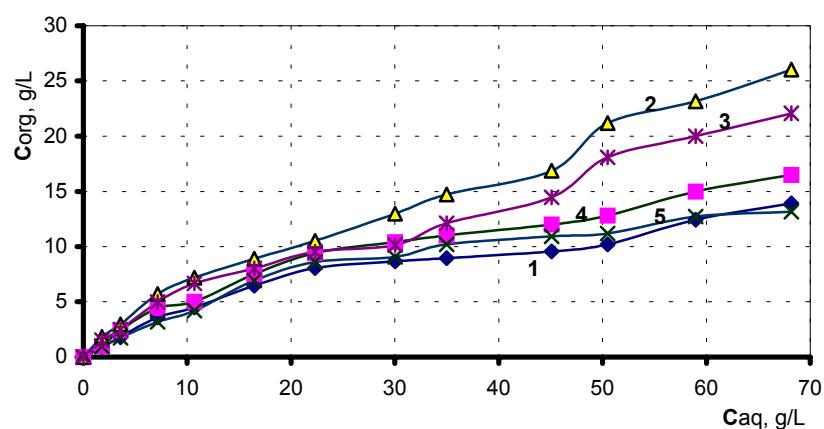

Figure 5. Isotherms of zirconium extraction by TBP from nitric medium in the presence of *n*-butanol and *n*-octanol. [TBP] = 1.46 mol/L in toluene,  $[HNO_3]_{aq} = 4$  mol/L. 1-without alcohol, 2-butanol,  $U = 0.025$ ; 3- butanol,  $U = 0.1$ ; 4- octanol,  $U = 0.025$ ; 5- octanol  $U = 0.1$ .

Table 1 presents the values of water content in the organic phase received at the extraction of yttrium in the presence of different aliphatic alcohols. The concentration of added surfactant corresponds to the maximum of the metal distribution coefficient.

*Table 1. Composition of organic phase at the extraction of yttrium by HDEHP from hydrochloric medium.*

Alcohol	U	D	[Me] <sub>org</sub> , mol/L	[H <sub>2</sub> O] <sub>org</sub> , mol/L	[H <sub>2</sub> O]/[Me]
-	0	0.42	0.0295	0.044	1.48
butanol	0.2	0.55	0.0355	0.212	5.98
isopentanol	0.2	0.53	0.0342	0.157	4.60
hexanol	0.2	0.52	0.0340	0.116	3.42
octanol	0.1	0.50	0.0335	0.062	1.86
decanol	0.1	0.46	0.0315	0.053	1.68

Aqueous phase: [LnCl<sub>3</sub>] = 0.1 mol/L, pH 2.0. Organic phase: [HDEHP] = 0.2 mol/L in toluene

The data of Table 1 indicate that water content is higher in the alcohol presence as compared with system without alcohol. Water content in the organic phase decreases with the rise of the hydrocarbon length of aliphatic alcohol. The water content depends on the composition of initial aqueous phase. At the extraction of lanthanides from hydrochloric medium the water content in the organic phase is higher as compared with the value received at the extraction from nitric medium, presented in Table 2. The water content in the organic phase increases with increase of concentration of added alcohol.

*Table 2. Effect of alcohol concentration on composition of organic phase at the extraction of lanthanum by HDEHP from nitric medium.*

Alcohol	U	D	[Me] <sub>org</sub> , mole/L	[H <sub>2</sub> O] <sub>org</sub> , mole/L	[H <sub>2</sub> O]/[Me]
-	0	0.38	0.0273	0.027	1.34
butanol	0.05	0.41	0.0290	0.078	2.70
	0.1	0.44	0.0305	0.089	2.92
	0.2	0.51	0.0336	0.154	4.61
	0.4	0.43	0.0300	0.164	5.48
	0.6	0.37	0.0270	0.214	7.92
	1.0	0.32	0.0240	0.252	10.51

	0.1	0.43	0.0300	0.051	1.71
	0.2	0.37	0.0271	0.051	1.88
	0.4	0.31	0.0237	0.052	2.19
	0.6	0.28	0.0221	0.057	2.58
	1.0	0.23	0.0186	0.058	3.12

Aqueous phase: [Ln(NO<sub>3</sub>)<sub>3</sub>] = 0.1 mol/L, pH 2.0. Organic phase: [HDEHP] = 0.2 mol/L in toluene

The water content also depends on the nature of extractable metal. Table 3 presents the data of the water content at the extraction of Ca, La and Zr by HDEHP from hydrochloric medium at the presence of n-octanol, where the concentration of added alcohol corresponds to the maximum of the metal distribution coefficients.

*Table 3. Composition of organic phase at the extraction of same metals by HDEHP from hydrochloric medium in the presence of n-octanol.*

Metal	D	U	[Me] <sub>org</sub> , mol/L	[H <sub>2</sub> O] <sub>org</sub> , mol/L	[H <sub>2</sub> O]/[Me]
Ca	1.01	0.2	0.0502	0.380	7.56
La	0.50	0.1	0.0335	0.062	1.86
Zr	1.84	0.025	0.0486	0.075	1.54

Ca: [Me]=0.1 mol/L, pH 2.0; [HDEHP]=0.2 mol/L in toluene

La: [Me]=0.1 mol/L, pH 2.0; [HDEHP]=0.2 mol/L in toluene

Zr: [Me]= 0.075 mol/L, [HCl]= 2.0 mol/L; [HDEHP]=0.4 mol/L in toluene

The analysis of the data of Table 3 shows that the most water content is observed in the system containing calcium di-2-ethylhexylphosphates.

## CONCLUSIONS

It was found that the addition of co-surfactant to the extraction system could change the metal loading of the extractant. In the presence of surfactant in the extraction system, the metal loading of HDEHP and TBP increased as compared with the extraction process without surfactant. The metal loading of extractant depends on the added surfactant amount and on the conditions of the extraction process realisation.

## STRUCTURE-REACTIVITY STUDIES OF SOLVENT EXTRACTANTS IN METAL EXTRACTION

Chengye Yuan and Shusen Li

Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, Shanghai, China

The structure-reactivity relationship of solvent extractants in metal separation was studied both qualitatively and quantitatively. Pearson's HSAB principle is successfully applied to the qualitative prediction and molecular modification of solvent extractants. Molecular orbital calculations are a useful tool to estimate the charge density of the coordination atom or group. Molecular mechanics calculations are good for the evaluation of the steric contribution of the molecules. Based on experimental data a series of multiple regression analyses involving extraction constants and polar and steric parameters were established. Such treatments are helpful for the prediction and design of extractant molecules with high selectivity in cobalt and nickel separation in particular, since the formation of different configurations of coordination compounds plays an important role during the extraction process.

### INTRODUCTION

The technological and economical behavior of extraction systems are dependent on the performance of extractants that are closely related to the chemical structure of the latter. Consequently, structure reactivity studies of solvent extractants can, in very practical terms, contribute both to the discovery of new selective extractants and to the progress of extraction chemistry in general. Both qualitative and quantitative examinations of structure-reactivity relationship of extractants are helpful for the design and selection of extractants.

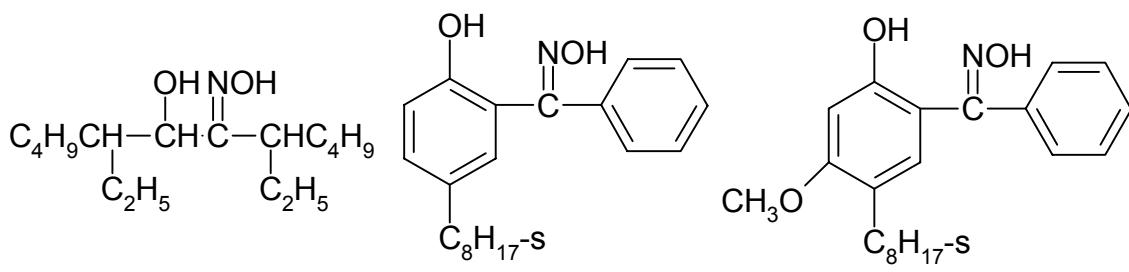

### QUALITATIVE STRUCTURE-REACTIVITY STUDIES

Metal extraction may be considered simply as the replacement reaction of water molecule in the hydration shells of metallic ions in aqueous solution by an organic ligand (extractant):

Both metal ions (acceptor) and coordinating atoms (donor) are classified as either hard, soft or borderline acids and bases according to Pearson's scale.

Oxygen-containing ligands, including ether, alcohol, carboxylate, phosphate and phosphonates are referred to hard bases, which prefer to coordinate with hard acids, such as lanthanides, actinides, niobium, tantalum, zirconium or hafnium. As soft bases, sulfur-containing ligand (thioether, thiourea, thiocarboxylate, or dithiophosphate) prefer to combine with soft acids such as copper. It is therefore not difficult to rationalize the fact that LIX 63 was replaced by LIX 64 for copper extraction in acidic medium.

LIX 63 (N-509)

LIX 64 (N-510)

N-530

Since in the molecule LIX 63, both OH and N–OH are coordination groups in which O is a hard base, while Cu<sup>++</sup> is a soft acid. Consequently as an aliphatic hydroxyoxime, LIX 63 is poor in copper extraction. However, the hardness of the donor atoms can be modified by the inductive or conjugative effect of the neighboring atom and group. LIX 64 being an aromatic hydroxyoxime, the conjugation effect of benzene ring decreases the hardness of the base and the extraction ability of copper will be enhanced accordingly. Moreover, introduction of additional electron-withdrawing groups (NO<sub>2</sub>, Cl) makes the molecule more powerful in copper extraction. Unfortunately, in such case, the resulting loaded organic phase turns out to have poor stripping ability towarding the back extraction process. It is very interesting to note that the compound N–530, chemically known as *p*–octyl–*m*–methoxyl benzophenone oxime, is an excellent copper extractant. Structurally it is understandable, located on the *meta*-position, the methoxyl group possesses electron-withdrawing ability that makes the phenolic OH more acidic. On the other hand, the methoxyl group is a well-known electron-donating group toward the *para*–substituent, that results the higher electron density on the oximido nitrogen atom. Consequently, N–530 exhibits high extraction ability and loading capacity in copper extraction. Beside these, the copper extraction kinetics of this reagent are quite good. As an empirical principle, HSAB is therefore not only useful for the prediction but also helpful for the design of extractants.

Molecular orbital calculations were applied by us to estimating the charge density and bond order of hydroxyoxime-type extractants (Table 1). The calculation results are fully consistent with the experimental data [1,2] and theoretical predictions. Unfortunately, such treatment is not in a position to evaluate the contribution of steric effect of substituents that are very important in solvent extraction.

Concerning the quantitative structure activity relationship (QSAR) studies, we have demonstrated that the reactivity of solvent extractants is dependent on the polar and steric effect of the substituent as well as solubility contributions as represented by the equation:

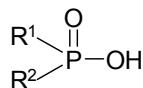

$$\log K_{\text{ex}} = \log K_{\text{ex}_0} + \rho \sum \sigma + \delta \sum E_s + k \sum C$$

Nevertheless, our equation consisted of three most important structural effects of substituents, since solvent extraction is a multiple component equilibrium process between two heterogeneous phases. Moreover, the contribution of the configuration of extracted species, dimer constant of extractants and influence of diluents are not included in such treatment. Consequently this equation can only be regarded as an approximate approach.

Table 1. Molecular orbital calculation of hydroxyoxime extractants.

As shown by us, in structure-reactivity studies of organophosphorus compounds, the classic Taft constants could be used as a substituent polar parameter. It is not necessary to have another set of polar parameters specific for organophosphorus compounds [5]. There are no suitable parameters for long-chain alkyl or alkoxy groups that are critical for the extractant molecule. Based on the measurement of pKa values of mono-basic phosphorus acids, we estimated a series of alkyl and alkoxy groups directed linked to phosphorus atom and showed that these parameters are related to "Group Connectivity" [6] and chemical properties including IR,  $^{31}\text{P}$  NMR as well as hydrolytic constant in alkaline hydrolysis [7]. In this study, it is important to establish steric parameters for substituents, of extractants. We used Charton's v parameters, that are based on the Van der Waals radius between atoms, as the measure for the steric effect. During the nickel and cobalt extraction, formation of extraction species with different configurations takes place. Cobalt forms complexes with tetrahedral configuration, while nickel gives a complex with square planar configuration. The influence of the steric effect on these two configurations is significant remarkable. Therefore we introduce  $\Sigma E_{\text{ex}}^{\text{Co}}$  and  $\Sigma E_{\text{PA}}^{\text{Ni}}$  parameters for cobalt and nickel extraction correspondingly.

$$\log K_{\text{ex}}^{\text{Co}} = 0.86 \sum \sigma^p + 1.00 \sum E_{\text{PA}}^{\text{Co}} - 3.17$$

$$\log K_{\text{ex}}^{\text{Ni}} = 3.03 \sum \sigma^p + 1.00 \sum E_{\text{PA}}^{\text{Ni}} + 5.86$$

In the above formulae,  $\Sigma E_{\text{PA}}^{\text{Co}}$  and  $\Sigma E_{\text{PA}}^{\text{Ni}}$  could be used, as we expected, as the steric parameter for metal extraction with related configurations (Table 2).

## COLLOID STRUCTURES FORMED IN EXTRACTION SYSTEMS WITH ORGANOPHOSPHORUS EXTRACTANTS

E.V. Yurtov and N.M. Murashova

Mendeleyev University of Chemical Technology of Russia, Moscow, Russia

Colloid structures, such as organogels, microemulsions, liquid crystals and amorphous sediments, found in extraction systems with organophosphorus extractants are discussed. Micellar organogels, microemulsions and liquid crystals are shown in the system sodium di(2-ethylhexyl)phosphate/decane/water. The formation of crystalline organogels and amorphous sediments was studied in the systems di(2-ethylhexyl)phosphoric acid/copper hydroxide/ hydrocarbon/water and di(2-ethylhexyl)phosphoric acid/neodymium hydroxide/ decane/water. Concentration regions and rheological properties of the structures were investigated. Properties of emulsions, stabilized by disperse structures of copper and neodymium di(2-ethylhexyl)phosphates were studied. Some ways of prevention of disperse structures formation in systems with organophosphorus extractants are discussed.

### INTRODUCTION

Colloid structure formation in extraction systems, near the interface and in the bulk, leads to interfacial films and crud formation. It can be an undesirable phenomenon because it can result in extraction rate reduction and phase separation difficulty, which impedes performance of the extraction equipment. On the other hand, the processes of structure transformation can increase the interfacial mass-transfer. The structures may arise from the formation of surface-active or low-soluble compounds during the extraction process. Such colloid structures, as reverse micelles and microemulsions, are known in extraction systems with organophosphorus extractants [1-5]. Formation and properties of different colloid structures in the extraction systems with di-(2-ethylhexyl)phosphoric acid (DEHPA) and alkali, non-ferrous and rare-earth metals were investigated in this contribution.

The formation of crud, a highly viscous and stable disperse structure, which looks like a deposit, paste, emulsion or gel at the interface between two partially settled phases, is known for a number of extraction systems, containing, for example, the organophosphorus compounds TBP and dibutylphosphoric acid. Investigation of colloid structure formation in the extraction systems gives the possibility of clarifying the behavior and properties of extraction systems and to predict the formation of interfacial films and crud in technology processes.

## EXPERIMENTAL

The following extractants were used in this work: di(2-ethylhexyl)phosphoric acid (DEHPA) from Merck (Germany) with the main substance content more than 98 % and DEHPA of technical grade from OAO Himprom (Russia), which contained 66.0 % di(2-ethylhexyl)-phosphoric and 19.5 % mono-(2-ethylhexyl)phosphoric acid. Copper and rare-earth elements' hydroxides were obtained by the reaction of NaOH with copper sulfate or rare-earth metal nitrate solution.

The samples were prepared by mixing DEHPA organic solution with the required quantity of water and the hydroxide. Emulsions were obtained by means of water phase (water + hydroxide precipitate) and organic phase (DEHPA solution) mixing for 2 min with stirrer (rotation rate  $3000\text{ min}^{-1}$ ). The ratio of water and organic phase volume was 3:2). Emulsion stability was determined by the method of phase separation in centrifuge (at acceleration 90 g). A rotation viscometer, Rhoetest 2, was used for viscosity measurement.

## RESULTS AND DISCUSSION

### Micellar Organogels, Microemulsions and Liquid Crystals

A number of extractants and extracted compounds including DEHPA and its salts can form disperse structures, typical for surfactants are normal and reverse micelles, micellar organogels, microemulsions, vesicles, liquid crystals. Di(2-ethylhexyl)phosphates are able to form reverse micelles (spherical in the systems DEHPNa/benzene/water [1] and DEHPNa/toluene/water [5], and giant cylindrical in the systems cobalt di(2-ethylhexyl)phosphate/heptane/water [2] and DEHPNa solution in dry heptane [4]). When the concentration of the surfactant exceeds a critical value, long and flexible cylindrical micelles can entangle, forming the micellar organogel structure. The gelation is accompanied by viscosity growth. Viscous and thixotropic (*i.e.*, able to restore the structure after mechanical destruction) micellar organogels of DEHPNa arise in the system DEHPA/NaOH/decane/water both with pure and technical DEHPA. The organogels in the system with technical DEHPA form only at the excess of NaOH ( $[\text{NaOH}]/[\text{DEHPA}] = 1.4 - 1.8$ ) [6].

Salts of di(2-ethylhexyl)phosphoric acid are able to form bilayer structures: vesicles and lamellar liquid crystals. For example, addition of small amount of  $\text{CCl}_4$  to crystalline di(2-ethylhexyl) phosphates of rare-earth metals leads to the formation of anisotropic and viscous liquid crystals [7]. Liquid crystals are formed in the system DEHPNa/decane/water in the region of high concentrations (90% mass and more) of DEHPNa. The picture of DEHPNa liquid crystal under a polarizing microscope is shown in Figure 1.

Microemulsion formation is possible in DEHPA salts systems, both containing aliphatic alcohols and without cosurfactants. The formation of microemulsion of W/O (water-in-oil) type was described in the extraction system: water solution of NaOH or  $\text{NH}_4\text{OH}$ /DEHPA and sec- octyl alcohol solution in kerosene [3]. Bicontinuous and O/W (oil-in-water) microemulsions are found to exist in the ternary system DEHPNa/hexane/water [4].

The peculiarity of the DEHPA/NaOH/decane/water system is the possibility of the formation of several colloid structures, such as reverse micelles, micellar organogels, microemulsions and liquid crystals. These structures can coexist with each other and with DEHPNa solution in water and in decane. The regions of different phase equilibria in the system DEHPA (technical)/NaOH/decane/water are shown in Figure 2. Similar regions of phase equilibria were obtained in the system with pure DEHPA.

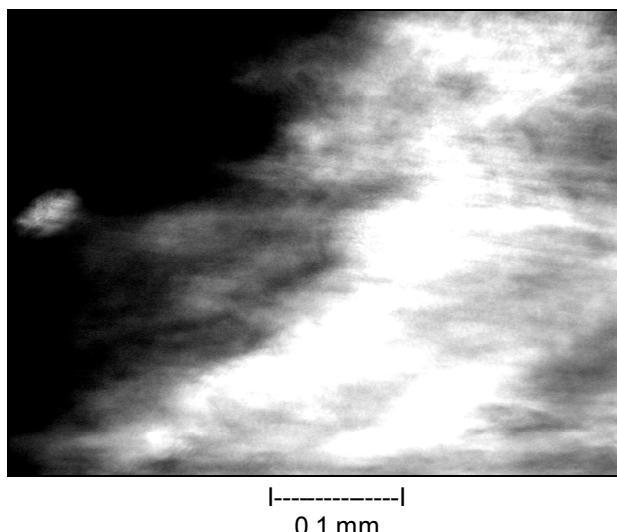

Figure 1. The picture under a polarizing microscope of the liquid crystal in the system DEHPNa/decane/water.  $[DEHPNa] = 2.7 \text{ mol/l}$ ,  $W = [H_2O]/[DEHPNa] = 16.0$ .

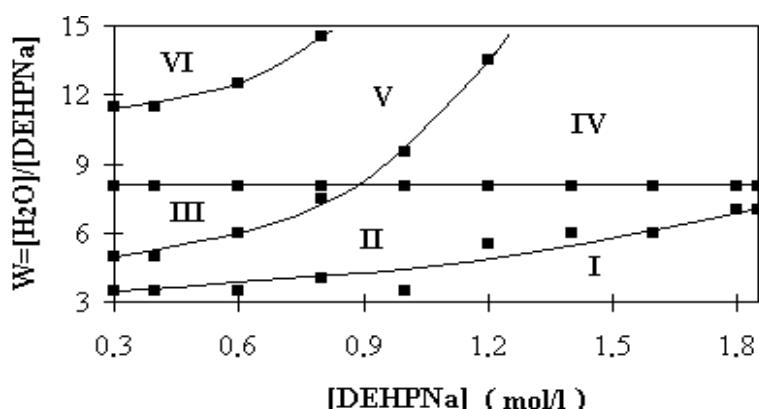

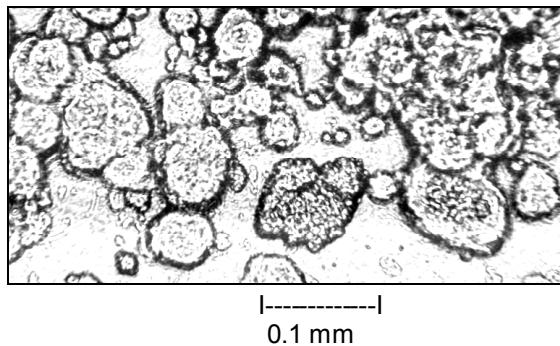

Figure 2. Phase equilibria in the system DEHPA (technical)/NaOH/decane/water at 20 °C.  $[NaOH]/[DEHPA] = 1.5$ . I - spherical DEHPNa micelles solution; II - micellar organogel; III - DEHPNa organic solution/microemulsion; IV - microemulsion/liquid crystal; V - DEHPNa organic solution/microemulsion/liquid crystal; VI - DEHPNa organic solution/liquid crystal.

The considered disperse structures of DEHPNa possess different values of viscosity. At low shear rate ( $1\text{-}10 \text{ s}^{-1}$ ) and 20 °C viscosity of liquid crystals is in the range  $10^1$  to  $10^3 \text{ Pa.s}$  (their viscosity strongly depends upon water concentration), viscosity of micellar organogels is  $10^0$  to  $10^{-1} \text{ Pa.s}$ , microemulsions are  $10^{-1}$  to  $10^{-2} \text{ Pa.s}$ , while the viscosity of spherical micelle solutions is close to the viscosity of the solvent. Viscous disperse structures such as liquid crystals and, possibly, micellar organogels can take part in crud formation.

### Crystalline Organogels and Amorphous Sediments

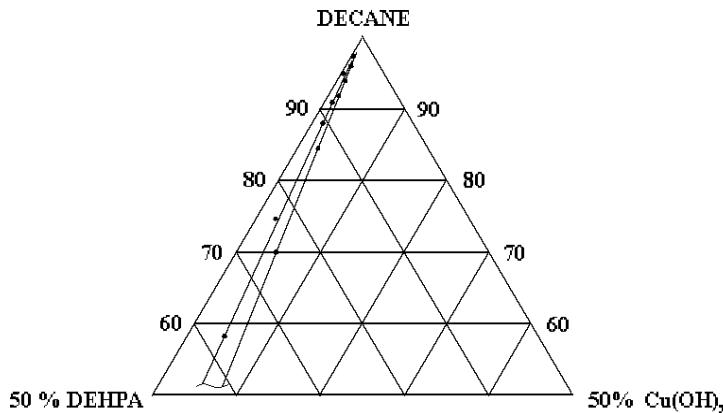

Beside the disperse structures arising due to the association of organic-soluble extractants and extracted compounds, formation of colloid structures of low-soluble compounds is possible. For example, the formation of water gels in extraction systems containing organophosphorus extractants (TBP and dibutylphosphoric acids) and such elements as Si and Zr is known [8-10].

It was found that basic copper di(2-ethylhexyl)phosphate ( $\text{Cu(OH)DEHP}$ ) formed a gel in organic phase (organogel). Because little crystals build the structure of this gel, it can be called crystalline organogel. A picture of the crystalline organogel in the system DEHPA (technical)/ $\text{Cu(OH)}_2$ /decane/water obtained under an optical microscope is shown in Figure 3. The organogels of  $\text{Cu(OH)DEHP}$  are blue, transparent or slightly cloud, they are irreversibly destroyed by mechanical stress.

*Figure 3. Picture under an optical microscope of the organogel in the system DEHPA (technical)/ $\text{Cu(OH)}_2$ /decane/water. [DEHPA] = 0.05 mol/l; [DEHPA]/[Cu] = 1.4.*

The region of gelation in the system DEHPA (technical)/ $\text{Cu(OH)}_2$ /decane/water is shown in Figure 4. Water, present in the system and arising from the hydroxide neutralization, separates from the organic phase (organogel), so the water phase is not considered in the diagram. The gelation takes place in narrow diapason of the acid and the base concentration ratio. If the ratio of the acid and the base concentrations exceeds the region of the gelation (at the acid excess), organic solution is formed. At the base excess crystalline sediment arises. The limits of the gelation of basic copper di(2-ethylhexyl)phosphate slightly alter in different hydrocarbon solvents. The values of the gelation limits in decane, hexane and toluene are presented in Table 1. Gelation is also possible in other organic solvents, for example, in decanol.

*Figure 4. The region of the crystalline organogel existence at 20 °C. DEHPA technical.*

*Table 1. The gelation limits in the systems DEHPA (technical)/ $\text{Cu(OH)}_2$ /organic solvent/ water at 20 °C.*

Solvent	Minimum concentration of DEHPA, necessary for the gelation, mol/l	Ratio of molar concentrations of the acid and the base ([DEHPA] : [ $\text{Cu(OH)}_2$ ])	
		Lower limit of gelation	Upper limit of gelation
decane	0.025	1.0 : 1.0	1.6 : 1.0
hexane	0.010	1.2 : 1.0	1.8 : 1.0
toluene	0.050	1.2 : 1.0	2.2 : 1.0

Amorphous sediments, consisting of basic di(2-ethylhexyl)phosphate and organic solvent, arise in the systems DEHPA (technical)/lanthanide hydroxides/decane/water in the determined region of the ratio of the acid and the base concentrations. In the system with  $\text{Nd}(\text{OH})_3$  the formation of bulk amorphous sediment is found in the region  $[\text{DEHPA}]/[\text{Nd}(\text{OH})_3] \leq 1.5$  (concentration of technical DEHPA: 0.3 mol/l). This region corresponds to the existence of mono-substituted basic salt  $\text{Nd}(\text{OH})_2\text{DEHP}$ . Compact crystalline sediments and organic solutions are observed at higher  $[\text{DEHPA}]/[\text{Nd}(\text{OH})_3]$  values. Colloid structure formation in the systems with other lanthanides (Ho, Yb, Dy, Sm) is found to be similar.

### Emulsion Stabilization

In the region of the amorphous sediments existence in the system DEHPA (technical)/ $\text{Nd}(\text{OH})_3$ /decane/water stable emulsions can be obtained. The emulsions can stay at ambient conditions more than six months without visible change. Their separation in a centrifugal field was studied. Curves of the organic phase separation for the emulsions with different  $[\text{DEHPA}]/[\text{Nd}(\text{OH})_3]$  values are shown in Figure 5. Unlike stable emulsions (curve 1), arising in the region of the amorphous sediment existence, emulsions obtained in the region of the crystalline sediment existence, are unstable (curve 3).

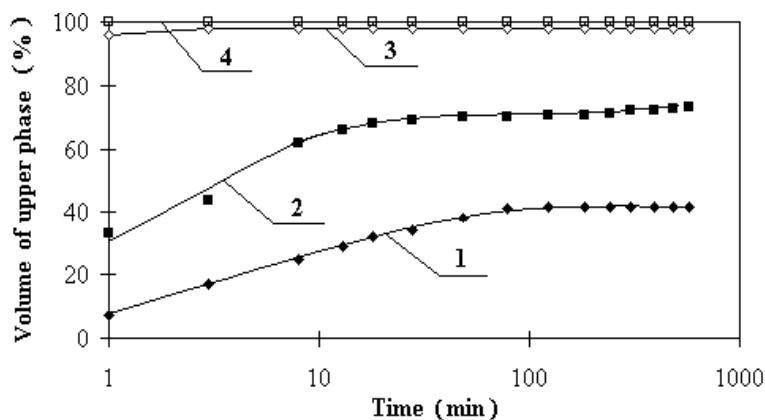

Figure 5. Separation of the emulsions stabilized by copper and neodymium di(2-ethylhexyl)-phosphates in a centrifugal field 90 g.  $[\text{DEHPA}] = 0.3 \text{ mol/l}$ ; DEHPA - technical  
**1** -  $[\text{DEHPA}]/[\text{Nd}(\text{OH})_3] = 1.2$ ; **2** -  $[\text{DEHPA}]/[\text{Cu}(\text{OH})_2] = 1.2$ ; **3** -  $[\text{DEHPA}]/[\text{Nd}(\text{OH})_3] = 2.0$ ;  
**4** -  $[\text{DEHPA}]/[\text{Nd}(\text{OH})_3] = 2.0$ .

Stability of emulsions in the system DEHPA (technical)/ $\text{Cu}(\text{OH})_2$ /decane/water changes with increase of the ratio of the acid and the base concentrations in the same manner. Stable emulsions can be prepared in the system at  $1.0 < [\text{DEHPA}]/[\text{Cu}(\text{OH})_2] < 1.6$ , i.e., in the region of  $\text{Cu}(\text{OH})_2$  and DEHPA concentration ratio, corresponding to the crystalline organogel formation. The curves of the organic phase separation for the emulsions in the system DEHPA (technical)/ $\text{Cu}(\text{OH})_2$ /decane/water within the gelation region (curve 2) and outside it (curve 4) are presented in Figure 5. In the systems, containing micellar organogel, microemulsion or liquid crystal of DEHPNa the formation of stable emulsions was not found.

Knowledge of the regions of existence and properties of disperse structures which can take part in crud formation permits recommending methods of prevention of undesirable structurization in extraction systems.

### Prevention of Crud Formation

Methods which prevents formation of a colloid structure of one certain type can not prevent a structure of another type arising. For example, octanol addition (1 mol of the alcohol per 1 mol of DEHPA salt) prevents the formation of DEHPNa micellar organogel, but this method is not effective in the case of crystalline organogel of  $\text{Cu}(\text{OH})\text{DEHP}$ .

The common recommendation for reduction of crud formation is to carry out the extraction process far from the region of the corresponding structure formation. For example, the probability of formation of micellar organogels, crystalline organogels and amorphous sediments will decrease at low concentrations of extracted compound, at great excess of the extractant and at low pH values in water phase.

Purification of the extractant can prevent crud formation. For example, purification of TBP from radiolysis products decreases crud formation [10]. The removal of mono(2-ethylhexyl)phosphoric acid from technical DEHPA by alkaline washing results in the narrowing of the gelation region in the system DEHPA/Cu(OH)<sub>2</sub>/decane/water from [DEHPA]/[Cu(OH)<sub>2</sub>] = 1.0 - 1.6 (without purification) to [DEHPA]/[Cu(OH)<sub>2</sub>] = 1.6 - 1.8 (after washing).

## CONCLUSIONS

Various colloid structures can take part in crud formation in different extraction systems:

- water gels (arising, for example, in the systems with organophosphorus compounds and such elements, as Si and Zr [8-10] ;
- micellar organogels (formed, for example, by sodium di(2-ethylhexyl)phosphate);
- crystalline organogels (as in the case of basic di(2-ethylhexyl)phosphate of copper);
- bulk amorphous sediments (as basic di-(2-ethylhexyl)phosphates of lanthanides);
- emulsions, stabilized by water gels or crystalline organogels or amorphous sediments.

The regions of existence and properties of these disperse structures are different, so various methods are necessary to prevent their formation.

# A STRUCTURE PARAMETER CHARACTERIZING THE STERIC EFFECT OF ORGANOPHOSPHOROUS ACID EXTRACTANTS

Tun Zhu

Institute of Chemical Metallurgy, Chinese Academy of Sciences, Beijing, P.R. China

It is suggested in the present paper to take the angle between the two substituting groups and the phosphorus atom,  $\Delta RPR'$  as the steric parameter of the extractants. For extracted coordination compounds with an octahedral configuration, the substituting groups from two coordinated organophosphorous acids are approximately in the same plane, thus the larger the angle  $\Delta RPR'$ , the larger the interaction between them, resulting in a greater steric effect. In a tetrahedral configuration, the substituting groups are located in two perpendicular planes, and the interaction is much weaker.

## INTRODUCTION

Steric effects have great influence on the selectivity of organophosphorous acid (OPA) extractants. Extractants with stronger steric effects usually have better separation abilities for metal ions with similar properties. Steric hindrance has been adopted by many authors as a means of interpreting the extraction ability of organophosphorous acids, but there is a lack of a clear description of the steric hindrance of these compounds from structural point of view. Usually it is believed that for extractants with the same structure, the steric effect is decided by the bulk and the degree of branching of the substituting groups in the compounds.

Systematic studies on alkylphosphorous acids (AOPA) have been done by Yuan and coworkers [1]. An empirical equation relating the extraction equilibrium constants and the polarity and the steric hindrance of the substituents in the AOPA has been established, based on the regression of the solvent extraction constants of cobalt and nickel extracted by more than twenty AOPA. For one AOPA there are two different steric parameters for cobalt and nickel, respectively. These parameters are not factors characterizing the structure of the extractant molecule itself, but rather coefficients denoting the selectivity of this reagent for a specific metal, although it may relate to the steric effect of the substituting group in the compound.

## EXPERIMENTAL

### Calculation Molecular Parameters

Molecular parameters of some AOPA were calculated by use the Sybyl programm of the molecular mechanics(force field) program, produced by Tripol Company and the Gasteiger-Marsili-Hückel method.

## RESULTS AND DISCUSSION

### Stability Energies of $\text{Co}^{2+}$ and $\text{Ni}^{2+}$

Of the seven d electrons in the weak octahedral ligand field of cobaltous ions, five electrons are in the lower energy  $t_{2g}$  orbital, four of which are paired, and the other two are in the higher energy  $e_g$  orbital and unpaired. In a tetrahedral field, on the other hand, four are paired in the lower energy  $e_g$  orbital and the remaining three unpaired in  $t_{2g}$ . Strong interactions between the ligands, such as steric or electronic effects, will weaken the formation of the higher coordination number octahedral coordination compound and favor the tetrahedral complex. Cobalt(II) forms a large number of tetrahedral coordination compounds compared to the other first row transition metal ions. This is in accordance with the fact that for  $d^7 \text{ Co}^{2+}$  the ligand field stabilization energies have the least adverse effect on the tetrahedral field relative to the octahedral field as compared to any other d-transition element ions with one to nine d electrons.

For the  $d^8 \text{ Ni}^{2+}$  ion in an octahedral coordination environment, six electrons are paired in the lower energy  $t_{2g}$  orbital and two unpaired in the  $e_g$  orbital, whereas in tetrahedral coordination compounds, four electrons remain paired in the lower energy  $e_g$  orbital with the other four in  $t_{2g}$ , of which two are paired. It will be noted that compared with Co(II), Ni(II) has one more electron in the low energy orbital (although it is paired) in a weak octahedral coordination environment, and in the tetrahedral symmetry one more electron (paired) in the higher energy orbital. The difference in the electronic configuration offers much more stabilization energy for Ni(II) in octahedral coordination compounds than the tetrahedral ones. This explains the existence of a much larger number of Ni(II) octahedral coordination compounds than those having other configurations. The different behaviour of Co(II) and Ni(II) in forming coordination compounds provides a chemical basis for the separation of the two metals.

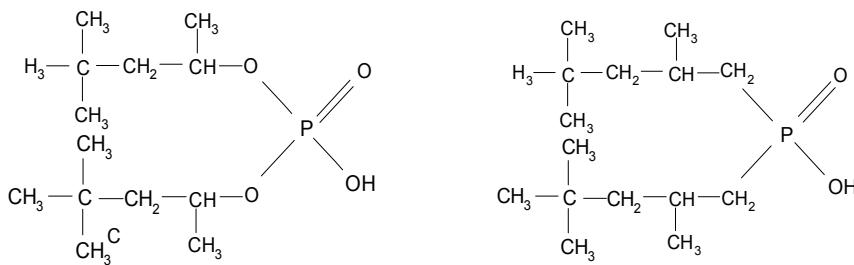

The sulphate system occupies the most important place in the hydrometallurgy of cobalt and nickel. In sulphate solution cobalt and nickel exist as divalent hydrated ions, with solvent extraction of cobalt and nickel usually taking place through cation exchange, and consequently, acidic extractants, particularly AOPA are mostly widely used. These AOPA are di(2-ethylhexyl)phosphoric acid (DEHPA), 2-ethylhexyl-phosphonic acid mono-2-ethylhexyl ester (EH(EH)PA) and di(2,4,4-trimethylpentyl)phosphinic acid (DTMPPA, Cyanex 272). The separation ability of the above reagents for cobalt over nickel increases along the sequence, it is believed, because of increasing the steric hindrance.

### The Distance between Substituting Groups and The Phosphorus Atom

For the same kind of alkylphosphorous acids, it is obvious that the larger the bulk of the component groups the higher is the steric hindrance. In addition, Danesi and coworkers believed that as an oxyalkyl group is substituted by an alkyl one, the distance between the group and the phosphorus atom was shortened due to the elimination of the oxygen atom, and thus the steric hindrance was increased [2].

Some data quoted in that work [2] are not in harmony with this statement. One such example is the extraction ability of di(1,3,3-trimethylbutyl)phosphoric acid (denoted as I) and di(2,4,4-trimethyl pentyl)phosphinic acid (as II see Figure 1) for cobalt and nickel.

The extraction equilibrium constants,  $K_{\text{ex}}$  of Co(II) and Ni(II) as extracted with I were,  $5.6 \times 10^{-6}$  and  $1.5 \times 10^{-6}$ , and with II were  $6.0 \times 10^{-8}$  and  $1.6 \times 10^{-10}$ , respectively for formation of  $\text{CoA}_2\text{.H}_2\text{A}_2$ , and  $\text{NiA}_2\text{.2H}_2\text{A}_2$ . The ratio  $K_{\text{ex(Co)}}/K_{\text{ex(Ni)}}$  is 3.7 and  $3.8 \times 10^2$ , for I and II, respectively, and thus the separation factor of II over I is greater than  $10^2$ . If one takes account of the steric hindrance only in terms of bulk of the substituting groups and their distance from the central ion in the AOPA, these two acids should have similar steric effects.

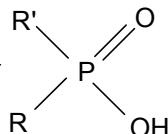

*Figure 1. Di(1,3,3-trimethylbutyl)phosphoric acid (I) and di(2,4,4-trimethyl pentyl) phosphinic acid (II).*

The covalent radii of O and C are 74pm and 77.2pm, respectively. The bond length of P-O on average is 162 pm and that of P-C is 185 pm, respectively, therefore, the distance of the bulk of the substituents from the central ion in complexes is only marginally different, and the bulk of the two substituents are also similar. The other factors determining the value of  $K_{ex}$ , such as partition coefficients of the extractants and the extracted species are also not expected to be so different. The large difference in separation factor of cobalt over nickel, or the ease of conversion of the octahedral to the tetrahedral cobalt complex in case II should not be attributed to the distance between the central ion and the substituting groups. In order to obtain a sound explanation for this large difference in the extraction abilities of I and II, a close look at the structure of the compounds is necessary.

### The Bond Angle and The Steric Hindrance

OPA's coordinate either their two oxygen atoms to the central ion or one to the central ion, with the second forming a hydrogen bond with another OPA molecule. However, the ligand cannot

rotate around the ligand-central ion  $\sigma$  bond freely. The bulk of the substituents and the angle  $\Delta RPR'$ , where R and R' represent the alkyl substituents, are the main factors governing the steric hindrance of the acid molecules. The angle  $\Delta RPR'$ , the dihedral angle between the R-P-R' plane and the O-P-O' plane of the acid, the electrostatic point charge of the P and the two O atoms of the aforementioned three commercial AOPA have been calculated by use of the Sybyl program. Some of the results obtained are shown in Table 1.

*Table 1.  $\Delta RPR'$ , dihedral angles and charges of atoms in alkylphosphorous acids,  $R(R')P(O')OH$ .*

Extractants	Groups*		$\Delta RPR'$ degree	Dihedral angle degree	charge		
	R	R'			P	O	O'
DEHPA	OEH	OEH	104.68	90.18	0.161	-0.345	-0.772
EH(EH)PA	OEH	EH	115.65	91.19	0.028	-0.367	-0.794
DTMPAA	TMP	TMP	120.09	89.48	0.092	-0.393	-0.814

\*OEH = oxy-2-ethylhexyl, EH = 2-ethylhexyl, TMP=2,4,4-trimethylpentyl.

It can be seen from the calculation results that the direct bonding of an alkyl group to P, increases the angle  $\Delta RPR'$  and the charges on the two O atoms, but hardly affects the value of the dihedral angles, which are all nearly  $90^\circ$ .

When an OPA molecule coordinates to a metal ion, these parameters calculated in the free state will certainly undergo change, but some inferences may be deduced from the calculated results.

- (1) When two such acid molecules coordinate to the central ion in a square planar configuration (*i.e.*, in an octahedral configuration), all the four substituting groups extend into a space nearly vertical to the oxygen coordination plane (*i.e.*, X-Y plane). The hindrance along z and -z direction is expected to rise with an increase of the  $\Delta RPR'$  angle as well as the bulk of R and R'.
- (2) When two such acid molecules coordinate with tetrahedral symmetry, the substituting groups extend into two different spaces, the central planes of which are almost perpendicular, then the interaction between the substituted groups should be very weak, no matter what the  $\Delta RPR'$  is.

### **Configuration Change of Extract and Steric Hindrance**

In the literature [1,2] the extraction constant  $K_{ex}$  is taken as a measure of steric hindrance, but  $K_{ex}$  does not only reflect steric hindrance, it is also dependent on the acidity of the OPA, the partition coefficient of the reagent itself and the extracted metal complexes, and even on some other factors. For the extraction of cobalt and nickel the steric effect of the OPA mainly causes a change in the configuration of the cobalt extract. Therefore, the equilibrium between the tetrahedral and octahedral configuration complexes could much more directly reflect the steric effect of the extractants. Data in Table 2, which were determined earlier in this laboratory [3,4], show that the trend of  $\Delta RPR'$  is in good accord with the thermodynamic parameters of the configuration equilibrium of the cobalt tetrahedral and octahedral extracts. In a neutral octahedral configuration, four oxygen atoms from two coordinated AOPA are in the same plane (*i.e.*, X-Y plane), the other two neutral ligands, which usually are water molecules, are aligned alone the Z axis. The IR spectra of nickel extracts demonstrate a strong water absorption peak, which reveals a high water content in the extract [3,4].

As aforementioned, for the  $d^7$   $Co^{2+}$  the ligand field stabilization energies have the least adverse effect on the tetrahedral field relative to octahedral field. The value of  $\Delta G^\circ$  for the equilibrium between the octahedral and tetrahedral configuration decreases with increasing  $\Delta RPR'$  value, while the value of  $\Delta S^\circ$  increased significantly, and so the latter may reflect more directly the effect of the steric hindrance.

*Table 2.  $\Delta RPR'$  and the thermodynamic parameters of tetrahedral and octahedral equilibrium of extracted cobalt complexes.*

Extractant	$\Delta RPR'$ degree	$\Delta G^\circ$ kJ/mol	$\Delta H^\circ$ kJ/mol	$\Delta S^\circ$ J/mol · K
DEHPA	104.68	0.638	66.1	221
EH(EH)PA	115.65	-10.1	63.2	245
DTMPPA	120.09	-15.6	124	459

### **The Effect of Electron Density of Donor Atoms**

The steric effect of OPAs is not the only factor determining the configuration of the cobalt extracts. The electron density of the donor oxygen atom in the OPA is, in some cases, an even more important factor. The calculated charge on the oxygen atoms in Table 1 increases along the series of phosphoric acid, phosphonic acid, and phosphinic acid. The charge on the oxygen atom in the P-OH group will be significantly increased with increasing dissociation of the  $H^+$ . It is obvious that the higher the oxygen negative charge on the POH group, the weaker is the acidity.

The negatively charged donor atoms around the central ion repel one another. This, just as for steric hindrance, will destabilize complexes of high coordination number. The fact is that weak ligands with high negatively charged donor atom, even in the presence of only a small steric effect likely to form tetrahedral coordination compounds with Co(II) rather than octahedral ones. Further evidence supporting this statement is the fact that anionic ligands, such as  $\text{Cl}^-$ ,  $\text{SCN}^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$ , form tetrahedral coordination compounds with cobalt, but no stable octahedral coordination compounds have been detected.

The electron density of the oxygen atoms in organophosphorous acids is determined by the electron withdrawing ability of the substituting groups. The replacement of oxyalkyl groups with weaker electron withdrawing alkyl groups results in an increase in the electron density on the oxygen atoms of the  $\text{P=O}$  and  $\text{POH}$  groups. When a metal coordination compound is formed with these ligands, there is an energy balance between the enhancement of donor strength of the ligand and the strengthening repulsive interaction between the donor atoms.

This energy balance favours the extracted tetrahedral coordination compounds of cobalt(II) over the octahedral ones, because of the inherent low degree of stability of the octahedral coordination configuration. The higher oxygen electron density in an OPA results in a higher ratio of the tetrahedral to octahedral configuration in the extracted compounds. There is another reason for the increase of the ratio along the sequence of dialkylphosphoric acid, alkyl-phosphonic acid mono-alkyl ester and dialkyl phosphinic acid. The cobalt tetrahedral complexes contain no water (as demonstrated by the IR spectra [3,4]) and are more lipophilic than the octahedral extracts, and, therefore, have higher partition coefficients between the organic and aqueous phases. The increase in the proportion of the cobalt tetrahedral complexes increases the extractability, and partly compensates for the decrease of extraction caused by the reduction in the acidity of the AOPA along the above sequence. Therefore, the cobalt extraction equilibrium constants are only slightly decreased, as shown in Table 3. This different behaviour of the two metals results in an increase of the separation factor of cobalt over nickel along the same sequence.

*Table 3. Extraction constants of cobalt and nickel with alkylphosphorous acid<sup>#</sup>*

Extractants	$pK_a^*$	$K_{\text{ex(Co)}}$	$K_{\text{ex(Ni)}}$	$K_{\text{ex(Co)}} / K_{\text{ex(Ni)}}$
DEHPA	3.57	$5.50 \times 10^{-6}$ ( $4.3 \times 10^{-6}$ )	$1.10 \times 10^{-6}$ ( $2.2 \times 10^{-6}$ )	5(2.2)

## MASS TRANSFER COEFFICIENTS OF SINGLE LIQUID DROPS IN EXTRACTION COLUMNS

Mohsen A. Hashem and J. Saien\*

Dept. of Chem. Eng., Faculty of Eng., El-Minia University, El-Minia, Egypt

\*Dept. of Applied Chem., University of Bu-Ali Sina, Hamadan, Iran

Hydrodynamic behaviour and mass transfer coefficients of single liquid drops have been measured in a 150 mm diameter column. The column was operated in two different modes as a spray tower and perforated plate tower. The systems employed were toluene/water for the hydrodynamic study and toluene/benzoic acid/water for the mass transfer study. Experiments were performed using different needle sizes to obtain drops of different diameter. The relationship between the drop velocity and the down flow of the continuous phase was examined experimentally. Mass transfer coefficients (MTCs) have been measured for single liquid drops rising through nonflowing and flowing water and have been compared with the coefficients measured for free rise conditions in an empty column. The MTCs were determined as a function of drop size, mass transfer direction, compartment height and down flow of the continuous phase.

From the data obtained, it is concluded that the drop size is a key variable affecting hydrodynamics and mass transfer processes. The drop velocities were found to decrease as down flow rate of continuous phase increased. The effect of continuous phase velocity on the MTC is significant with a slight increase in drop size occurring with increasing flow rate. The degree of enhancement of the dispersed phase film coefficient due to the presence of plates has been ascertained. Finally the coefficients for mass transfer direction from the dispersed phase into the continuous phase ( $d \rightarrow c$ ) are slightly higher than that for the opposite direction, ( $c \rightarrow d$ ).

### INTRODUCTION

In the field of solvent extraction processes various types of equipment have been developed during the last few decades. Therefore, the user is faced with a critical choice between contactors and most of the time has to decide according to subjective criteria. Nowadays, various extractors that are operated with and without a supply of mechanical energy are available in industry. Spray and perforated-plate (sieve plate) columns are commonly used in commercial liquid-liquid extraction systems. In these towers many drops are formed simultaneously and rise (or fall) in a swarm.

One of the ways to increase the mass transfer rates between the dispersed and the continuous phase is to provide for frequent coalescence and redispersion of the drops especially for the systems which show high internal circulation in the drop during formation at orifice or nozzles [1]. Perforated plate extraction towers are unique in that they provide repeated coalescence and redispersion for the drops and offer the advantage of cross flow of the continuous phase in addition to yielding high extraction coefficients with practically no axial mixing. The perforated plate columns may be considered as a series of short spray columns arranged one above the other. In practice, however, there are numerous applications of liquid-liquid extraction where perforated columns are preferred [2].

The present work aims at the prediction of mass transfer rates from single liquid drop to a continuous phase and investigates the effect of drop size, mass transfer direction, height of compartment and continuous phase velocity on the mass transfer coefficients of single liquid drop in a perforated plate (sieve-plate) and spray columns. Since knowledge of particle velocity is of fundamental importance for the description of mass transfer process, it is necessary to consider some aspects of the fluid mechanics of a single particle in free motion through a continuous fluid phase. Hence, the relevant hydrodynamics to mass transfer consideration are first reviewed briefly, with respect to drop size and terminal velocity because the primary focus of this paper is on mass transfer of a single liquid drop.

## EXPERIMENTAL

### Systems Tested

The systems investigated in this work were, toluene / water for the hydrodynamic studies and toluene / benzoic acid / water for the mass transfer studies. Solute concentration was determined by using a spectrophotometer (UV-1601 Shimadzu). The organic liquid were special-grade chemicals and were used without further purification. The physical properties of the system used (toluene / water) are as following:  $\rho_c = 998 \times 10^3 \text{ g/m}^3$ ,  $\rho_d = 862 \times 10^3 \text{ g/m}^3$ ,  $\mu_c = 0.00098 \text{ g/ms}$ ,  $\mu_d = 0.00059 \text{ g/ms}$ ,  $\gamma = 34 \text{ mN/m}$ , where  $\gamma$  interfacial tension,  $\rho_c$ ,  $\rho_d$  density of the continuous and dispersed phase and  $\mu$  its viscosity, respectively.

### Single Drop Apparatus

The experimental apparatus were essentially the same as described in a previous paper [3]. A summary of column details is given in Table 1. Main parts of the apparatus consisted of Perspex extraction column 0.150 m diameter, a glass funnel for sample collection and one of several sizes of glass capillary for drop formation. The rising time of the drops through given distance was measured with a stopwatch and the equivalent spherical drop diameter,  $d$ , was calculated knowing the flow rate and counting the number of drops formed in unit time.

*Table 1. Perforated column details.*

Column diameter, mm	150
Plate hole diameter, mm	5
Number of holes	37
Plate thickness, mm	3
Variable plate spacing, mm	20, 40, 60
Area of perforations, %	47

## Experimental Procedure

Prior to the commencement of measurements the apparatus was thoroughly cleaned and the system run to achieve saturation of the phases. The column was filled with the aqueous phase (distilled water) before the solvent (dispersed phase) is fed. Rotameters on the lines to and from the column enabled accurate flow settings and adjustment to be made thus ensuring that balanced flows were rapidly achieved and then maintained. A positive displacement pump was used to introduce the organic phase into the bottom of the column. Experiments were performed using different glass needles to obtain drops of different size. At least 300 drops were timed for each run. This was considered long enough for steady state conditions to be achieved [4]. Drops were spaced more than 30 mm apart typically, sufficient to avoid interactions according to Skelland [5]. In the perforated plate column, the droplets leaving the plates were allowed to rise a measured distance through the aqueous phase before being collected by suction through a small inverted funnel. The interfacial area in the funnel was kept small by occasionally pulling the drops into a pipette. After each experiment the column was thoroughly cleaned with decontaminating agent (Decon 90) to prevent the problem of contamination.

## Interpretation of Data

The overall mass transfer coefficients for drops of known size may be measured by passing solvent drops of known composition through an aqueous phase of known composition and collecting drops in an inverted glass funnel at the top of the column [6]. Analysis of solvent drops after passage through the column in a known time allows an overall time-averaged mass transfer coefficient, ( $K_{od}$ ), to be calculated from the following equations:

$$(C_o - C_i) / (C^* - C_i) = (1 - \exp(-6 K_{od} t / d)) \quad (1)$$

$$K_{od} = -(d / 6 t) \ln(1 - E) \quad (2)$$

where  $E = (C_i - C_o) / (C_i - C^*)$  and  $C_i$  is the inlet and  $C_o$  outlet solvent concentration, and since there was no solute initially in the water, the drop concentration in equilibrium with the aqueous phase,  $C^* = 0$ .

## RESULTS AND DISCUSSION

### Hydrodynamics

#### *Terminal velocities of single drops*

The experimental terminal velocities for toluene/water system are plotted versus drop diameter in Figure 1. Also shown are the terminal velocities for the drops raising singly as predicted by the correlations of Grace [7] for comparison with measured values. The terminal velocity is observed to increase with increasing droplet diameter. The reasonable agreement indicates that all drops in this work experienced some internal circulation.

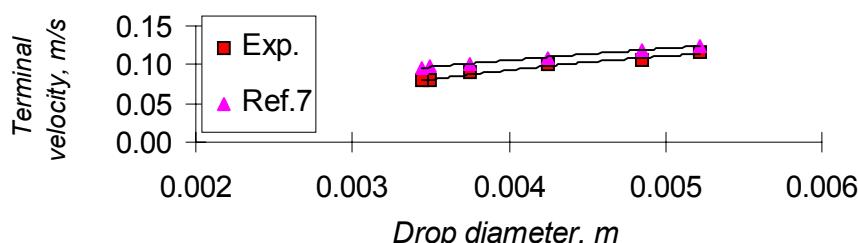

Figure 1: Terminal velocity versus drop diameter.

### **Effect of continuous phase velocity**

Figure 2 shows the profile of down flow of the continuous phase against the velocity under various flow rates conditions. The drop velocity decreases as the down flow rate increases as expected.

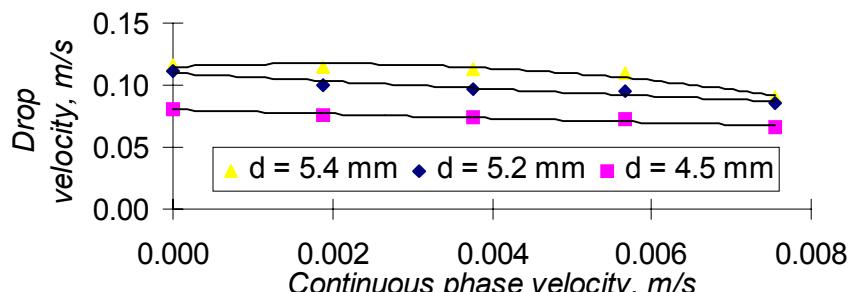

Figure 2: Effect of continuous phase velocity on drop velocity.

### **Mass Transfer**

#### **Spray and perforated columns**

Figure 3 shows the mass transfer coefficient for spray and perforated columns. The mass transfer coefficient in the presence of a sieve plate is higher than that without plates. This is due to the fact that during the operation of a spray column the use of continuous phase cause convection currents through the column leading to axial mixing in that phase. This reduces the extraction rate because of the deviation from true counter current behaviour. In a sieve plate contactor the distortion of the drop by direct contact with the edge of the plate holes during the passage disturbs the concentration profile inside the droplet and increases the mass transfer coefficient. The enhancement of up to about 80 % presumed due to the influence of plates is far greater than the value of 30 % obtained in the absence of plates. The results obtained are in qualitative agreement with observations of other investigators [8].

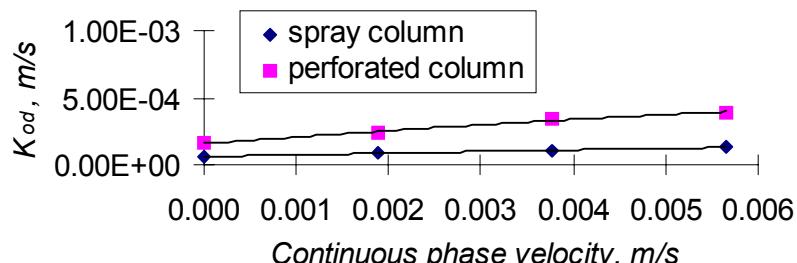

Figure 3: Mass transfer coefficient in spray and perforated plate column.

### **Effect of drop size and direction of solute transfer**

Figure 4 shows the dependence of the average mass transfer coefficient on drop size and direction of the mass transfer. The coefficients of mass transfer from the continuous to the dispersed ( $c \rightarrow d$ ) appear to be smaller than those obtained for the opposite direction of transfer ( $d \rightarrow c$ ). The difference in the coefficient is, however, small with slight increase in drop size from  $d \rightarrow c$ . Direct comparison of the results is difficult owing to the variation of drop size with direction of solute transfer. With solute transfer from  $d \rightarrow c$ , the drop size increased probably due to changes in interfacial tension. In addition the mechanism of mass transfer is known to be dependent on drop size, with the mass transfer mechanism varying from molecular diffusion for very small drops, which behave as a rigid spheres, to the development of internal droplet circulation, oscillation and turbulent eddy transfer mechanisms as the drop size is increased.

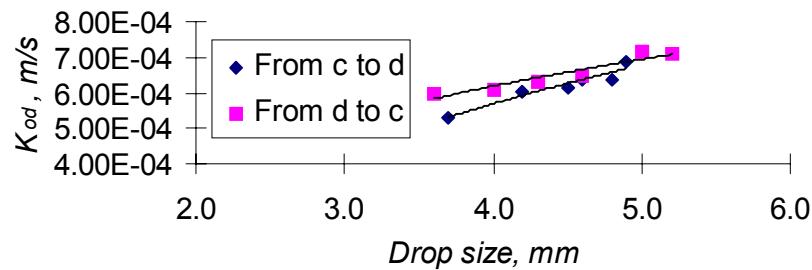

Figure 4 : Dependency of the MTC on drop size and direction of solute transfer.

### Effect of continuous phase velocity

The effect of the continuous phase velocity on the mass transfer coefficient was found to be significant [9] with only a slight increase in the drop size occurring with increasing the continuous phase velocity. The enhancement factor ( $E$ ), defined as the ratio of mass transfer coefficient at a given value of down flow to that at zero down flow,  $K_{od}/K_{odo}$ , as a function of continuous phase velocity (Figure 5) shows how increase of the continuous phase velocity increases the ratio. The study of the continuous phase velocity was also useful in that it enable a comparison between the unsteady state and the stationary phase methods for single liquid drops. The obtained results were in good agreement with those of other workers [10-11]. The effect of down flow on the dispersed phase mass transfer coefficient is associated directly with movement of drops through holes. Other important effects are obtained by reducing drop relative velocities [12] and increasing in contact time leading to reduction in  $k_d$  and a change in the product  $K_d t / d$  which affects the fraction extraction. The main benefit is the enhancement of mass transfer through the droplet/continuous phase interface as demonstrated by other investigators [13-15].

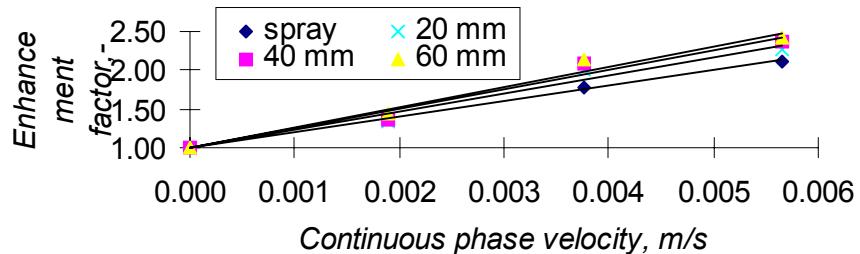

Figure 5: Enhancement factor vs. continuous phase velocity in perforated plate column.

### Effect of compartment height

The mass transfer coefficients slightly increase by increasing the height through which drops rise after leaving the plate (Figure 6). This may be due to the period of time needed to reach maximum velocity after leaving a plate. For liquid-liquid extraction, it can be concluded that efficiencies in the order of 70 % to 80 % are normally obtained for a perforated plate. The degree of enhancement of the dispersed phase film coefficient due to the presence of plates has been ascertained. The experiments using variable rise heights indicate that most of the mass transfer during rise is important and the mass transfer during formation is not dominant. A common plate design with a free area of 42 % was used throughout the experiments.

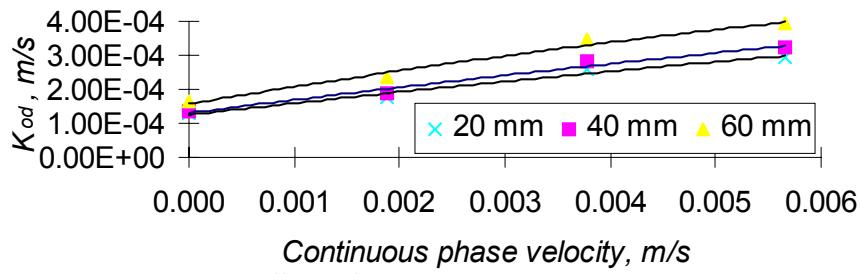

Figure 6 :Effect of compartment height on mass transfer coefficients.

## CONCLUSIONS

The drop size is a key variable affecting hydrodynamics and mass transfer processes. The drop velocity was found to decrease as down flow rate of continuous phase increased. The mass transfer coefficient in the presence of plates is higher than that without plates. The coefficients for mass transfer from the dispersed phase into the continuous phase direction ( $d \rightarrow c$ ) are slightly higher than that for the opposite direction of transfer ( $c \rightarrow d$ ). The effect of continuous phase velocity on the mass transfer coefficient is significant with a slight increase in the drop size occurring with increasing flow rate. The mass-transfer coefficients slightly increased by increasing the height through which drops rise after leaving the plate.

# THE DEVELOPMENT OF MATHEMATICAL CORRELATIONS FOR MASS TRANSFER OF FILM CONTACTING OF TWO AQUEOUS PHASES

Jamaliah Jahim and M. J. Slater\*

Department of Chemical & Process Engineering, Universiti Kebangsaan Malaysia,  
Bangi, Malaysia

\*Department of Chemical Engineering, University of Bradford, West Yorkshire, UK

The use of a thin film-type contactor appeared sensible and might be applicable to aqueous two-phase systems (ATPS), as well as many other liquid-liquid systems when the phase ratio is extreme. In drop contactors at high phase ratio (continuous/dispersed) there are operating difficulties with low hold up and entrainment of many small drops. A study of a thin flowing film of one phase exposed to the other was made and the kinetics of mass transfer using such film contact were investigated. The experiments reported here concern PEG 3350 (light phase)/Na<sub>2</sub>SO<sub>4</sub> (heavy phase) with bovine serum albumin (BSA) plus  $\alpha$ -amylase dissolved in the heavy phase. The heavy phase was allowed to flow down a sloping metal channel in a bath of light phase. Mass transfer occurred from the heavy phase; samples of heavy phase were collected at the end of the channel for different flow rates and slope angles. Data of mass transfer coefficients have been interpreted using various empirical equations for mass transfer across a horizontal, vertical and sloping system. A correction factor to describe the enhancement of both film mass transfer coefficients caused by rippling or/and internal circulation in the film has been used.

The best fit correlation for BSA that is for single resistance in the top phase was found to be an equation derived by Baird, whilst for two-phase resistance with  $\alpha$ -amylase for mass transfer in the top phase and bottom phase, the combination of Baird [1] and Higbie [2] equations was found to give good agreement. Correlations for predicting overall effective diffusivity, D<sub>oe</sub> for both systems have also been made but do not give satisfactory results since the range of D<sub>oe</sub>/D<sub>m</sub> values is very large.

## INTRODUCTION

Aqueous two-phase systems (ATPS) have a great potential in future industries when the formation of two liquid phases that occurs can give the basis for analogies with liquid-liquid (organic-aqueous) extraction processes, which are quite common in chemical industries. These aqueous two-phase systems could become a suitable alternative for large scale processing of microbial products especially for the extractions concerning complex, polar and water-soluble products (antibiotics, sugars, glycolipeptides, etc.). Details of the use of such systems in downstream processing on a large scale have been published elsewhere [3-5].

Although the systems are capable of processing streams with small particulate material, it can be difficult to carry out solid-liquid separation on a large scale like centrifugation in the early stage of a protein recovery process [6]. Therefore, the removal of solids using ATPS can be integrated into a liquid-liquid separation step and the clarification steps can be combined with an initial purification. At present, ATPS are only successful on the laboratory scale, and are not widely used in large-scale industrial operations. The potential of commercial mixer-settler systems and centrifugal separators of various design for processing of large flow rates have been investigated by several authors in ATPS [4,5,7].

The separation on a pilot scale (1-20 kg ATPS) in the presence of microbial cells has been successfully demonstrated by continuous phase separation in a disk stack centrifuge and in a nozzle discharge disk stack centrifuge when they are compared with the settling under gravity [8]. Continuous countercurrent column extractions with ATPS have also recently been investigated. Sawant *et al.* and Pawar *et al.* studied a spray column (in which the PEG phase is dispersed into fine droplets) [9-11]. Bhawsar *et al.* have investigated the mass transfer and hydrodynamics in a pulse sieve plate column [12]. Studies on York-Scheibel columns with alternating zones of mixing and coalescence have been reported by Pawar *et al.*[11]. This simple, effective pilot-plant scale equipment is of great interest for industrial extraction.

In this work, the use of ATPS for the recovery and separation of proteins such as  $\alpha$ -amylase and bovine serum albumin (BSA) was investigated. The work covers the experiments to prepare the equilibrium diagram for the proteins since no information on this has been published. The equilibrium diagram is used to determine the partition coefficients in the studied systems. A novel preliminary study is focused on the kinetics of the mass transfer behaviour in an inclined film flow channel using ATPS. The mass transfer experiments that involve the estimation of film thickness and contact time and determination of degree of extraction to be able to calculate the experimental mass transfer coefficients of the system.

## MATERIAL AND METHODS

### Chemicals

PEG with an average molecular weight of 3350 was purchased from Sigma Ltd. Co., England while  $\text{Na}_2\text{SO}_4$  was purchased from BDH Chemicals Ltd, Poole UK. Both chemicals were analytical grade. BSA and  $\alpha$ -amylase produced by bacteria, *B. subtilis* were industrially prepared and supplied by Sigma Ltd. All stock of the solutes was stored at temperature below 4°C. Enzyme  $\alpha$ -amylase was supplied freeze-dried in a mixture of starch powder while BSA was supplied in a solution with 8.5% of sodium chloride.

### Preparation of Phase Systems

The pre-mixed immiscible PEG-rich phase and salt-rich phase solutions were prepared to be used in all kinetic experiments. These phases were made by adding weighed amounts of PEG 3350 and  $\text{Na}_2\text{SO}_4$  to the amount of water that gave the required total system of 7.6% mass PEG 3350/ 9.7% mass  $\text{Na}_2\text{SO}_4$ /82.8% mass water. The phase diagram of the PEG3350/ $\text{Na}_2\text{SO}_4$ /water system has been prepared by Snyder and co-workers [12]. The mixture was stirred by means of a stainless steel disk turbine attached to a stirrer RZR-200 (Heidolph, Germany), for about 2-3 hours to equilibrate. The mixture was left overnight in the separating funnel to allow settling at room temperature. The two phases were then separated and they were filtered to obtain clear phases free from any particles.

### System Compositions and Physical Properties.

The phase composition and the physical properties of viscosities and densities based on the data prepared by Snyder are shown in Table 1. They used the analysis technique using high-performance liquid chromatography (HPLC)-gel chromatography to determine compositions of the ATPS. The determination of density was repeated and the results obtained were little

different from Snyder's data [12]. Density measurements were carried out using a vibrating U-tube densitometer DMA 35 (Anton Paar, Austria) at  $25 \pm 0.5^\circ\text{C}$ . The reproducibilities of the densities of the bottom phase and top phase were estimated to be  $1125 \pm 5 \text{ kg m}^{-3}$  and  $1071 \pm 5 \text{ kg m}^{-3}$ , respectively.

*Table 1. Composition, density and viscosity of the phases at  $20^\circ\text{C}$  on PEG3350/ $\text{Na}_2\text{SO}_4$  tie line [12].*

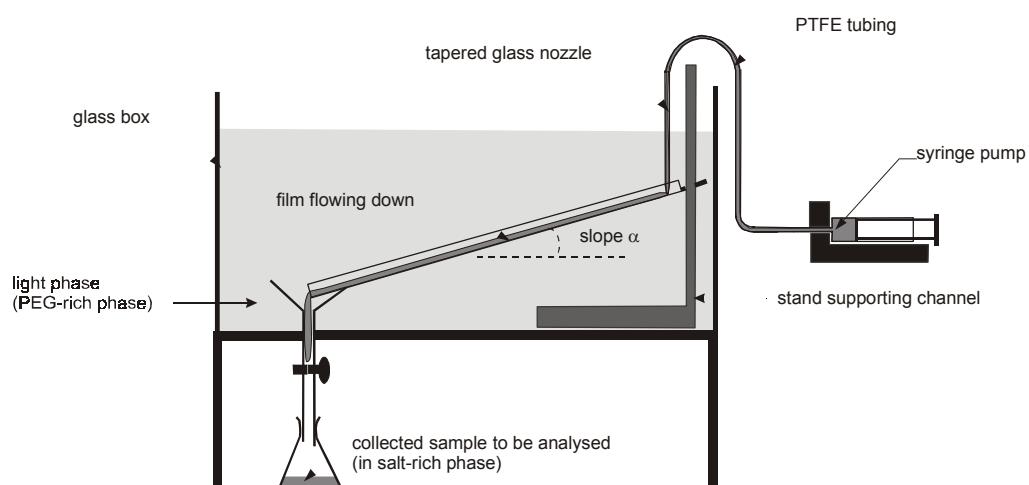

Tie line	Top phase			Bottom phase		
	PEG/Salt/Water (%w/w)	Viscosity $\mu/(\text{Pa.s})$	Density, $\rho/(\text{kg/m}^3)$	PEG/Salt/Water (%w/w)	Viscosity $\mu/(\text{Pa.s})$	Density, $\rho/(\text{kg/m}^3)$
F	23.6/4.9/71.5	0.0134	1076.6	1.3/12.1/86.7	0.0015	1106.6

### Enzyme and Protein Assay

The determination of  $\alpha$ -amylase using  $\alpha$ -Amylase Diagnostic® kit is based on hydrolytic activity or catalytic activity of  $\alpha$ -amylase in the sample. One unit of  $\alpha$ -amylase is defined as the millimolar absorptivity of para-nitrophenol (PNP) at 405 nm degraded from hydrolysis of substrates (ET-G<sub>7</sub>PNP) per minute at  $37^\circ\text{C}$ . The procedure to measure protein using Protein Assay Kits supplied by Sigma Ltd. Co. is based on Peterson's modification of the micro-Lowry method. Absorbance is read at suitable wavelength between 500 nm to 800 nm and protein concentration is determined from a calibration curve using BSA as standard.

### Mass Transfer Experiments Using a Sloping Channel.

The experiments were performed in a square glass tank with capacity of 50 L of top phase as shown in Figure 1. The mass transfer coefficients were measured for the flow of thin film on the sloping channel (length between 0.25-0.4 m) at room temperature of  $25 \pm 1^\circ\text{C}$ . The lower end of the channel was held with a wire mounted to a metal strip which was placed across the tank, while the other end was plugged into a slot on a supporting stand for particular required angles. Five different flow rates controlled by means of a syringe pump were used; 16, 20, 26, 28 and 36  $\text{mm}^3/\text{s}$ . The initial concentration of both solutes were 6024.0 U/L (slope  $14.5^\circ$ ) and 6576.2 U/L (slopes  $23.7^\circ$  and  $45^\circ$ ) for  $\alpha$ -amylase and 3790.64 mg/L for BSA.

*Figure 1. Experimental set-up of flowing film on a sloping channel.*

The thickness of the film was calculated from the hold-up of the film. This was done by allowing the film to flow into a beaker that was placed next to the funnel collector for two minutes to obtain a steady flow. The channel was then moved quickly sideways using the holding wire, draining the flow into the funnel collector and at the exact moment the pump was turned off. When the film had drained off, the bottom phase plus some top phase was collected. The bottom phase was separated and weighed to obtain the volume by dividing the weight with the known bottom phase density. Knowing the wetted area of the channel, the mean film thickness can be determined. The width of the film was taken to be 4.5 mm, the width of the channel. The contents of protein and  $\alpha$ -amylase left in the bottom phase were analysed. This was done by letting the film flow to run for 2-3 minutes to reach steady state before the sample was taken. Samples collected were diluted before further analysis.

### **Calculations**

The degree of extraction, E was calculated using the equation defined as

$$E = 1 - (c_{\text{out}}/c_{\text{in}}) \quad (1)$$

where  $c_{\text{in}}$  is the concentration of the heavy phase at inlet flow and  $c_{\text{out}}$  is the concentration at the outlet flow. The overall mass transfer coefficient from the experiment can be calculated from

$$K_{\text{od}} = -h/t * \ln(1-E) \quad (2)$$

where h is the measured film thickness and t is the contact time of the film travelling from the inlet to the outlet of the flow.

The film thickness, h can be calculated from the mean of film thickness for laminar film flow given by Nusselt, for two-film liquid flow,

$$h = [3\mu Q/wg(\rho - \rho_c)\sin \theta]^{1/3} \quad (3)$$

where w is the width of the liquid film, Q is the liquid volumetric flowrate per unit width,  $(\rho - \rho_c)$  is the density difference for adjoining phases and  $\theta$  is inclination of the channel to the horizontal.

## **RESULTS**

The overall mass transfer coefficient,  $K_{\text{od}}$  is given as

$$1/K_{\text{od}} = 1/k_b + 1/mk_t \quad (4)$$

where  $k_b$  and  $k_t$  are film mass transfer coefficient for dispersed and continuous phases respectively.

The mass transfer coefficient for both films, dispersed in film form (bottom phase) and continuous (top phase) can be calculated using existing correlations that are for films flowing or rising on sloping, horizontal or vertical surfaces. For both films, a time-dependent process is assumed and diffusion coefficients are needed. The values of  $K_{\text{od}}$  found from these correlations were lower than those from the experiment if molecular diffusivity is used. Therefore the second term of effective diffusivity proposed by Handlos and Baron (1957), originally proposed for drops, here multiplied by a correction factor  $k_H$  was used to estimate the diffusivity due to the mixing in the film caused by rippling or wave motion at interface [14,15]. The effective diffusivity is defined as

$$D_e = k_H h u / 2048 [1 + (\mu_d / \mu_c)] \quad (5)$$

where  $u$  is velocity of the film and  $k_H$  is a correction factor which is adjusted so that overall mass transfer coefficients agree with results from experiment. The overall diffusivity,  $D_{oe}$  is given as

$$D_{oe} = D_M + D_e \quad (6)$$

Molecular diffusivity,  $D_M$  for  $\alpha$ -amylase and BSA is calculated using the correlation of Young-Carrodd-Bell [13] which was adapted from the Stokes-Einstein equation. The best correlation to be considered here is the correlation that has lowest value of  $k_H$  since high values may be unrealistic. In the comparison for the two-film system for  $\alpha$ -amylase, it was found that the combination model of Baird [1] for continuous phase and Higbie [2] for film or dispersed phase gave the lowest correction factor  $k_H=1$  at the lowest slope of the channel and lowest  $k_H$  at highest slope. For the results of the BSA system, where the resistance is in the continuous phase, the best equation fitted with the experiments found was by using the Baird equation [1]. The data are shown in Figure 2.

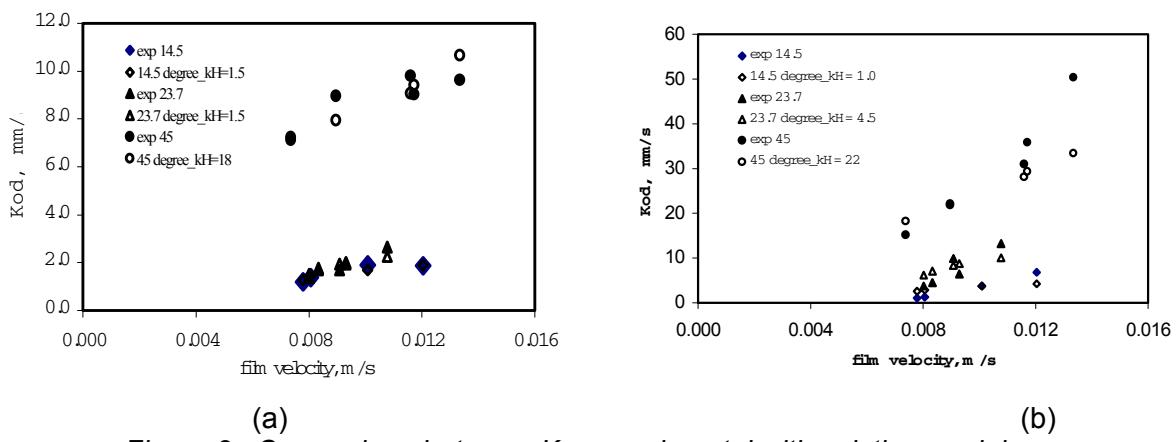

Figure 2. Comparison between  $K_{oe}$  experimental with existing model:  
 (a) for BSA (b) for  $\alpha$ -amylase.

The results also show that mass transfer coefficients of  $\alpha$ -amylase are higher compared to those found for BSA. There are marked increases for both  $\alpha$ -amylase and BSA at angle  $45^\circ$  with increasing velocity compare to those at lower angle at  $14.5^\circ$  and  $23.7^\circ$ . As the velocity of the film increases, the film thickness also increases, and perhaps more mixing within the film or at the interface.

### Empirical Correlation of Mass Transfer Coefficient

In an attempt to find empirical correlations for mass transfer in films, the forces that might affect the mass transfer process are gravity forces, interfacial shear stress, viscous forces, interfacial tension force and inertia forces. Large number of correlations have been tried using dimensionless numbers with regards to the mentioned forces with data from various organic-aqueous system, and the best correlations found were in the form of

$$D_{oe}/D_M = 1 + b \cdot Re^m [1 + a Eot^n] \quad (7)$$

where for  $D_{oe}/D_M \rightarrow 1$ ,  $a$   $Re \rightarrow 0$  and  $Eot \rightarrow 0$  for conditions with no rippling. The curve fitting between the experimental data and the empirical model was carried out using Microcal Origin® to obtain best fit constants of  $a, b, m$  and  $n$ .  $D_{oe}$  can then be calculated and used in calculating  $K_{oe}$  values. It was found that the exponents are unrealistically high, so the method of correlation is not satisfactory from a physical point of view.

## CONCLUSIONS

The application of ATPS in particular appears promising for biochemical separations, although few investigations of chemical engineering aspects have been made. Much work has been done on theoretical prediction of film thickness on sloping plates for laminar flow. There are only a few equations for turbulent flow. Some work has been done to model rippling on film surfaces (mainly gas/liquid) but the subject is complex and most correlations are empirical, and there is little agreement between them. Measurements of film thickness have been made in this work in a simple way and reasonable agreement with theory for laminar flow was found. According to Baird et al. [1], rippling occurs in laminar flow at Reynolds numbers between 6 to 500. No obvious agreement with correlations was found, therefore more work is required to determine the validity of the correlations. More accurate methods of film thickness measurement are desirable for liquid-liquid systems. Only when this work is done can mass transfer coefficients be better correlated.

# THE EFFECT OF IONIC SURFACTANTS ON THE MASS TRANSFER AT THE LIQUID-LIQUID INTERFACE FOR A TOLUENE/WATER/ACETONE SYSTEM

**M. A. Mendes-Tatsis, M. Pursell, S. Tang and G. San Miguel**

Department of Chemical Engineering and Chemical Technology,  
Imperial College of Science, Technology and Medicine, London, United Kingdom

The study of the transfer of a solute across an interface between two immiscible liquid phases is fundamental in liquid-liquid extraction. When that transfer causes spontaneous interfacial convection (Marangoni convection) and/or when the system is "contaminated" by surfactants, theoretical predictions for the rate of solute transfer may become invalid.

In this work the transfer of acetone from toluene into water has been studied using a Schlieren optical system for the visualisation of the interface and a Mach-Zehnder interferometer to obtain measurements of concentrations close to the interface. The effect of the presence of soluble ionic surfactants in the system was found to decrease the total moles transferred per unit area when compared to the case of the "clean" system.

## INTRODUCTION

Mass transfer in liquid-liquid systems has been studied for many years and the knowledge acquired has been applied to the design of mass transfer contacting equipment such as liquid/liquid extractors [1]. This type of contactor is used successfully in various production processes such as in the extraction of metals from aqueous solutions, in the field of biotechnology and in the chemical and pharmaceutical industries and also in the treatment of effluents from the same plants.

Usually, industrial effluent streams are "soups" containing different chemicals and chemicals with surfactant properties. However, this is normally not taken into consideration in the design of contacting equipment where the system is considered "clean"; it is often assumed that the material to be extracted is the only one present in the "soup" and the only one being transferred.

Another commonly applied simplifying assumption is the exclusion of the role of the interface in the mass transfer process. Interfacial area and ways of maximising it are always given consideration but interfacial phenomena, which may be present, such as Marangoni phenomena, are usually ignored. However, for a fixed interfacial area, mass transfer rates may be increased if interfacial phenomena are taken into account, as has been well documented (e.g., [2-5]). It is, therefore, very important to get an accurate picture of the role played by the interfacial region in realistic systems. The interface acts not only as the boundary across which mass transfer happens but also where adsorption/desorption effects, from small concentrations of "minor" components in the "soup", occur which may cause or inhibit interfacial convection and therefore affect the mass transfer process.

Traditional mass transfer theories describe processes where ternary systems are involved but many times they fail when applied to industrial cases. In the case of liquid-liquid extraction, the European Federation of Chemical Engineers (EFCE) has proposed several ternary test systems so that an experimental database could be created against which theories could be tested. Although useful as a start, the test systems proposed are not fully representative of real industrial systems where, in most cases, more than one species undergoes mass transfer, most certainly in the presence of surface active impurities. The presence of surfactants in the systems is usually accepted as being detrimental to the mass transfer process (e.g., [1,6,7]), as their adsorption at the interface may create a barrier to the transfer of other species or dampen any interfacial movements. On the other hand, reports, which conclude that the adsorption/desorption of surfactants at an interface may produce Marangoni convection, which enhances mass transfer, have also been published [5,8].

The objective of this work is to study the interphase transfer of acetone from toluene into water for the cases when the interface is "clean" and when it is "contaminated" with soluble ionic surfactants, when the system is quiescent. Comparisons are made between the two systems using visual observations made with a Schlieren optical system and using quantitative results obtained with a Mach-Zehnder interferometer.

## EXPERIMENTAL SYSTEMS AND METHODS

The system toluene/acetone/water was chosen for this investigation for several reasons: (i) it has been selected by EFCE as a model ternary system and physical properties are easily available [9]; (ii) it has been part of previous investigations (e.g., [10-12]) and was found to be Marangoni unstable, contrary to predictions by Sternling and Scriven's stability criteria [13]; and (iii) its optical properties make it a good choice to be used with the apparatus employed in this study.

Two easily available ionic surfactants have been selected: sodium dodecyl sulphate (SDS), which is anionic, and dodecyl trimethyl ammonium bromide (DTAB), which is cationic.

The apparatus used for the experiments has been described in detail elsewhere [5]. It consists of a Schlieren system to obtain images which indicate the stability of the interfaces under study and a Mach-Zehnder interferometer to obtain interferograms. These interferograms have been obtained for planar interfaces for the toluene+acetone/water system and have been analysed to enable the calculation of the values of concentrations at different locations from the interface and at different times, from which concentration profiles were plotted.

Theoretical mass transfer predictions have been made for the ternary system, based on Fickian diffusion of the solute into water. The theoretical concentration profiles may be obtained from the solution of Fick's 2<sup>nd</sup> law [14]:

$$C_S = C_{Si} \operatorname{erfc} \left( \frac{x}{2\sqrt{D_S t}} \right) \quad (1)$$

where  $C_S$  is the concentration of solute at any distance  $x$  from the interface at time  $t$ .  $C_{Si}$  is the interfacial concentration, which in the case of a ternary system may be estimated through the solute partition coefficient.

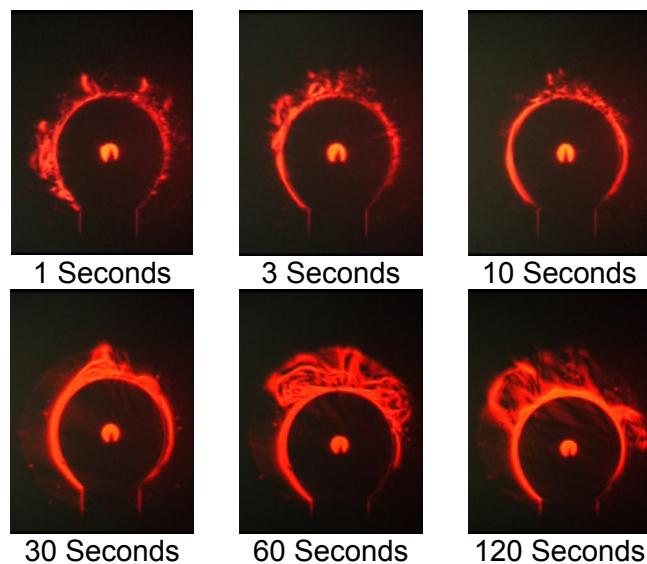

Instead of discussing plots of concentration profiles for the different conditions, it may be preferable to show the integral mass transfer results, i.e., results in terms of the summation of the molar mass transferred at all the planes of reference in the phase, as opposed to transfer at a single plane of reference. The reason for this is that if the mass transfer rate closer to the interface is higher than that further away from the interface, then a comparison between the experimental concentrations measured at near the interface and their theoretical predictions may give a distorted result.

Therefore, the mass transfer results are presented in terms of the total moles of acetone transferred per unit area,  $M_S$ , which is given by the area under the corresponding curve of concentration,  $C_S$ , plotted against distance from the interface.

## EXPERIMENTAL RESULTS

### Toluene+Acetone/Water

Figure 1 shows the Schlieren image sequence for the transfer of acetone (0.8 M) from toluene (in the drop) into the continuous “clean” water phase. These images clearly show that interfacial convection started immediately after formation of the drop and lasted for several minutes, which is in agreement with similar results obtained in the literature (e.g., [10-12]).

*Figure 1. Schlieren image sequence for the transfer of acetone (0.8 M) from the toluene drop into “clean” water.*

In Figure 2, the theoretical and the experimental results for the total moles transferred up to a distance of 6 mm from the interface are presented. A comparison of the two curves shows that the experimental results are in close agreement with those theoretically predicted by Fick’s 2<sup>nd</sup> Law. This is really unexpected from the Schlieren images presented in Figure 1, which show intense interfacial convection, usually indicating a higher mass transfer rate than theoretically predicted. Further work is necessary to investigate this result.

### Toluene+Acetone/Water +SDS

Experiments have been carried out to investigate the effect the addition of an anionic surfactant, SDS, to the water has on the interfacial stability and on the integral mass transfer of acetone into water.

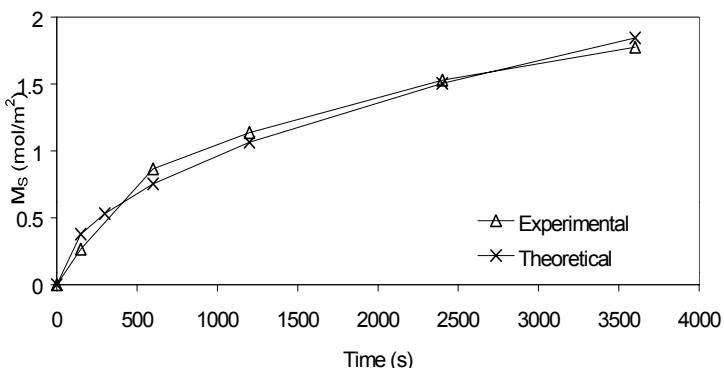

Figure 2. Comparison between experimental and theoretical values of the total moles of acetone transferred per unit area from toluene into “clean” water vs. time.

A Schlieren image sequence for the transfer of acetone (0.8 M) from toluene into water with SDS (0.05 g per 100 ml) is presented in Figure 3. It shows that the addition of SDS to the aqueous phase dampens interfacial convection that was present in the “clean” system shown in Figure 1.

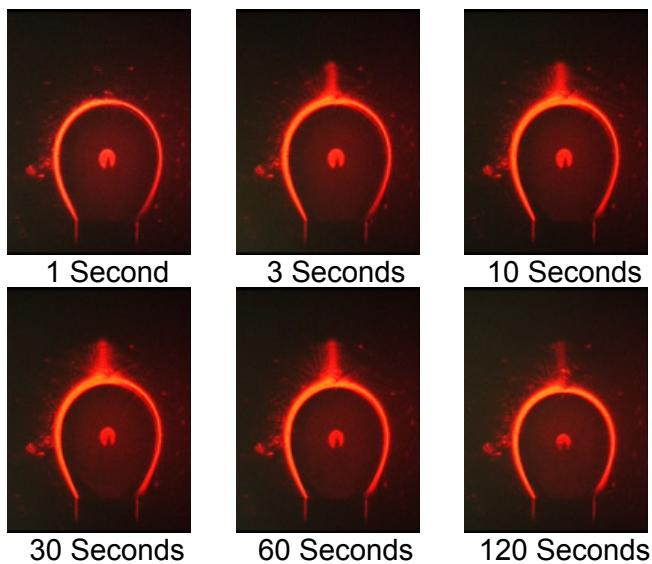

Figure 3. Schlieren image sequence for the transfer of acetone (0.8 M) from the toluene drop into water containing SDS (0.05 g/100 ml).

The plot of the total moles transferred per unit area vs. time for this case of transfer of acetone into water with the added surfactant SDS is shown in Figure 4. The addition of SDS to the aqueous phase decreases the integral mass transferred per unit area in comparison to the “clean” system, which is consistent with the observed damped interfacial convection in the Schlieren images. This is in agreement with the accepted idea that the presence of surfactants in a system decrease mass transfer rates.

#### Toluene+Acetone/Water +DTAB

Experiments have also been carried out to investigate the effect of DTAB, a cationic surfactant on the interfacial stability of the toluene+acetone/water system. Just like for the previous experiments the surfactant was added to the aqueous phase.

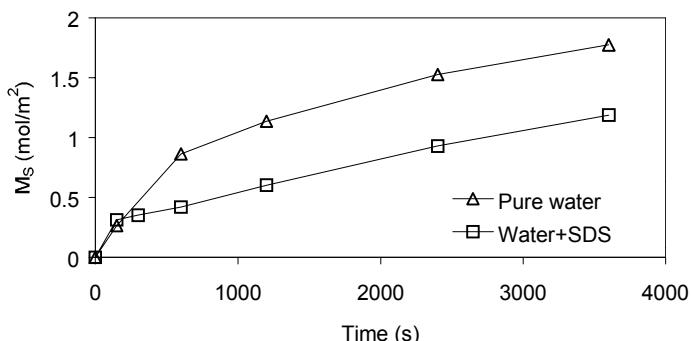

Figure 4. Total moles of acetone transferred per unit area from toluene into “clean” water and into water containing SDS (0.05 g/100 ml).

Figure 5 shows the corresponding Schlieren image sequence for the transfer of acetone from toluene in the drop into water with DTAB (0.05 g/100 ml). The effect of this cationic surfactant on the interfacial stability is found to be similar to that of the anionic surfactant, SDS, described above, *i.e.*, the interfacial convection is dampedened.

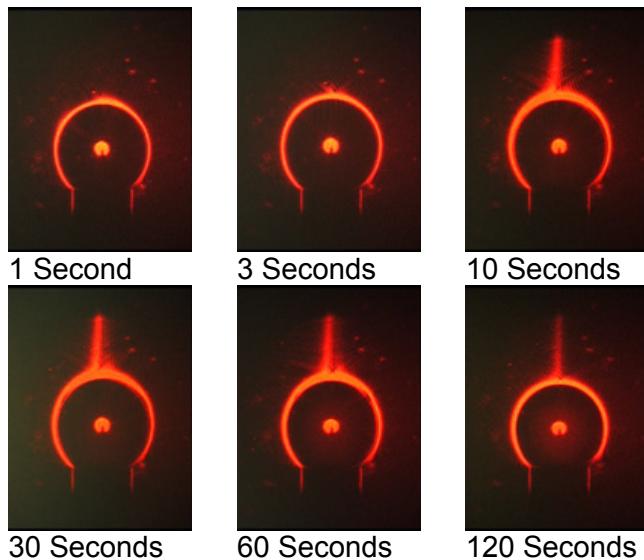

Figure 5. Schlieren image sequence for the transfer of acetone from the toluene drop into water containing DTAB (0.05 g/100 ml).

Figure 6 shows the change with time of the total moles of acetone transferred per unit area from the toluene to the water with the added surfactant DTAB as well as the curve for the transfer of acetone into a “clean” water phase. As for the case of the addition of SDS there is a decrease on the total moles transferred when DTAB is added to the water in comparison with the “clean” system. This is also consistent with the dampedened interfacial convection observed in Figure 5.

## CONCLUSIONS

Schlieren images and interferometric results have been presented for the transfer of acetone from toluene into “clean” water and into water “contaminated” with two different ionic surfactants. In the “clean” system mass transfer is accompanied by interfacial convection, which is not predicted by stability criteria but is in agreement with previous experimental work published. However, the interfacial convection observed does not have much effect on the

integral mass transferred in comparison with the theoretical prediction. This is unexpected and further work is under way to investigate this finding.

The effect of the addition of the ionic surfactants investigated is similar for both cases and it indicates a decrease in the total moles transferred per unit area when compared to the case of the “clean” system.

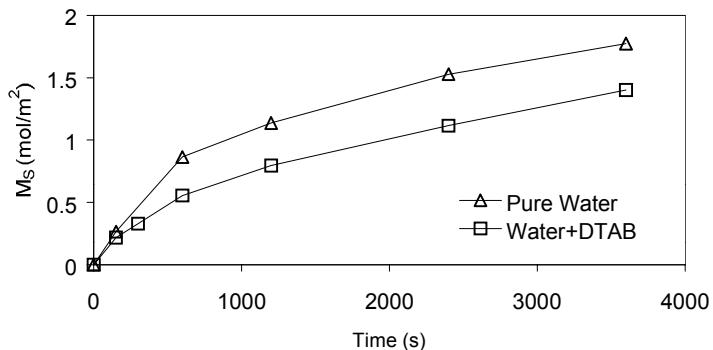

Figure 6. Total moles of acetone transferred per unit area from toluene into “clean” water and into water containing DTAB (0.05 g/100 ml).

## NUMERICAL APPROACH TO THE MOTION AND EXTERNAL MASS TRANSFER OF A DROP SWARM BY THE CELL MODEL

Zai-Sha Mao and Jiayong Chen

Institute of Process Engineering, Chinese Academy of Sciences, Beijing, China

The cell model developed for solid particles sedimentation and viscous flow through porous media was extended to simulate the drop behavior in a dense swarm. Zero shear stress or zero vorticity condition was designated at the external cell boundary. Numerical simulation in terms of stream function and vorticity was carried out to shed light on the interaction between drops and bulk liquid phase. The drag coefficient and external mass transfer rate from the simulation was also compared with correlations reported in literature. It is found that the cell model with the zero shear at the external cell boundary was satisfactory on the overall performance of prediction, but more modeling efforts are necessary to get closer agreement with experimental data.

### INTRODUCTION

Understanding of drop behavior in swarms is the prerequisite for establishing the mathematical model of a multiphase system for scientific scale-up of related process equipment. To approach this goal, numerous experimental data have been accumulated, but it is quite difficult to retrieve universal correlations for the purpose of prediction and process design. As for theoretical analysis, significant progress has been achieved in interpretation of the behavior of single drops and bubbles by theoretical and numerical approaches. For examples, Leal and coworkers solved numerically the buoyancy-driven motion of single deformable bubbles and drops in a curvilinear orthogonal coordinate system [1,2]. The authors also used the similar numerical scheme for interpretation of the motion and mass transfer of single drops in extraction systems [3-5]. However, theoretical approach to a drop swarm remains a great challenge.

In view of the successful application of the cell model to solid particle assemblages [6,7], efforts are taken to extend its use to fill the gap in the knowledge between single drop and drop swarm. As for the fluid particles, only one report is available on studying the motion and transfer of a bubble swarm [8].

To meet the pressing need for understanding the motion and transport behavior of drops in a swarm, the cell model is tentatively used for numerical simulation of spherical drops in a swarm. The prediction of drag coefficient and external mass transfer rate by the cell models is compared with several correlations. It is found that the Happel cell model gives more reasonable prediction of drop swarm behavior in the dispersion at low Reynolds numbers, and the Kawabara cell model tends to overestimate the friction to drops.

## FORMULATION OF CELL MODELS

A spherical cell is depicted in Figure 1. To resolve the fluid flow and mass transfer to the drop, the Navier-Stokes and convective diffusion equations are solved in an axisymmetrical coordinate system. For this purpose, we adopted the numerical scheme used previously for buoyancy-driven motion of single particles and deformable drops in an infinite medium [1-5,9].

For mathematical formulation of the viscous flow in such an assemblage, it is usual to adopt the following assumptions. (1) the liquid is incompressible, viscous and Newtonian; (2) the flow is laminar and axisymmetric; (3) the drop remains spherical; (4) the flow and mass transfer are steady-state; (5) the physical properties are not altered by mass transfer, so the mass transfer and liquid flow problems are not coupled. Thus, the liquid flow in a cell is described by the Navier-Stokes equations and the external mass transfer by a convective diffusion equation.

The axisymmetrical flow in the cell may be described by a set of partial differential equations in terms of stream function  $\psi$  and vorticity  $\omega$  in a sectional plane ( $x,y$ ) passing through the axis of symmetry as indicated in Figure 2. The non-dimensional governing equations are expanded in the computational plane ( $\xi,\eta$ ) which is the orthogonal mapping of the physical domain in the plane ( $x,y$ ) as follows [1,4]:

$$L_1^2(y_1\omega_1) - \frac{Re_1}{2} \frac{1}{h_{\xi_1} h_{\eta_1}} \left[ \frac{\partial \psi_1}{\partial \xi_1} \frac{\partial}{\partial \eta_1} \left( \frac{\omega_1}{y_1} \right) - \frac{\partial \psi_1}{\partial \eta_1} \frac{\partial}{\partial \xi_1} \left( \frac{\omega_1}{y_1} \right) \right] = 0 \quad (1)$$

$$L_2^2 \psi_1 + \omega_1 = 0 \quad (2)$$

$$L_2^2(y_2\omega_2) + \frac{Re_2}{2} \frac{1}{h_{\xi_2} h_{\eta_2}} \left[ \frac{\partial \psi_2}{\partial \xi_2} \frac{\partial}{\partial \eta_2} \left( \frac{\omega_2}{y_2} \right) - \frac{\partial \psi_2}{\partial \eta_2} \frac{\partial}{\partial \xi_2} \left( \frac{\omega_2}{y_2} \right) \right] = 0 \quad (3)$$

$$L_2^2 \psi_2 + \omega_2 = 0 \quad (4)$$

$$\frac{u_\xi}{h_\xi} \frac{\partial c}{\partial \xi} + \frac{u_\eta}{h_\eta} \frac{\partial c}{\partial \eta} = \frac{1}{Pe h_\xi h_\eta y} \left[ \frac{\partial}{\partial \xi} \left( \frac{h_\eta y}{h_\xi} \frac{\partial c}{\partial \xi} \right) + \frac{\partial}{\partial \eta} \left( \frac{h_\xi y}{h_\eta} \frac{\partial c}{\partial \eta} \right) \right] \quad (5)$$

where the differential operator is

$$L^2 = \frac{1}{h_\xi h_\eta} \left[ \frac{\partial}{\partial \xi} \left( \frac{f}{y} \frac{\partial}{\partial \xi} \right) + \frac{\partial}{\partial \eta} \left( \frac{1}{fy} \frac{\partial}{\partial \eta} \right) \right] \quad (6)$$

As depicted in Figure 2, the external domain is affixed with a left-handed reference frame ( $\xi_1, \eta_1$ ) and the drop domain is in a right-handed reference frame ( $\xi_2, \eta_2$ ). The typical grid on which partial differential equations are discretized and solved may be specified analytically for the domain between two concentric spheres [9].

Most of the boundary conditions for the cell model are routinely used: no slip and  $\psi=0$  at the drop surface,  $\psi=0$  and  $\omega=0$  at the axis of symmetry. Uniform flow is *a priori* assumed at the outer cell boundary. For the second boundary condition at the outer cell boundary, Happel proposed the shear-free boundary condition [6], and Kuwabara adopted the zero vorticity

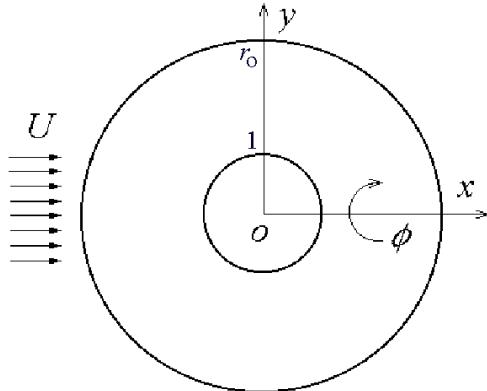

Figure 1. Schematic of the unit cell with the axisymmetrical reference coordinate system fixed on the spherical drop.

boundary condition [10] as listed in Table 1. The aim of these two conditions is to isolate a cell from the neighboring cells, but it seems that the zero vorticity boundary condition forces a more stringent constraint on the inter-cell interaction. Mass transfer controlled by external resistance occurs rarely in practical solvent extraction. This case is simulated in this work as a first effort. For external mass transfer,  $c=0$  at the interface is assumed since no mass transfer resistance exists in the drop phase,  $c=1$  is designated to the upstream half of the outer cell boundary and at the downstream half the zero gradient of  $c$  along the flow direction is adopted.

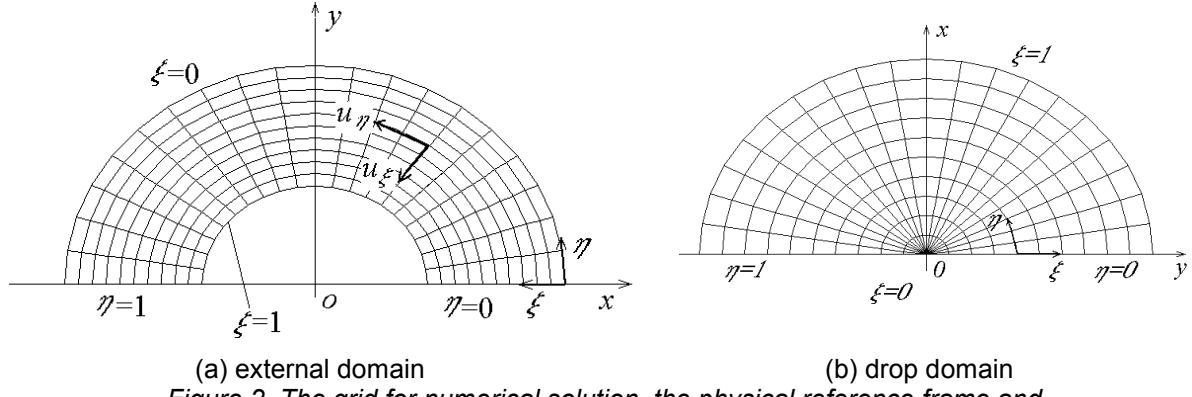

Figure 2. The grid for numerical solution, the physical reference frame and the computational coordinate system.

Table 1. Outer cell boundary conditions for the cell models.

Model H (Hapell) [6]	
$\psi = \frac{1}{2}y^2$	(uniform flow)
$\tau_{\xi\eta} = 0$	(free shear boundary)
Model K (Kuwabara) [10]	
$\psi = \frac{1}{2}y^2$	(uniform flow)
$\omega = 0$	(zero vorticity boundary)

The drag coefficient may be evaluated by the following line integral along the drop surface:

$$C_D = 2 \oint \left( \tau_{\xi\eta} \frac{\partial y_2}{\partial \eta_2} - \tau_{\xi\xi} \frac{\partial x_2}{\partial \eta_2} \right) y_2 d\eta_2 \quad (10)$$

and evaluation of terms in equation (15) is referred to [2,5]. The Sherwood number based on  $k_{od}$  is

$$Sh_c = \frac{2Rk_{od}}{D_1} = - \frac{2 \int_0^1 f_1 y_1 \left. \frac{\partial c}{\partial \xi_1} \right|_{\xi_1=1} d\eta_1}{\int_0^1 y_1 h_{\eta_1} d\eta_1} \quad (11)$$

## NUMERICAL SIMULATION

First the grid-independence of numerical simulation was tested. For a drop moving at  $Re=100$  with  $\lambda=1.33$  and  $\zeta=0.91$  in a swarm with the voidage  $\varepsilon=0.9$ , numerical simulation was repeated with Model H on successively denser meshes of  $41\times 21$ ,  $41\times 41$ ,  $81\times 41$ ,  $81\times 81$ ,  $121\times 81$  and  $121\times 121$ . It is found that the simulations on grids finer than  $41(\text{in } \xi)\times 81(\text{in } \eta)$  grid give similar numerical value of  $C_D$  within 0.7%. Sherwood numbers predicted by  $81\times 81$  and  $161\times 161$  grids differ at a level of 3%. Therefore, all the subsequent simulation were done on the uniform  $81\times 81$  grid.

For a spherical drop at  $Re=100$  with the voidage  $\varepsilon=0.7$  and  $0.9$ , the streamline contours are presented in Figure 3, showing the wake region is much smaller than that of a single buoyant drop in an unbounded medium. Since Model K imposes most stringent constraint on liquid flow by uniform liquid flow and zero vorticity at the outer boundary, it predicts greater drag coefficient than Model H as shown in Figure 4.

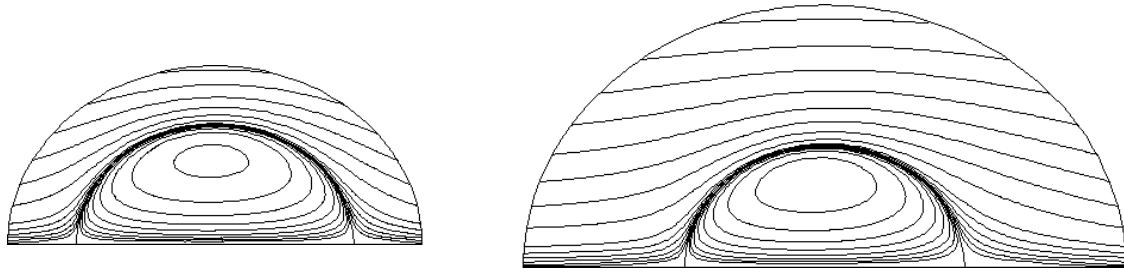

Figure 3. The streamline maps for a spherical drop with  $Re=100$ ,  $\lambda=1.33$ ,  $\zeta=0.91$ .

## COMPARISON OF MODELS WITH LITERATURE CORRELATIONS

### Drag Coefficient

To date many works have been published on the drag coefficients of drop swarms and many correlations were proposed. Among them, the correlation by Kumar and Hartland [11] is thought more reliable. The explicit expression for the drag coefficient is

$$C_D = \left( 0.53 + \frac{24}{Re} \right) \frac{1 + 4.56(1-\varepsilon)^{0.73}}{\varepsilon} \quad (12)$$

Comparison between the correlation and the prediction is shown in Figure 4, suggesting that Model H is in close agreement with the correlation when  $Re \leq 20$  and  $\varepsilon \geq 0.7$ , but Model K gives overestimated drag coefficients.

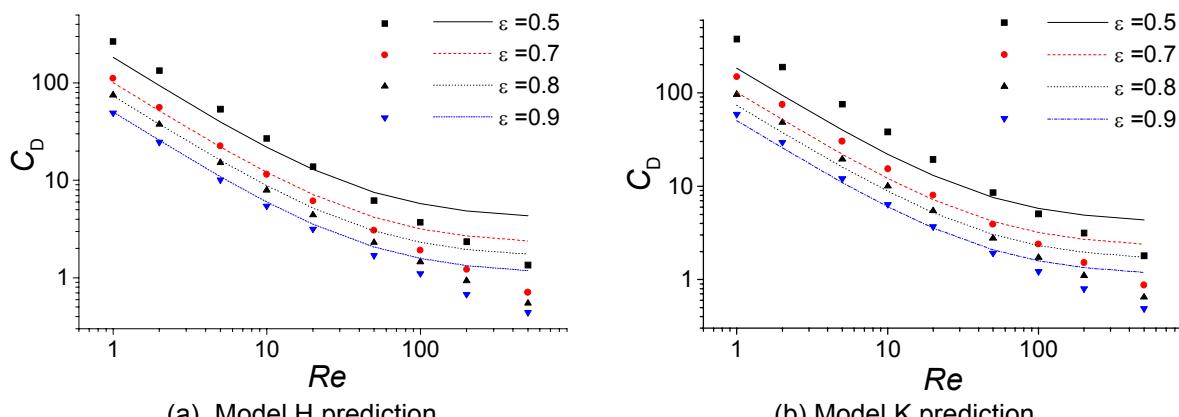

Figure 4. Comparison of the Kumar-Hartland correlation with the predicted drag coefficients for two cell models. Symbols stands for model prediction, lines are the correlation values.

## Mass Transfer Coefficient

Figure 5 shows the contour lines of solute in the continuous around a drop. It suggests that the most effective region for external mass transfer is the drop front where the solute concentration gradient is large, and that the recirculation in the drop wake distorts the concentration contour lines. The rate of external mass transfer to single drops has been studied by many authors, and Steiner [12] presented a new correlation for external mass transfer of single rigid drops ( $Re$  between 10 and 1000):

$$\frac{Sh_c - Sh_{cr}}{Sh_{ca} - Sh_{cr}} = 1 - \exp(-4.18 \times 10^{-3} Pe^{0.42}) \quad (13)$$

$$Sh_{cr} = 2.43 + 0.775 Re^{1/2} Sc_c^{1/3} + 0.0103 Re Sc_c^{1/3} \quad (14)$$

$$Sh_{ca} = (2/\sqrt{\pi}) Re^{1/2} Sc_c^{1/2} \quad (15)$$

However, the report on external mass transfer of drop swarms is rare and inconvenient. Tentative comparison between the Steiner's correlation and the prediction of  $Sh_c$  is shown in Figure 6, suggesting only partial agreement in the middle and low range of Peclet numbers. The prediction indicates obvious dependence of Sherwood number on the voidage, but the Steiner correlation ignored such a relation. It is believed that the cell model needs to be improved by taking the factors such as drop deformation, turbulence or drop oscillation into account. Besides, more proper and physical outer cell boundary conditions are desired.

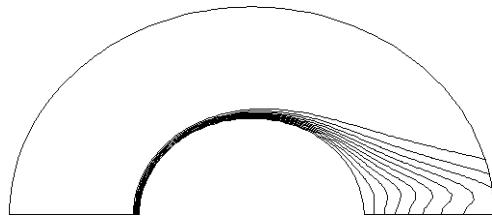

Figure 5. Concentration contour lines around a spherical drop with  $Re=100$  and  $Pe=1000$  ( $\lambda=1.33$ ,  $\zeta=0.91$ ).

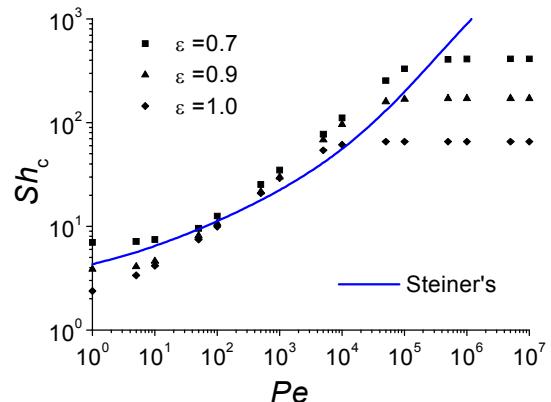

Figure 6. Comparison of the Steiner correlation with the predicted mass transfer coefficients for two cell models ( $Re=100$ ,  $\lambda=1.33$ ,  $\zeta=0.91$ ). Solid line for Steiner's correlation and symbols for cell model H prediction.

## CONCLUSIONS

Comparison of free surface cell model and free vorticity cell model with the correlations of drag coefficient of drops in spray towers indicates that Model H (free shear at the outer cell boundary) presents smaller deviation from the correlations in the range of  $Re$  below 20 and  $\epsilon$  greater than 0.7. Model K seems to overestimate the drag coefficient. Model H gives reasonable value of  $Sh$  with the same order of magnitude as the empirical correlation and presents the qualitatively correct trend. However, the cell model needs further development if its applicability is to be extended to higher Reynolds number and dense drop swarms.

## NOMENCLATURE

$C_D$	drag coefficient in a swarm, $8Rg\Delta\rho/3\rho_c U^2$
$c$	solute concentration
$D$	molecular diffusivity of solute, $\text{m}^2\cdot\text{s}^{-1}$

## MASS TRANSFER AND MICRODROPS AT INTERFACES INVESTIGATED ON MOLECULAR LEVEL

Tatiana Merzliak, Marita Schmäh, Robin Schott and Andreas Pfennig

Lehrstuhl für Thermische Verfahrenstechnik, RWTH Aachen, Germany

To investigate the origin of the various instabilities when mass transfer takes place across an interface molecular simulations have been performed on different levels of detail. Very detailed molecular-dynamics simulations give insight into the mobility of the molecules at an interface. To investigate the behaviour of a larger number of molecules for a larger time span, Monte-Carlo simulations for a lattice system have been performed. In these simulations the occurrence of nano droplets of some 1000 molecules has been observed. Based on diffusional and thermodynamic properties of the system a first stability criterion for the occurrence of the nano droplets has been derived.

### INTENTION OF THE PROJECTS

Interfaces and especially the mass transfer at interfaces as well as in the interfacial region are of great importance in many fields of chemical engineering. However, there are no models available so far which could describe mass transfer correctly in detail. Even some phenomena such as Marangoni instabilities can not be fully explained to satisfaction although it is known that these instabilities have a great influence, e.g., on liquid-liquid extraction (see e.g. [1]). The following projects were initiated aiming at examining liquid-liquid interfaces using different space and time scales. Basis for all models is the microscopic understanding of the phenomena at interfaces which is achieved by simulations on a molecular level.

### SIMULATION TECHNIQUES

For the simulation of interfaces and the interfacial region as well as in the bulk phases molecular-dynamics (MD) simulations are performed. In MD the trajectories of up to some 1000 molecules are determined by solving the equations of motion of all particles acting in the force field of all neighbours. The systems are only some nm in size and simulation times are some ns on a high-performance computer. The results correspond very well to macroscopic data regarding, e.g., equilibrium information and diffusion coefficients. Since diffusion is a relatively slow process MD is not a very efficient technique to simulate diffusion for larger systems.

Thus we have chosen to augment these simulations with a technique which does not take the detailed movements of all molecules into account but is able to model diffusive phenomena on a larger scale correctly. With lattice Monte-Carlo (MC) simulations some million particles can be simulated for a simulation time of some  $\mu$ s. Instead of solving the differential equations of motion exchange energies and probabilities of exchange between neighbouring molecules which are located on fixed lattice sites are considered. Comparison of the results obtained with both techniques show very good agreement. Thus a combination of MD and lattice-MC techniques can bridge the gap in space and time scales usually encountered.

## MD RESULTS

With MD simulations a system with a stable liquid-liquid interface was simulated consisting of Lennard-Jones particles with appropriate interaction energies. Self-diffusion coefficients are calculated based on the mean square displacement using different time steps. For an adequate time step the coefficients are examined as function of distance from the interface for the three spatial directions. The result is shown in Figure 1.

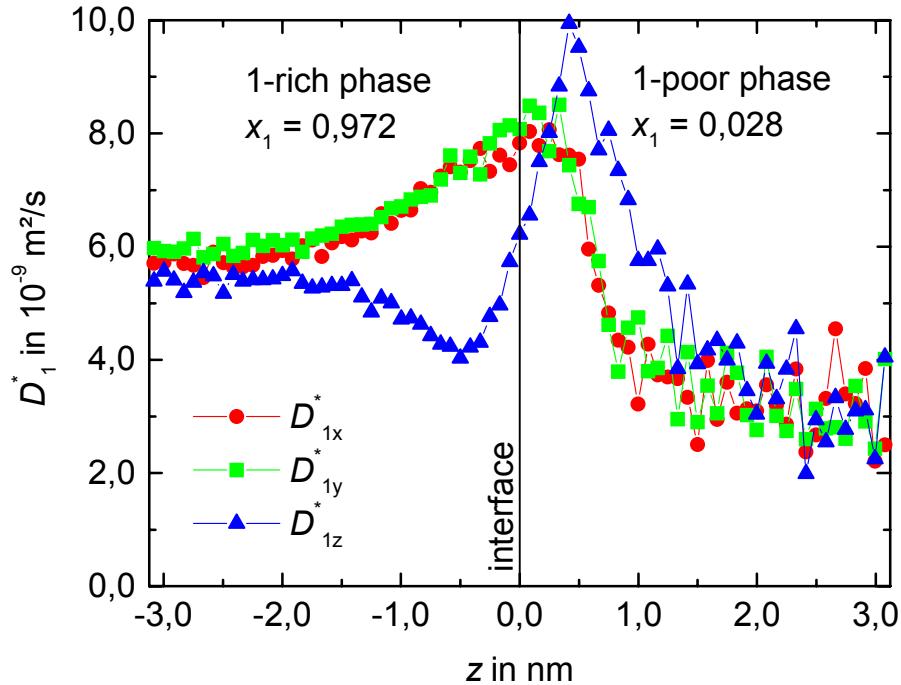

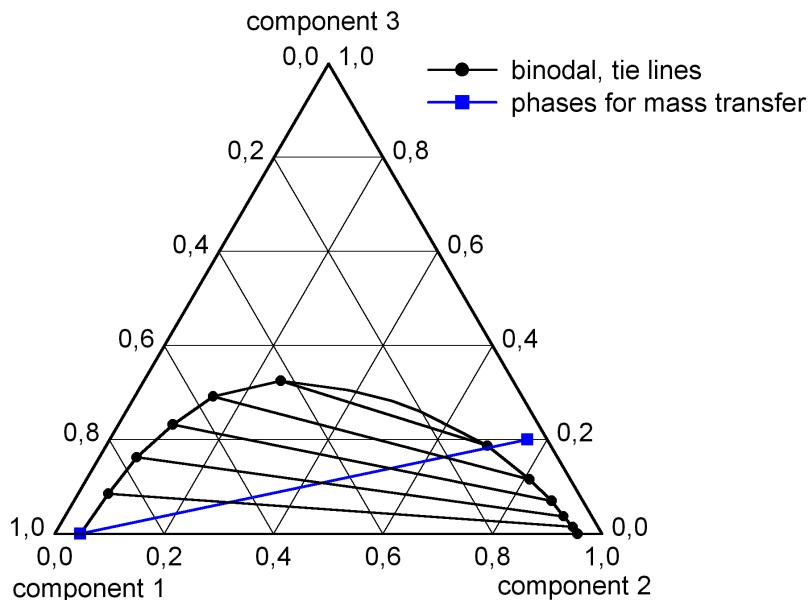

Figure 1. Diffusion coefficients as function of the distance to the interface.

In Figure 1 the self-diffusion coefficients of component 1 are shown. Since all properties of the two components present in the system are symmetrical with respect to component index, the properties of component 2 correspond to the mirror image of this plot with respect to the interface. The mutual solubility of the two components which are modelled with argon parameters is 2.8 %. The miscibility gap is induced by a less attractive cross-interaction energy between the components. Since at the interface the two phases have to interact due to geometrical reasons while they would rather prefer to separate the overall density at the interface is reduced and the mobility of the molecules described with the self-diffusion coefficient is thus increased. In the spatial directions parallel to the interface, x and y, the mobility of the molecules is identical as expected.

The deviation of the diffusion coefficient in z-direction (perpendicular to the interface) from that parallel to the interface can be explained by recalling that the partition coefficient deviates from unity. Thus the molecules of one component crossing the interface in one direction have a reduced tendency to return while this tendency is much higher when the interface is crossed in the opposite direction. Thus in this case particles of component one crossing the interface from the left to the right will return with a higher probability than if the interface would not be present. Thus the apparent mobility is reduced which leads to a smaller self-diffusion coefficient in z direction directly to the left of the interface. The opposite argument holds directly to the right of the interface leading to a self-diffusion coefficient somewhat higher than that parallel to the interface.

## LATTICE-MC RESULTS

Results of various MC simulations show that under certain conditions mass transfer across interfaces induces the formation of nano droplets in the close vicinity of the interface. It should be noted that for the occurrence of this effect roughly a million particles have to be simulated for some  $\mu\text{s}$ . The simulations are performed for a diffusion tube where the compositions of the phases brought into contact are shown in Figure 2. One of the phases is a binary equilibrium phase while to the other binary equilibrium phase 20% of the transfer component 3 are added.

*Figure 2. Phases brought into contact which lead to the formation of nano droplets.*

In Figure 3 the resulting concentration profiles in the diffusion tube are shown as function of the contact time. The grey scale shows the concentration of component 2 which is the solvent in the upper phase. To this phase the transfer component has been added which then starts to be transferred into the lower 1-rich phase. After roughly  $2 \mu\text{s}$  the occurrence of a nano droplet can be seen, where a stable region of 1-rich phase is formed within the 2-rich phase. Because of the sharp change in grey value between the nano droplet and the surrounding phase it can be concluded that this droplet has a distinct interface [2]. Some nano droplets directly above the interface are shown in Figure 4. Here only molecules of component 1 are shown which are directly connected via next-neighbour contacts to more than 100 molecules of component 1. Thus only clusters of molecules of component 1 are visualized. The rough nature of the major interface is nicely seen. Also several nano droplets of some 1000 molecules have formed at a distance of approximately 20 nm from the interface

These nano droplets can now interact among each other and with the major interface via attractive or repulsive long-range forces. The long-range forces may be assumed as resulting from attractive van-der-Waals forces between nano droplets accounted for, e.g., by the Hamaker constant and from electrostatic forces due to orientation of polar molecules at the interface and the formation of diffusive double layers at the interface if ionic species are present [3]. The different combination of the nano-droplet behaviour due to attractive or repulsive forces together with the characteristics of coalescence may then lead to different macroscopic interfacial instabilities like, e.g., spontaneous emulsification or large eruptions.

To investigate the origin of the nano droplets further and to derive a quantitative stability criterion the diffusive properties of the chosen lattice system are evaluated according to Fick and Maxwell-Stefan theory where thermodynamic behaviour is well described by the GEQUAC model [4].

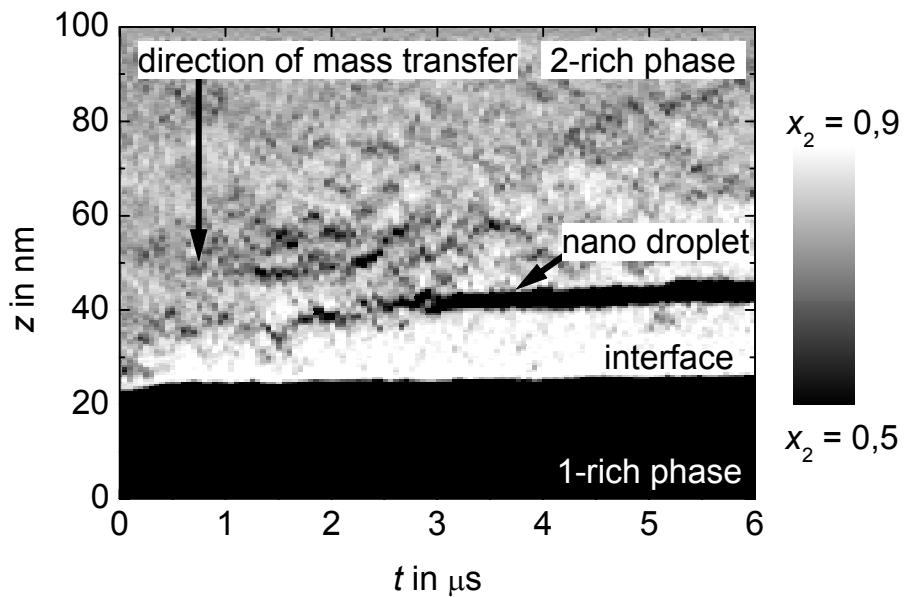

Figure 3. Formation of nano droplet induced by mass transfer.

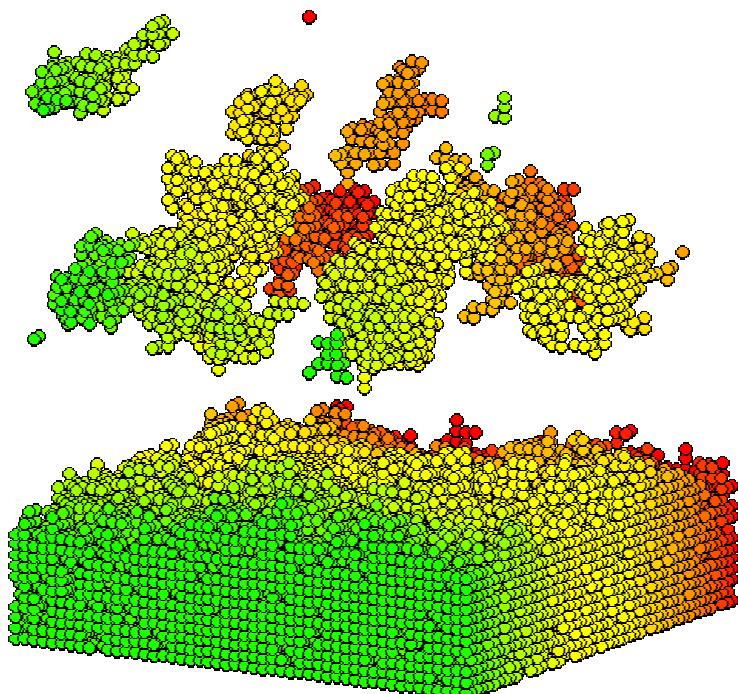

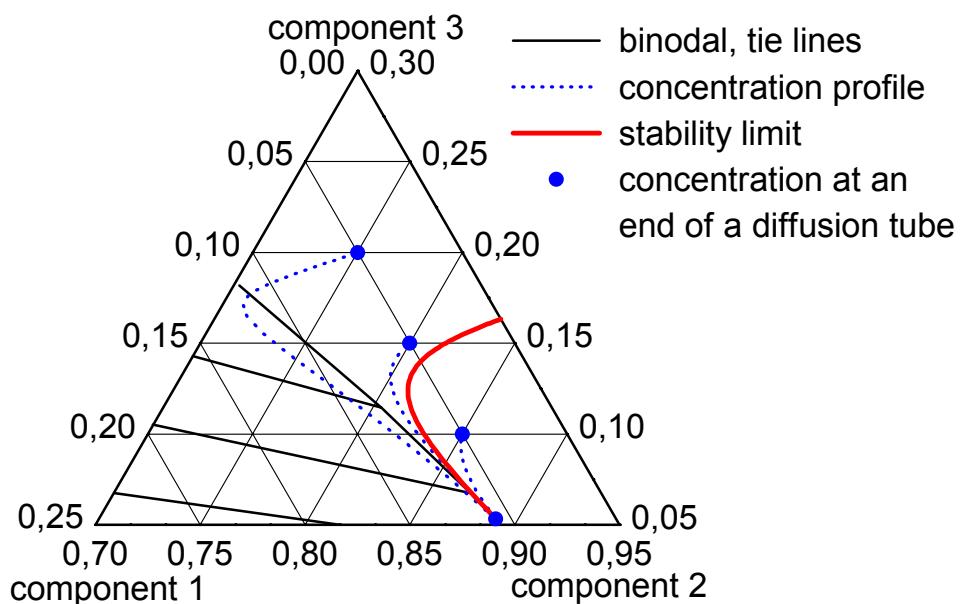

Figure 4. Some nano drops directly above the interface.

## DISCUSSION OF RESULTS

Based on the diffusive and thermodynamic properties a first stability criterion for nano-droplet formation was developed. Calculations show that the concentration profile in a diffusion tube may cross the binodal even if the connecting line between the concentrations corresponding to the ends of a diffusion tube runs outside the miscibility gap (Figure 5). The stability criterion in Figure 5 does not yet take interfacial tension into account. The consideration of the interfacial tension causes shifting of the stability limit towards the spinodal.

*Figure 5. Stability criterion.*

Future work will be directed at the development of a quantitative understanding of the discussed effects and an improvement of the stability criterion.

# STUDY OF SALT EFFECTS ON THE KINETICS OF SOLUTE TRANSFER AND EXTRACTION AT A FREE LIQUID/LIQUID INTERFACE

Jean-Pierre Simonin and Hendrawan Hendrawan

Laboratoire Liquides Ioniques et Interfaces Chargées, Université P.M. Curie, Paris, France

The effect of a salt on the kinetics of (*i*) transfer of acetic acid and (*ii*) extraction of metal cations, Co<sup>2+</sup> and Zn<sup>2+</sup>, by di(2-ethylhexyl) phosphoric acid (D2EHPA), was studied using the rotating membrane cell technique. In case (*i*), the kinetic rate of transfer could not be correlated with the value of the activity coefficient of solute in the aqueous phase. In case (*ii*), it was found that the reaction is unlikely to be purely interfacial. The effect of salt on the kinetics was interpreted in terms of metal-(salt anion) association, transfer of extractant into the aqueous phase and primary electrolyte effect on the extractant-metal reaction in the aqueous phase.

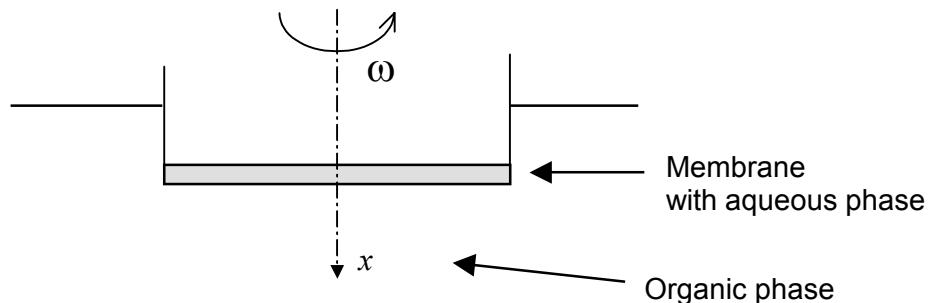

## INTRODUCTION

The use of a salt, added to the aqueous phase, to modify the partitioning or the extraction velocity of a solute is well known. In contrast with the former issue, references that have addressed the latter issue are rather scarce: one of the first papers mentioning this effect was written by McClellan *et al.* in 1971 [1] in which acceleration of the kinetics of extraction of Fe(III) was observed by addition of NaClO<sub>4</sub>. The papers published subsequently have generally considered the effect of simple inorganic salts such as LiCl, NaCl, NaClO<sub>4</sub> on the extraction kinetics of metal cations, including Fe(III) [2,3], Cu(II) [4] or Zn(II) [5], by an extractant in a diluent. Another paper considered the extraction of HCl by trilaurylamine in toluene [6]. In these references, salt effects were regarded either from a chemical viewpoint when the major factor was expected to be the formation of a complex between the solute and an ion of the salt, or from a physical viewpoint, with a dominant effect of departures from ideality. In the latter case, quantitative descriptions rested on the assumption (e.g., [4-7]) that any kinetic parameter *k* appearing in the kinetic equations should be replaced by *kγ*, where *γ* denoted an activity coefficient. This procedure sometimes [4] involved an estimation of the individual activity coefficient of an ion, with well-known problems associated with assessing this quantity [8]. In other papers [6,7], the mean salt activity coefficient was taken instead of the individual activity coefficient. So, influence of the salt on the solute in the bulk alone was taken into account, although the reaction was believed to occur at the interface. Besides, if the main reaction pathway is not interfacial and involves transport of the extractant into the aqueous phase, then addition of salt may change the solubility of the extractant and this could contribute to modify the kinetics. This is what may happen for an acidic extractant such as di(2-ethylhexyl) phosphoric acid (D2EHPA) [2,5] for which complexation has been reported to occur in a region near the interface [9,10].

In this paper, a study of salt effects on solute transfer [11] kinetics, which topic has not been investigated before, is presented first. Next, the case of the extraction kinetics of metal cations by D2EHPA is considered; this first approach is aimed at an elucidation of the mechanisms of extraction, which are still unclear, and electrolyte effects on this type of system. The use of a technique that controls the hydrodynamics is of primordial importance for that purpose. Here, the rotating membrane cell technique is employed. Its principle is described in the following section.

## DESCRIPTION OF THE TECHNIQUE

The characteristics of the rotating membrane cell (RMC) technique [12] are described below. A sketch of the set-up is shown in Figure 1. The cell consists of a thin Millipore™ membrane (hydrophilic PVDF, HVLP type), ca. 120 µm thick and 0.8 cm in diameter, that is glued on the base of a cylinder made of Perspex with the use of a polyurethane mastic (Scotch-Seal 5300). This mastic was chosen for its excellent chemical resistance to organic solvents.

*Figure 1. Sketch of the RMC. Membrane: thickness = 120 µm, diameter = 8 mm.*

The membrane contained the aqueous phase. It was set into rotation at a known speed and, at  $t=0$ , it was immersed into the organic phase. Analysis of the extracted matter was performed by using radio-labelled species. The membrane was chosen for its good chemical compatibility with acid solutions and aliphatic solvents. Its average pore size was 0.45 micron (manufacturer's value). The experimental value found for the void porosity was  $\sigma = 0.685 \pm 0.015$ , compared to the manufacturer's value of 0.70.

The main feature of the RMC is that diffusive transport is controlled in both phases. Moreover, the diffusion coefficients of solute may be measured experimentally with a suitable technique. Then, the contributions from Fickian diffusion in the membrane and convective transport in the outer phase may be subtracted from the overall process, so yielding the contribution from interfacial transfer alone. Previous work [13] has shown that good control of the hydrodynamics is achieved with this technique. Thus the RMC technique does not require prior calibration.

In contrast with the rotating diffusion cell of Albery, the RMC method operates in a transient regime. For a purely interfacial reaction, the proportion of matter transferred from the aqueous phase (denoted by A) to the organic phase (B) may be expressed as [12]

$$P(t) \approx 1 - \exp(-t/\tau) \quad (1)$$

in which  $\tau$  is the mean time for the transfer of solute from A to B. It is given by

$$\tau = \tau_f + \tau_A + \tau_B \quad (2)$$

with

$$\tau_f = L / k_f \quad ; \quad \tau_A = L^2 / (3 D_A) \quad ; \quad \tau_B = L \sigma \delta / (K D_B) \quad (3)$$

Here  $L$  is the membrane thickness,  $D_X$  is the diffusion coefficient in phase X,  $k_f$  is the A-to-B ("forward") rate constant,  $\tau_f$  is the characteristic time for the interfacial forward reaction,  $\tau_A$  represents the mean diffusion time in the membrane and  $\tau_B$  is the mean residence time of the species in the diffusion layer. The parameter  $\delta$  represents the diffusion layer thickness, given by

$$\delta = 1.612 (\nu/\omega)^{1/2} / Sc^{1/3} \quad (4)$$

in which  $Sc = \nu/D_B$  is the Schmidt number,  $\nu$  is the kinematic viscosity of B and  $K$  is the partition coefficient ( $K = k_f/k_r$ , with  $k_r$  the reverse rate constant). In the case where the interfacial kinetics are very fast ( $k_f$  and  $k_r$  infinite, but still  $k_f/k_r = K$ )  $\tau$  becomes

$$\tau_\infty = \tau_A + \tau_B \quad (5)$$

which gives the diffusive limit (DL) for the extracted rate of matter :  $P_\infty(t) = 1 - \exp(-t/\tau_\infty)$ .

## STUDY OF SOLUTE TRANSFER KINETICS

The solutions were composed of  $0.01 \text{ mol L}^{-1}$  HCl,  $10^{-3} \text{ mol L}^{-1}$  acetic acid (to avoid adsorption), salt and were spiked with tracer amounts of radio-labelled acetic acid. The organic phase was isopropyltetradecanate (isopropylmyristate). The diffusion coefficients of acetic acid (AA) in the aqueous phases (containing salt),  $D_{\text{sol}}$ , were determined using the open-ended capillary technique. Then the apparent diffusion coefficient in the membrane,  $D_A$ , was obtained from the values of  $D_{\text{sol}}$  and the measurement of the membrane tortuosity factor, performed using impedance spectroscopy [12], yielding:  $D_A = D_{\text{sol}}/1.88$ . The activity coefficient of acetic acid in the aqueous phase was determined experimentally by classic solvent partitioning. All experiments were conducted at room temperature  $22 \pm 1^\circ\text{C}$ . In absence of salt, we obtained a value for the rate constant,  $k_f^{(0)} = (2.4 \pm 0.1) \times 10^{-6} \text{ m s}^{-1}$ . This value compares well with a previous value of  $2 \times 10^{-6} \text{ m s}^{-1}$  obtained with a similar cell [14], in which a gel was used instead of membrane.

In Figure 2, the experimental values for  $k_f$  vs. LiCl concentration are compared [13] with the quantity  $\gamma k_f^{(0)}$ ,  $\gamma$  being the activity coefficient of AA in the solution containing salt.

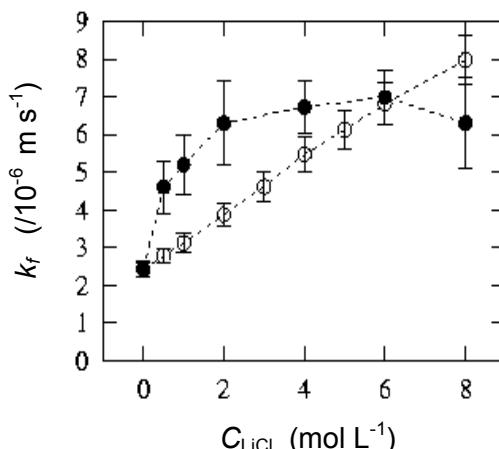

Figure 2. Kinetic rate  $k_f$  variation vs. LiCl concentration. Experimental result (●) compared with  $\gamma k_f^{(0)}$  (○). Vertical bars indicate experimental uncertainty.

It is seen that, for finite salt concentrations, the two plots do not coincide, except at high concentration around  $6 \text{ mol L}^{-1}$ . The same qualitative behaviour was observed in the case of NaCl and KCl. Therefore, the common assumption that activity should replace concentration is not verified in the present case. This observation may be attributed to the fact that, as mentioned in the Introduction section, the effect of the salt on the solute at the interface has not been taken into account. However a conclusive interpretation of this phenomenon seems difficult to give at present. A priori this effect may result from interplay between several effects such as ion-solute interactions, change of solute hydration, as well as dynamical effects, all occurring in the interfacial region. Nonetheless, the model assuming that  $k_f$  should coincide with the quantity  $\gamma k_f^{(0)}$  may be supplemented by the introduction of the activity coefficient of an “intermediate”, or “activated” species, as in Brönsted's postulate [15]. This gives

$$k_f = \gamma k_f^{(0)} / \gamma_X \quad (6)$$

where X denotes the “activated” AA. This relation may be justified by using a barrier-crossing model, as utilised in earlier work [14]. In this framework, X is located at the barrier top and is expected to correspond to an intermediary state of incomplete solvation. Then, equation 6 may be derived [13] by noting that the activation energy is decreased by a quantity of  $k_B T \ln(\gamma/\gamma_X)$  ( $k_B$  is the Boltzmann constant and  $T$  the temperature) corresponding to the change in the difference between the chemical potential of the solute in the aqueous bulk and at transition state. The results of Figure 2 show that  $\gamma_X \leq 1$  between 0 and  $6 \text{ mol L}^{-1}$ ; this suggests that the free energy of the solute at the interface be decreased by addition of salt; at higher concentration  $\gamma_X > 1$ . The

decrease of  $\gamma_X$  at low and moderate salt concentration may be interpreted in terms of direct ion-solute (e.g. ion-dipole), or indirect water-mediated attractive interactions and excluded volume effects that are less important at the interface than in the bulk because of the depletion in the interfacial ionic population. However, one must keep in mind that dynamical effects, that are not included in the above barrier model, may play an important role [16] because the time scale for solvation exchange dynamics is likely to be comparable with the time scale of the interfacial transfer process. So, ions may modify the water re-organisation dynamics around the acetic acid molecules in the interfacial region and this could facilitate the transfer of acetic acid.

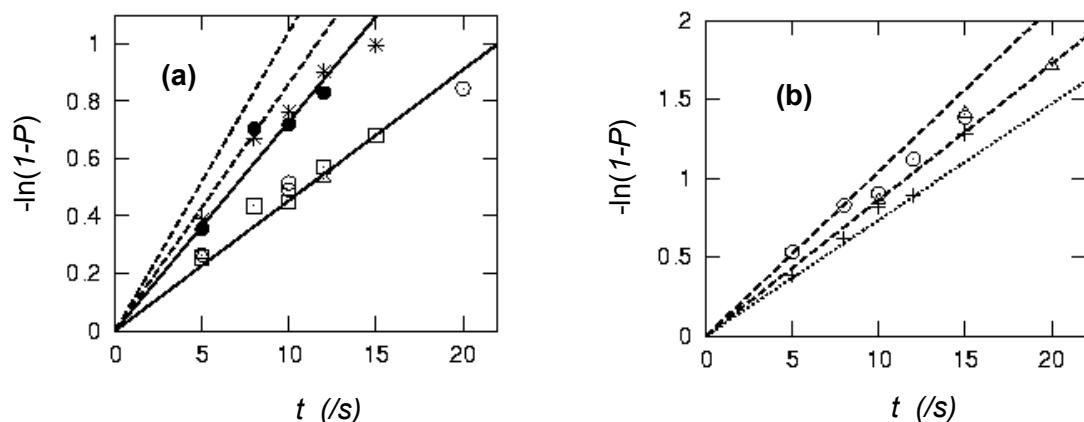

## STUDY OF EXTRACTION KINETICS

The effect of a salt, added to the aqueous phase, on the kinetics of extraction of Co(II) and Zn(II) by 0.02-0.5 mol L<sup>-1</sup> D2EHPA in dodecane were studied for various salts, at pH's between 3 and 5. The concentration of radioactive Zn(II) in the aqueous phases was on the order of 10<sup>-4</sup> mol L<sup>-1</sup>; for Co(II) it was 2×10<sup>-8</sup> mol L<sup>-1</sup>. No inactive solute was added (it was verified that addition of 10<sup>-3</sup> mol L<sup>-1</sup> metal ion did not change the result). The possibility of using tracer amounts of Co(II) was an interesting feature (see below). An advantage of Zn(II) was that it led to high values of the partition coefficient  $K$ . Thus, the processes on the organic side of the interface (re-extraction and transport) should not influence the kinetics of this solute [17]; instead, the kinetics may be expected to be controlled by diffusion in the membrane and processes in the interfacial aqueous region. In this study, the extractant D2EHPA was purified using the method of Partridge and Jensen. The diluent (dodecane) was purified using silica powder. In the case of metal cations extracted by D2EHPA, the extraction mechanism is not firmly established yet, some authors proposing an interfacial process while others suggest transport of the extractant into the aqueous phase accompanied by reaction in a thin zone near the interface [18]. Thus, the aqueous/organic partitioning of D2EHPA was studied experimentally, using standard phosphate titration.

Firstly, the influence of the identity of the anion was investigated. So, solutions of HCl, HNO<sub>3</sub>, HClO<sub>4</sub> and a 0.1 mol L<sup>-1</sup> acetate buffer, at pH=3, were prepared, together with a HNO<sub>3</sub> solution (pH 3) that was equilibrated with a 0.2 mol L<sup>-1</sup> D2EHPA. For these solutions the concentration of the anion of the salt is on the order of 10<sup>-3</sup> mol L<sup>-1</sup>. Then these solutions were used to study the extraction kinetics of Co(II) by a 0.2 mol L<sup>-1</sup> D2EHPA solution. The rotation speed of the cell was 800 rpm. The result of these experiments is depicted in Figure 3(a), in which -ln(1-P) is plotted against  $t$  (see equation 1). It is seen that the kinetics for the acetate buffer and the equilibrated HNO<sub>3</sub> are significantly above those for the other solutions. Moreover, for the latter, the extraction velocity is found to be independent of the nature of the anion.

The fact that the rates for equilibrated nitric acid (ENA) and acetate buffer coincide is striking. Moreover, they are close to the prediction for the diffusive limit (DL) for cobalt in ENA (the region between the two dashed lines in Figures 3(a) and (b)), which was computed as follows: the diffusion coefficients of Co(II) in ENA was measured (by spiking ENA solution with radio-labelled cobalt ion), yielding  $D_{CoENA} \pm SD$  within the membrane; then the values  $D_{CoENA} + SD$  and  $D_{CoENA} - SD$  were plugged into equations 1 and 5. Let us denote by CIDL the corresponding confidence interval for the DL. The difference observed between equilibrated and non-equilibrated HNO<sub>3</sub> solutions suggests that the presence of D2EHPA in the aqueous phase (concentration of D2EHPA measured in ENA pH3 = 1.1×10<sup>-4</sup> mol L<sup>-1</sup>) accelerates significantly the kinetics, which becomes diffusion-controlled. In this case, we may suppose that a complex is formed between Co(II) and the extractant in the aqueous phase; according to this picture,  $D_{CoENA}$  is the diffusion coefficient of the complex in the aqueous phase. Figure 3(a) shows that the rate of extraction from ENA seems to be mainly controlled by diffusion; the transfer of cobalt from ENA is fast. Results at pH 5 for a 0.1 mol L<sup>-1</sup> acetate buffer are shown in Figure 3(b). For this system, the experimental points are located above the diffusive limit for the cobalt ion in the buffer (lower dotted line); however, they lie within the CIDL (dashed lines) at 600 and 800 rpm. In the case of

Zn(II), the kinetics were found to be fast with all anions; moreover, they were faster than the DL for all aqueous solutions.

*Figure 3 (a) and (b). Influence of the nature of the anion on the kinetics. Plot of  $-\ln(1-P)$  vs. time. (a) Experimental results: equilibrated  $\text{HNO}_3$  (●), acetate buffer (\*)  $\text{HNO}_3$  (○),  $\text{HClO}_4$  (□),  $\text{HCl}$  (Δ). Solid lines: adjustments using equation 1; dashed lines: CIDL for cobalt in ENA. (b) Kinetics with acetate buffer at pH 5: rotation speed = 400 rpm (+), 600 rpm (Δ), 800 rpm (○). Dotted line: DL for cobalt ion in the buffer; dashed lines: CIDL for cobalt in ENA.*

The fact that the experimental rate can exceed the DL in some cases (in Figure 3(b) and for Zn(II)) is *a priori* an anomalous result. However, it may be interpreted according to a mass transfer with chemical reaction (MTWCR) process [9,10,18] in which the metal cation reacts with (the ionised form of) D2EHPA in the aqueous phase and is then transferred to the organic phase. Such a mechanism is suggested by the experiments using ENA. Besides, in Figure 3(b), the anomaly is removed if  $D_{\text{CoENA}}$  is taken to compute the DL because, actually, the value measured for  $D_{\text{CoENA}}$  was indeed found to be greater than that of cobalt in the pH5 buffer; then, the kinetics correspond to a diffusion-controlled process. Within this framework, the reaction of D2EHPA with Zn(II) is fast for all anions; it is fast with Co(II) for the acetate ion and slower for the other anions. We notice that fast kinetics have previously been found for Zn(II) in HClO<sub>4</sub> [9], and that the acceleration produced by the acetate ion has been observed in earlier work [19] for cobalt. The latter effect was explained by a complexation of cobalt by acetate, accompanied by a removal of co-ordinated water molecules; since the release of water was believed to be the limiting step, it was proposed that the acetate complex was a more reactive species. When the kinetics are slow, the present results do not help to discriminate between an interfacial and a MTWCR process; both processes may occur. For fast reactions, it must be underlined that the above scenario supposes that the extractant be transferred rapidly enough to the aqueous phase. However, to our knowledge, the transport process of D2EHPA into an aqueous phase is not well known. Besides, the kinetics were found to be independent of the D2EHPA concentration, in the range 0.1-0.5 mol L<sup>-1</sup>, for HNO<sub>3</sub> pH3 (results not shown); this fact seems difficult to reconcile with the MTWCR picture. Therefore, the elucidation of the extraction mechanism will require further investigation.

Lastly, the effect of salt concentration was studied at constant pH, pH=3. Figure 4 presents the variation of the quantity  $\tau - \tau_B$  vs. the concentration of the anion for zinc and cobalt extraction. Here,  $\tau$  was determined by fitting eq 1 to the experimental data;  $\tau_B$  was computed from eq 3. The value of  $\tau_A$  is ca. 10.6 s for Co(II) complexed by D2EHPA in ENA. Figure 4 shows that the kinetics of zinc extraction are not modified greatly by the addition of nitrate ion, the kinetics remaining apparently fast. In the case of cobalt, nitrate and perchlorate slow down the kinetics similarly (great values of  $\tau$  correspond to slow kinetics). In the latter case, if we assume that it is the reaction of D2EHPA (solubilised in the aqueous phase) with cobalt that controls the kinetics,

then it is easy to show that  $\tau_f$  should be replaced by  $k^{-1}$  in equation 3. With  $k$  the apparent rate constant for the reaction in the aqueous phase; then, taking  $\tau_A=10.6$  s, we find that  $k$  would be roughly decreased by a factor of 3 or 4 when the anion concentration is varied from  $10^{-3}$  to 1 mol L<sup>-1</sup>. It is interesting to notice that this variation of  $k$  may be interpreted by a primary kinetic salt effect on the homogeneous reaction between cobalt and D2EHPA: a plot of  $\log_{10}(k/k_0)$  against  $I^{1/2}$ , with  $I$  the ionic strength, can be represented using the extended Debye-Hückel version of Brönsted formula [20,21] with a closest approach distance of ca.  $8\times 10^{-10}$  m, which is a realistic value. It is clear however that, although appealing, such an interpretation will require prior confirmation of the extraction mechanism.

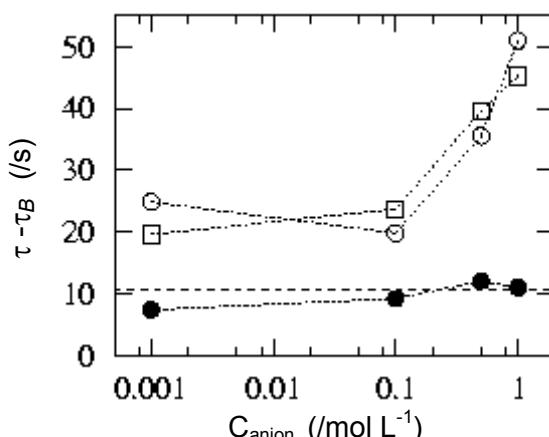

Figure 4. Influence of anion concentration on the kinetics. Plot of  $\tau - \tau_B$ . Kinetics for Co(II) in  $\text{HNO}_3$  ( $\circ$ ), in  $\text{HClO}_4$  ( $\square$ ), and Zn(II) in  $\text{HNO}_3$  ( $\bullet$ ). Horizontal dashed line:  $\tau_A$  for Co(II) in ENA.

# COMPUTER SIMULATION OF THE MASS TRANSFER PROCESS BETWEEN A SINGLE DROP AND AN UNBOUNDED CONTINUOUS PHASE

Agustín R. Uribe, Mariana P. Santamaría and W. J. Korchinsky\*

Universidad de Guanajuato, Guanajuato, México

\*University of Manchester Institute of Science and Technology, Manchester, England

A computer simulation of the mass transfer process of a single solute between two immiscible liquid phases is carried out by solving the dimensionless conservation equations for momentum and mass transport simultaneously using Computational Fluid Dynamics techniques. The simulation involves Reynolds numbers up to 450 and Peclet numbers of 100, 1000 and 10,000. In this work, the single drops are considered spherical in shape with no surface-active contaminants and no turbulence. Some concentration profiles and theoretical results are presented.

## INTRODUCTION

The study of fluid flow and mass transfer from drops to an immiscible continuous phase is of fundamental importance in many industrial processes such as liquid-liquid extraction. With the results from these studies it is possible to estimate the rate of extraction and, therefore, the efficiency of the extraction column. Although much experimental work has been carried out over the years, it is until recently that, with the use of powerful computers and sophisticated numerical methods, it has been possible to study this process from a more fundamental point of view. The Computational Fluid Dynamics (CFD) techniques developed and improved since the 1980s have helped increase the accuracy and speed of the solution to the conservation equations using more advanced and powerful hardware and software.

In general, multiphase flow is not solvable by CFD [1], but there are some cases where reasonable solutions are possible, such as when the second phase appears as a discrete particle of known size and shape whose motion may be approximately computed with drag coefficient formulations or rigorously computed with refined meshes applying boundary conditions at the particle surface. Attempts to predict the shape and movement of drops travelling through a continuous phase have been proposed by several authors [2].

Frequently, the study of mass transfer to or from liquid drops is carried out experimentally, but a numerical solution to the conservation equations is presented here. The results obtained from these studies are of importance in equipment design, since they allow the prediction of the mass transfer rate in multi-drop systems. In this work it is assumed that the drops are spherical and axisymmetric travelling at intermediate Reynolds numbers [3] and Peclet numbers ranging from 100 to 10,000. It is also assumed that there is only mass transfer of one solute between the phases.

## THEORETICAL TREATMENT

The conservation equations of motion and diffusion used in the present study are as follows:

$$\frac{\partial \mathbf{v}}{\partial \Theta} = \frac{1}{Re^C} \nabla^2 \mathbf{v} - \mathbf{v} \cdot \nabla \mathbf{v} - \nabla P \quad (1)$$

$$\frac{\partial \mathbf{v}}{\partial \Theta} = \frac{1}{Re^D} \nabla^2 \mathbf{v} - \mathbf{v} \cdot \nabla \mathbf{v} - \nabla P \quad (2)$$

$$\frac{\partial x_i}{\partial \Theta} = \frac{1}{Pe^C} \nabla^2 x_i - \mathbf{v} \cdot \nabla x_i \quad (3)$$

$$\frac{\partial y_i}{\partial \Theta} = \frac{1}{Pe^D} \nabla^2 y_i - \mathbf{v} \cdot \nabla y_i \quad (4)$$

where the superscript  $D$  represents the dispersed phase and  $C$  represents the continuous phase,  $x_i$  is the mass fraction of the solute in the continuous phase and  $y_i$  is the mass fraction in the dispersed phase. The following dimensionless variables are used

$$\mathbf{v}^* = \frac{\mathbf{v}}{U_\infty}, \quad \nabla^* = d \nabla, \quad P = \frac{P^*}{\rho U_\infty}, \quad y_i = \frac{y_i^* - y_i^0}{m x_i^\infty - y_i^0}, \quad m x_i = \frac{m x_i^* - y_i^0}{m x_i^\infty - y_i^0}, \quad r = \frac{r^*}{d}$$

where the superscript \* represents the untransformed variables and  $m$  is the mass distribution coefficient. The following dimensionless groups result from the conservation equations.

$$Re^P = \frac{\rho^P d U_\infty}{\mu^P} = \frac{\text{Convective transport of momentum}}{\text{Molecular transport of momentum}} \quad (5)$$

$$Pe^P = \frac{U_\infty d}{D^P} = \frac{\text{Convective transport of mass}}{\text{Diffusive transport of mass}} \quad (6)$$

$$\Theta = \frac{t U_\infty}{d} = \frac{\text{Drop rising time}}{\text{Time to travel a distance equivalent to a drop diameter}} \quad (7)$$

In these equations,  $U_\infty$  is the drop rising velocity,  $d$  is the drop diameter,  $y_i^0$  is the initial mass fraction in the dispersed phase,  $x_i^\infty$  is the solute mass fraction far from the drop interface into the continuous phase,  $\rho^P$  and  $\mu^P$  are the density and viscosity of the  $P$ -phase, respectively. The physical limiting conditions imposed on the problem are

$$x_i = 1, \quad y_i = 0, \quad \mathbf{v} = \delta_x \quad \text{at} \quad t = 0 \quad (8)$$

$$x_i = 1, \quad \mathbf{v} = \delta_x \quad \text{at} \quad r \rightarrow \infty \quad (9)$$

$$\frac{\partial y_i}{\partial r} = 0, \quad \frac{\partial \mathbf{v}}{\partial r} = 0 \quad \text{at} \quad r \rightarrow 0 \quad (10)$$

$$y_i = m x_i, \quad \mathbf{v}^x = \mathbf{v}^y \quad \text{at} \quad r = 1/2 \quad (11)$$

$$\mathbf{j}_r^x = \mathbf{j}_r^y, \quad \boldsymbol{\tau}_{r\theta}^x = \boldsymbol{\tau}_{r\theta}^y \quad \text{at} \quad r = 1/2 \quad (12)$$

Where  $r = 1/2$  at the drop surface and  $\delta_x$  is the unit vector in the  $x$ -direction. The initial solute mass fraction in the continuous and the dispersed phases, as well as the initial fluid velocity, are given in Equation (8); the solute mass fraction and the fluid velocity far from the drop surface into the continuous phase are given in Equation (9); the conditions of symmetry at the centre of the drop (zero flux) are given in Equation (10); the mechanical and the phase equilibrium at the drop surface are given in Equation (11) and, finally, the continuity of the mass and the momentum flux at the drop surface are given in Equation (12). The equations (1)-(4) are solved in their dimensionless form in order to simplify the representation and interpretation of the results and the possibility to use them for any liquid-liquid system. These equations are nonlinear due to the inertial terms, therefore the solution is complicated to

achieve. The ratio of the convective terms to the diffusive terms is given by the Reynolds number ( $Re$ ) for the momentum transport and by the Peclet number ( $Pe$ ) for the mass transport equation. At larger  $Re$  and  $Pe$ , the solution is quite difficult to achieve due to instability problems, leading to the use of a mesh with a very large number of nodes with the corresponding increase in the computational time. The larger  $Re$  used was 450 based on the properties of the continuous phase and the larger  $Pe$  was 10,000. Although these do not represent the real systems, the solution obtained is suitable for comparison purposes. The dimensionless hydrodynamic time,  $\Theta$ , represents the ratio between the rising time and the time taken by the drop to travel its own diameter.

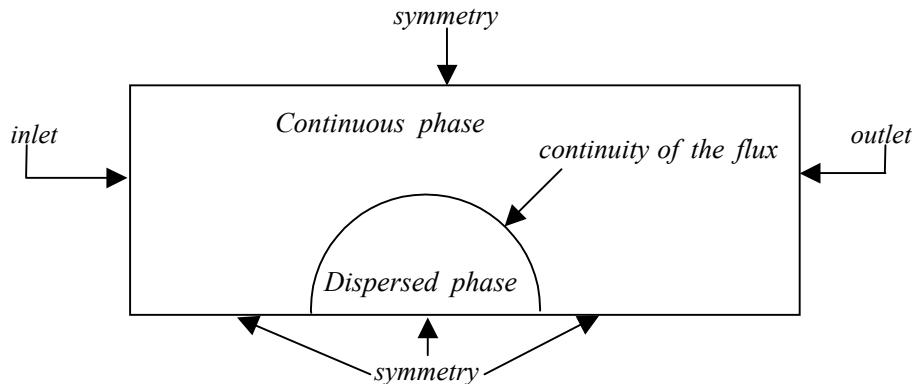

Figure 1. Schematic representation of the computational domain

The computational boundary conditions used here are different from those on the physical system, because they are adjusted to the computational domain, as shown in Figure 1.

## NUMERICAL RESULTS

The system of equations (1)-(4) was solved using the finite element method [4] in a Silicon Graphics Workstation model sgi 1400 with two Pentium-III Xeon processors. The Finite Element computer code FEMLAB [5], based on MATLAB for solving partial differential equations, was used. The momentum and mass transport equations were solved in unsteady state.

Two important assumptions were considered in the solution of the system of equations: a) the drops are completely spherical and b) the problem is axisymmetric. In this work it is considered that there is only one component transferring between the phases, although the presence of more than one component is common and it would lead to a more complicated solution.

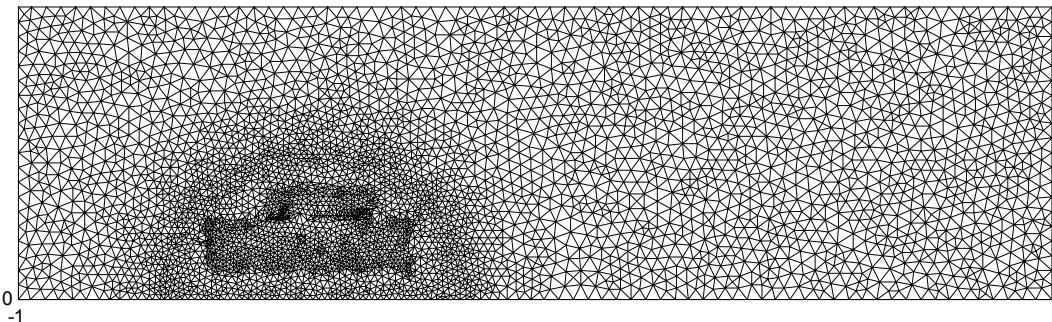

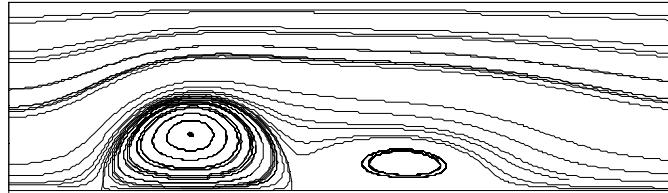

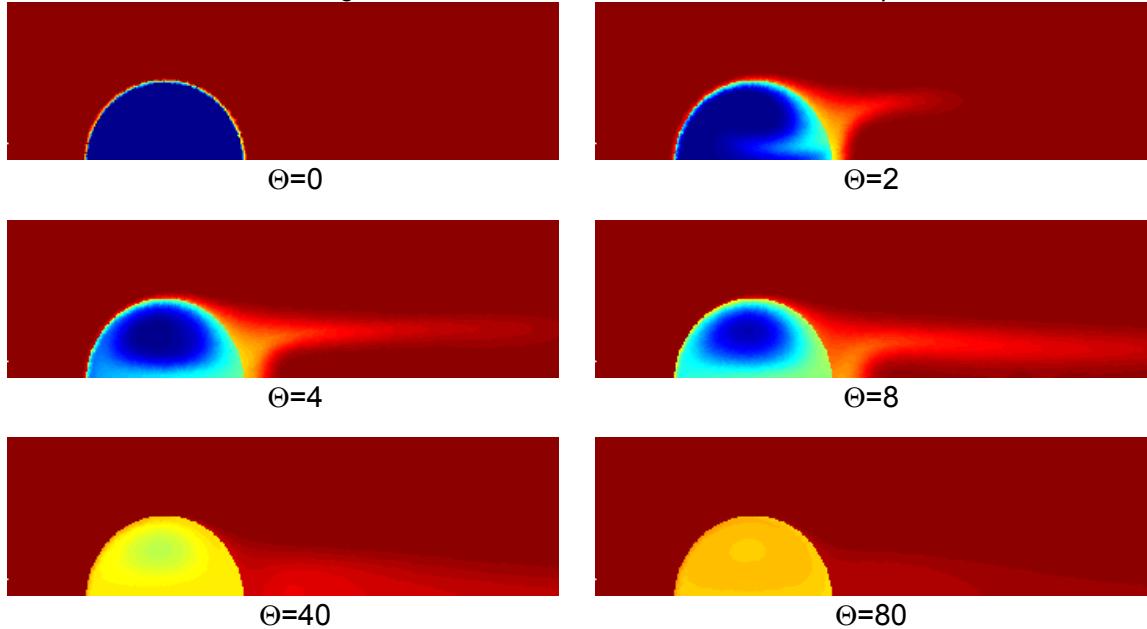

Figure 2. Typical computational mesh (nodes: 4563, triangles: 8906).

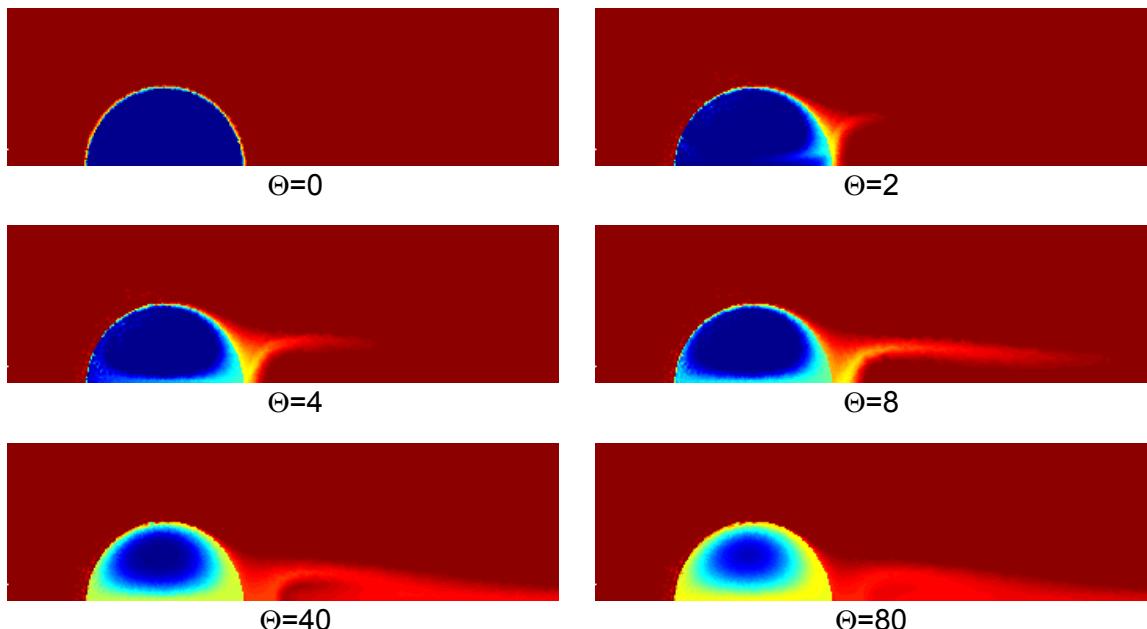

A typical mesh, which consists of 4563 nodes and 8906 triangles, is shown in Figure 2. The streamlines around the drop at the beginning of the mass transfer process are shown in Figure 3 which represent the velocity field. In this figure it can be observed that a wake is formed behind the drop, detached from the drop interface, which affects the drop movement and the mass transfer rate.

*Figure 3. Streamlines inside and around the drop.*

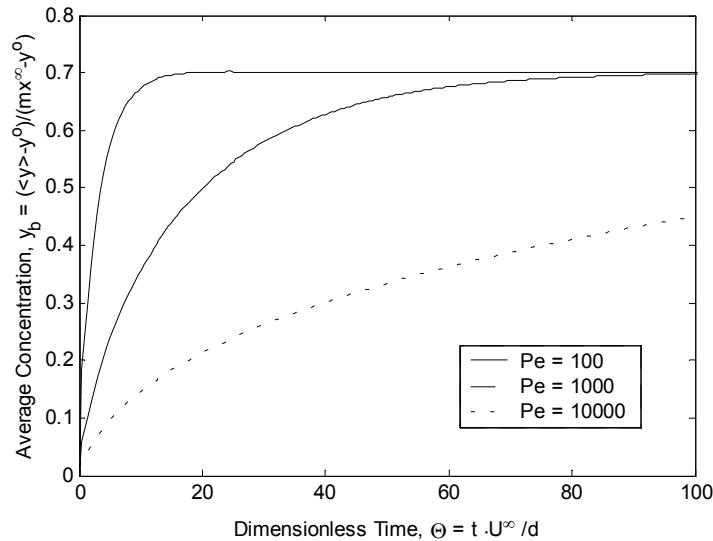

*Figure 4. Concentration profiles for  $Re^C = 26$ ,  $Re^D = 66$ ,  $Pe^P = 1000$ , at different values of  $\Theta$ .*

*Figure 5. Concentration profiles for  $Re^C = 26$ ,  $Re^D = 66$ ,  $Pe^P = 10,000$ , at different values of  $\Theta$ .*

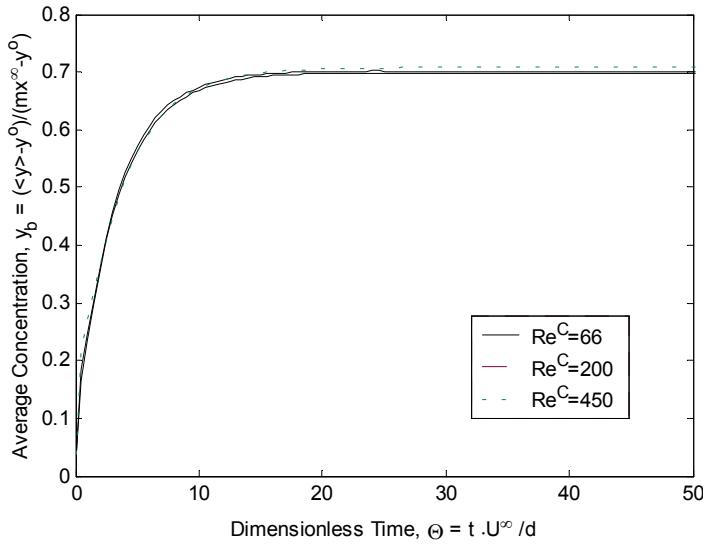

Two sequences of graphics representing the development of the concentration distribution of the solute between the drop and the continuous phase are shown in Figures 4 and 5. The value of the distribution coefficient ( $m$ ) used in these simulations is 0.7. It is worth noting that steady state is reached at approximately  $\Theta = 40$  for  $Pe^P = 1000$ ,  $Re^D = 26$  and  $Re^C = 66$ , whereas for  $Pe^P = 10,000$  at the same values of the Reynolds numbers, the steady-state is not yet reached at  $\Theta = 80$ .

It is observed that for larger Peclet numbers at the same Reynolds number, the time taken by the drop to reach the steady state is longer because the inertial terms remain the same, but the diffusive terms are smaller, therefore affecting the mass transfer rate. At larger Reynolds numbers, the nonlinear inertial terms become more important leading to a solution more difficult to achieve due to the presence of oscillation. In these figures, it can be observed that, in the absence of turbulence or oscillations, the solute travels around the drop in a circular motion passing from the front to the rear stagnation point along the surface and comes back to the front through the axis of symmetry. The solute is transported from the drop surface to the stagnation ring by diffusion. Since the diffusion is a slow process, the time taken by the solute to go from the drop surface to the stagnation ring is much longer than the time taken to travel around the drop surface. If the convective transport rate of mass is kept constant, as the Peclet increases the diffusive term decreases and therefore the solute takes longer to travel from the surface to the bulk of the drop.

*Figure 6. Plot of dispersed phase average concentration vs dimensionless time for  $Re^C = 26$  and  $Re^D = 66$  at different Peclet numbers.*

Three plots of the average concentration of the solute inside the drop for three different values of the Peclet number at the same Reynolds number against the dimensionless time are shown in Figure 6. Since the Reynolds is kept constant, the convective transport rate of mass is also kept constant. Therefore, it can be observed that for larger Peclet numbers, the time taken by the solute to reach the steady (equilibrium) state increases. Three plots of the bulk average concentration in the dispersed phase against the dimensionless time are shown in Figure 7 for three different values of the Reynolds number ( $Re^C = 66, 200, 450$ ) and  $Pe^P = 100$ . There is not an appreciable difference between the three plots. This can be explained by observing that, since the Peclet number is quite small, the diffusive mass transfer rate is more important than the convective transport rate and therefore the total mass transfer rate is almost constant with varying Reynolds numbers. It is expected that for larger Peclet numbers, the effect of the Reynolds number will also be large.

*Figure 7. Plot of dispersed phase average concentration vs. dimensionless time for  $Pe^P = 100$  at different Reynolds numbers*

## CONCLUSIONS

A numerical study of the mass transfer process between a single, spherical drop traveling through an unbounded, still continuous phase is presented. The studies were carried out assuming that no turbulence is present and, therefore, the flow is laminar and the mass transfer is carried out by convection around the drop and by diffusion towards the stagnation ring. It is observed that the most important dimensionless groups that represent this phenomenon are the Reynolds number, the Peclet number and the hydrodynamic time. For a constant Reynolds number, the mass transfer rate decreases as the Peclet number increases due to a constant convective term but a lower diffusive term.

The results presented in this work agree with qualitative observations in real systems [3]. This is an important step in the solution of the mass transfer process in drops in more complex situations where other influences are present such as bulk turbulence, interfacial turbulence (Marangoni effect), surface active contaminants, moving and varying drop shapes, multicomponent mass transport, etc. The study of the mass transfer process in single drops will allow us to extrapolate the results to mass transport in bubbles and in multidrop columns for design and process scale up.

## INFLUENCING THE RATE OF MASS TRANSFER IN REACTIVE EXTRACTION USING HIGH VOLTAGE

Andreas Wildberger and Hans-Jörg Bart

Institute of Thermal Process Engineering, University of Kaiserslautern,  
Kaiserslautern, Germany

Mass transfer of p-toluenesulfonic acid, PTA, dissolved in water extracted with tri-n-octylamine, TOA, dissolved in toluene was investigated in a planar mass transfer cell with a constant interfacial area when high electrostatic fields (DC) were applied. Mass transfer was found to be markedly accelerated, and this can be explained by the field induced potential gradient which is the driving force. An electrostatically extended kinetic model based on the Nernst-Planck equation was developed to quantify the enhancement of mass transfer. The theory was also proved with a cation exchange system as is zinc chloride/di-2-ethylhexylphosphoric acid ester (D2EHPA) in toluene.

### INTRODUCTION

Several studies have been conducted on the effect of applied electrical fields on liquid-liquid mass transfer rates between a drop (the dispersed conducting phase) and a nonconducting continuous phase [1-4]. The applied field was found to alter the shape of the droplet and charge the droplet, which influences drop rise velocity, phase separation, coalescence and mass transfer. Little has been reported on the effect of applied electrical fields on liquid-liquid mass transfer when such fields are applied across a plane interface [5]. Generally, interfacial turbulence, and increased mass transfer rates have been observed [6-9]. Kuipa and Hughes expected the enhanced mass transfer to be depended on the organic diluent and of local variations in surface tension and surface boundary layer created by the electrical field [5].

However, no attempt was made to study the influence of electric fields in a reaction controlled regime. This work focuses on the development of an electrostatically extended kinetic model which describes the mass transfer enhancement in reactive extraction.

### EXPERIMENTAL

Mass transfer was investigated in a stirring cell having a constant interfacial area [10], while high electric fields (DC) up to 25 000 volts were applied. The cell was modified with two teflon-coated ring-electrodes (Figure 1). The upper one (in organic phase) was positively charged, while the other one (in aqueous phase) was grounded. The distance of each from the interface was 1 cm. The external field applied between those electrodes was then perpendicular to the liquid-liquid interface.

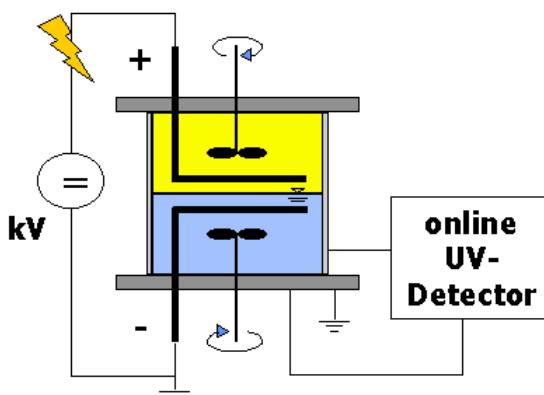

Figure 1. Mass transfer cell.

The reactive extraction system investigated was p-toluenesulfonic acid (PTA) dissolved in water, tri-n-octylamine (TOA) dissolved in toluene. The PTA concentration was determined by an online UV-detector (Fig. 1). All experiments were carried out at 298 K. All chemicals used were of analaR grade.

## EQUILIBRIA

PTA (HA) was found to chemically react with the amino-function of the liquid ion exchanger (TOA) at the interface to form a 1:1 complex.

Despite being under the influence of strong electric fields (up to 25 000 volts), no equilibrium shift was found. Thus the external field does not affect the extraction equilibria or induce further chemical reactions under these electrostatic conditions [11].

## MASS TRANSFER

### Kinetics

The following model can be applied to simulate mass transfer when mass transfer is kinetically controlled (plateau area) [12-16]. In order to model the reactive mass transfer of PTA, the equilibrium equation (1) is split into the following three partial reaction steps:

The index "ad" represents these species which are adsorbed at the interface. The first reaction step depicts the protonation of an at the interface adsorbed TOA molecule.

This reaction represents the formation of an ion-pair molecule which is adsorbed at the interface. This molecule is then replaced by a fresh TOA-molecule from the organic bulk phase in the third and last reaction step:

The interfacially adsorbed anion exchanger species are balanced according to the Gibbs' law:

$$[\text{TOA}_{\text{ad}}] + [\text{TOAH}^+_{\text{ad}}] + [\text{TOAHA}_{\text{ad}}] = \frac{\alpha_m \cdot \overline{[\text{TOA}]}}{\gamma_m + \overline{[\text{TOA}]}} \quad (5)$$

$\alpha_m$  and  $\gamma_m$  are the adsorption constants which have been determined by interfacial tension measurements to be  $8.49 \times 10^{-4}$  for  $\alpha_m$  and  $2.98 \times 10^{-2}$  mol/kg for  $\gamma_m$  in toluene [15]. The rate determining steps (Eq. (2)-(4) and Eq. (5)) are combined to obtain the kinetic rate equation,  $R'$ :

$$R' = \frac{(a_{H^+} \cdot a_{A^-} \cdot a_{\text{TOA}} - 1/K_{\text{EX}} \cdot a_{\text{TOAHA}}) \cdot (\alpha_m \cdot a_{\text{TOA}} / (\gamma_m + a_{\text{TOA}}))}{C_1 + C_2 \cdot a_{H^+} + C_3 \cdot a_{H^+} \cdot a_{A^-} + C_4 \cdot a_{H^+} \cdot a_{\text{TOA}} + C_5 \cdot a_{\text{TOA}} + C_6 \cdot a_{\text{TOAHA}}} \quad (6)$$

The constants  $C_1$  -  $C_6$  are functions of the kinetic parameters, where  $k_3$  is calculated from  $K_{\text{EX}}$  ( $K_1 = 503.908$  [kg/mol],  $k_2 = 93.016$ ,  $k_{-2} = 0.019$  [ $s^{-1}$ ],  $k_3 = 58.450$ ,  $k_{-3} = 12.934$  all in [kg/mol s]):

$$C_1 = \frac{k_{-2}}{k_2 \cdot k_3 \cdot K_1}, C_2 = \frac{k_{-2}}{k_2 \cdot k_3}, C_3 = \frac{1}{k_3}, C_4 = \frac{1}{k_2}, C_5 = \frac{1}{k_2 \cdot K_1}, C_6 = \frac{1}{k_{-2} \cdot K_{\text{EX}}} \quad (7)$$

The model was found to correlate the experimental data within a very good agreement over a wide concentration range (see Figure 2).

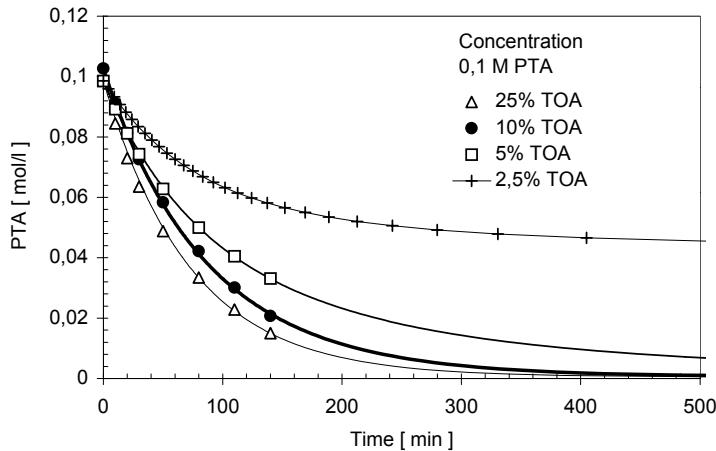

Figure 2. Simulation of the mass transfer kinetics of PTA with the kinetic model.

### Influence of Electric Fields

The Nernst-Planck equation (8) describes the movement of ions caused by diffusion and migration driving forces under isotherm conditions. Convection effects are neglected [13,17]:

$$\dot{N} = \dot{N}_{\text{diffusion}} + \dot{N}_{\text{migration}} \quad (8)$$

The molar Flux  $\dot{N}_{\text{diffusion}}$  [mol/s] becomes negligible because the system is kinetically controlled (plateau area) and only the migration term (Eq. (9)) becomes important as driving force for the movement of the ions inside the applied electric field:

$$\dot{N} = \dot{N}_{\text{migration}} = -A \frac{D_i c_i z_i e}{kT} \nabla \psi \quad (9)$$

(with:  $c_i$  concentration of the ionic species  $i$  [mol/l],  $A$  the mass transfer area [ $m^2$ ],  $D_i$  the diffusion coefficient of the ionic species  $i$  [ $m^2/s$ ],  $z_i$  charge number of the ionic species  $i$  [-],  $e$  elementary charge [C],  $\psi$  electrical potential [V],  $k$  Boltzmann constant [J/K],  $T$  temperature [K]).

For  $\Delta\psi = \psi_2 - \psi_1$ , with 2: interface and 1: bulk, as the driving force for the ion movement from bulk to interface equation 10 is obtained, which calculates the interfacial concentration of the ionic solute [17].

$$c_2 = -\frac{z_i e(\psi_2 - \psi_1)c_1}{kT} + c_1 \quad (10)$$

Equation 10 was integrated in the above used kinetic model. Thus an electrostatic expanded kinetic model was developed, which considers the field influence in the interfacial concentration of the ionic mass transfer components. The  $\text{A}^-$  concentration is increased at the interface by the applied field, while the interfacial concentration of the  $\text{H}^+$  ions is decreased. When no external field is applied and the interfacial potential becomes zero, the interfacial concentrations in the kinetic regime are the same as in the bulk.

### Computer Aided Determination of the Interface Potential

The potential drop which is generated by the applied electric field was determined considering the special geometry involved with the software program called EMAS (Ansoft Corporation Europe, UK). EMAS numerically evaluates potential fields by the finite element method based on the field theory of Maxwell [18]. EMAS considers the exact geometry of the electrostatic condenser (which is the geometry of cell and the used electrodes), the temperature, the electrical properties of the liquids used (like the dielectric constants or conductivity data) as well as the vectorial character of the field.

The potential was found to linearly drop from the interface to the grounded electrode inside the aqueous phase. The interface potential  $\psi_2$  was obtained to be 578 V, when a voltage of 20 kV was applied. The potential decreases from 20 kV at the upper electrode in organic phase till a value of 0 V at the other electrode in aqueous phase. Thus the bulk potential on aqueous side  $\psi_1$  is zero. It was also found, that the interface potential linearly increases with increasing the applied external voltage.

### Comparison of Theory and Experiment

Under the influence of a high electric field (DC) the mass transfer of PTA was found to be accelerated while the same equilibrium composition in the kinetically controlled regime is obtained (see Figure 3).

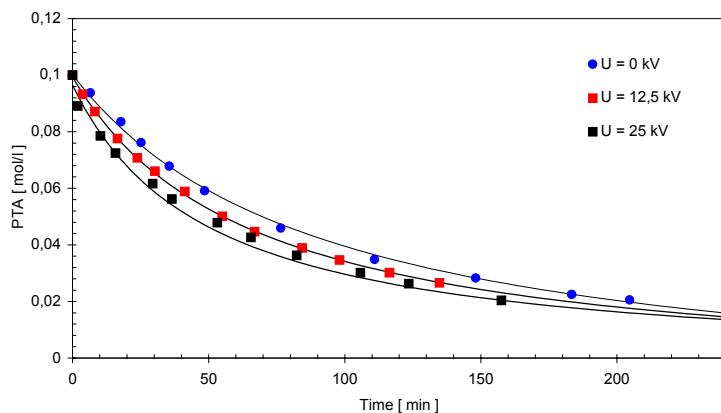

Figure 3. Mass transfer enhancement of PTA by a strong external field (DC) (PTA: 0,1 mol/l; TOA: 5%).

The acid anions are attracted by the positive charge of the upper electrode and move favourably to the interface. Thus the concentration of the acid anions is enhanced at the interface by the positive charge. The higher the voltage applied, the higher will be the interfacial concentration of the anions. The enhancement of mass transfer was found to be linear with increasing the voltage [11].

In light of proving the model it was also important to investigate mass transfer kinetics when using positively charged solutes (cationic ion exchange system) under the same conditions. In this case a diminution of mass transfer is expected. Zinc chloride was extracted with di(2-ethylhexyl)phosphoric acid ester (D2EHPA) dissolved in isododecane [15,19] under the same conditions as in Figure 3. The  $H^+$  concentration was measured online and zinc was analysed by atomic absorption spectroscopy.

As shown in Figure 4, the mass transfer kinetics of zinc ions are retarded under the same electric fields. This elucidates the correctness of the model assumption and is in accordance with the obtained concentration profiles in case of surfactant induced charging of the liquid-liquid interface [20]. The simulated mass transfer enhancement is given in Figure 5. A good representation of the experimental values is obtained.

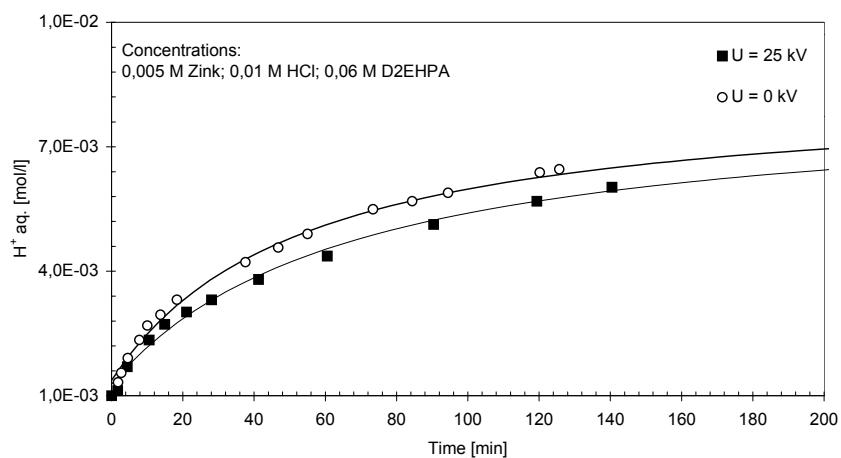

Figure 4. Mass transfer diminution of zinc ions by a strong external field (DC).

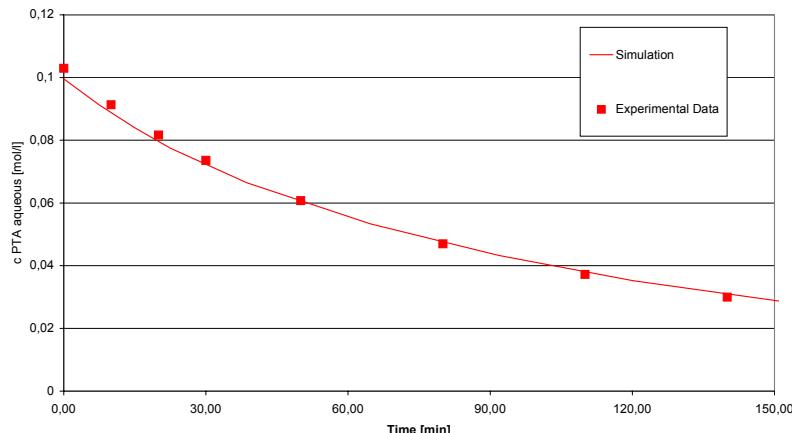

Figure 5. Simulation of mass transfer kinetics of PTA by a strong external field ( $U: 20\text{ kV}$ , PTS:  $0,1\text{ mol/l}$ ; TOA: 5%).

## CONCLUSIONS

Mass transfer was found to be accelerated (respectively reduced) in an electric high voltage field (DC). This is depending on either the field polarity or the charge of the solutes. Thus the application of high voltage in reactive extraction provides a potential to easily influence the selectivity of extraction. Because solutes are differently attracted by the field induced potential drop depending on the charge of the ionic solute. It is also possible to oppress a current flow by isolating the electrodes, which enables a low costing process and provides high safety aspects. This and the acceleration of mass transfer are interesting aspects in light of industrial application

of high voltage assisted extraction. In order to describe the process, a kinetic model was developed which satisfactorily correlates the experimental data.

## A STUDY ON MULTI-COMPONENT MASS TRANSFER COEFFICIENTS OF DROP SWARM

Haiguo Wei and Weiyang Fei

Department of Chemical Engineering, Tsinghua University, Beijing, P.R. China

The multi-component mass transfer coefficients of drop swarm of aromatic extraction by sulpholane were measured in a 100mm internal diameter glass column and compared with those of single drops. It is shown from the experiments that the mass transfer coefficients of benzene are larger than those of toluene and much larger than those of xylene.

Several kinds of equations for single drop mass transfer coefficients were used to estimate the multi-component ones and compare with those of experimental, but none of them could fit the results well. The situation becomes more complex since the Marangoni phenomenon exists for the aromatic extraction by sulpholane system. Therefore, further study is necessary for the estimation of multi-component mass transfer coefficients of drop swarm for this important commercial system.

### INTRODUCTION

Solvent extraction has been widely used in petrochemical, pharmaceutical, hydrometallurgical and environmental industries. However, the design of commercial extraction columns is still difficult. Scale-up of extractors is often dependent on pilot plant experiments, which are expensive and time-consuming. The uncertainty of estimation of mass transfer coefficients is one of the main problems faced by the design engineers.

Measuring mass transfer coefficient with single drop experiments seems a promising method to solve the problem. Many researchers [1-4] completed extensive studies on this field and proposed many equations to evaluate mass transfer coefficient. However, most of the equations are restricted to their experimental conditions. The interactions among drops in commercial extraction columns have significant impact on mass transfer but can't be considered in single drop mass transfer models. Therefore, it is essential to measure mass transfer coefficient of drop swarms directly.

The estimation of multi-component mass transfer coefficients of drop swarm is essential when the non-equilibrium stage model is used for the simulation of a commercial extraction column [5]. However, the literature on measurement and prediction of multi-component mass transfer coefficients are still scarce.

Therefore, the multi-component mass transfer coefficients of drop swarm for aromatic extraction by sulfolane system were measured and compared with those of single components in this paper. The complexity of calculating multi-component mass transfer coefficients of drop swarm was also discussed.

## EXPERIMENTAL

### Apparatus

Figure 1 shows a diagram of the experimental apparatus. The flanged glass column has a 100 mm internal diameter and 600 mm working height. Both ends of the column were sealed by plexiglass using flanges. The bottom plexiglass has ten 3 mm pores. One is in the center, and the others are evenly distributed on a 50 mm circle concentric with the center pore. Stainless steel needles with blunt tips were inserted into the column through the pores. Two funnels were arranged 100 mm and 500 mm away from the bottom to collect samples.

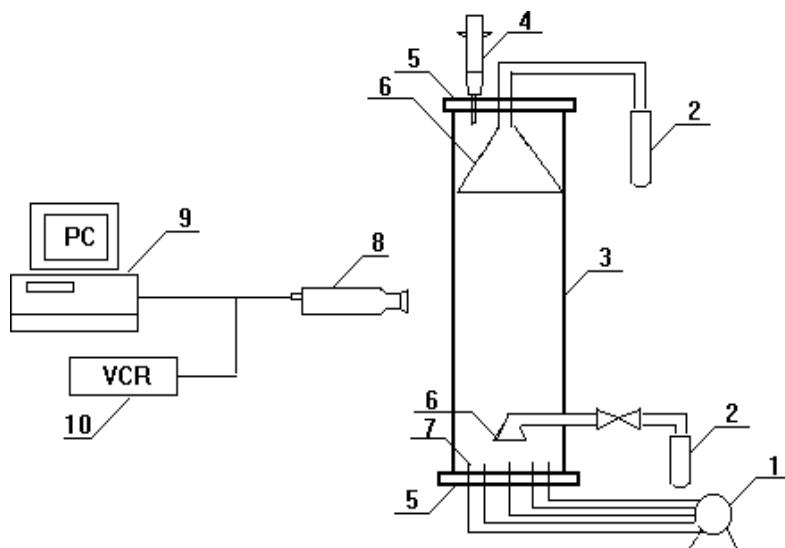

Figure 1. Diagram of experimental apparatus.

- 1.multichannel syringe pump 2.sampling tube 3.extraction column 4.syringe  
5.flange 6.funnel 7.needle 8.video camera 9. PC computer 10.video tape recorder.

The drop swarm was produced by a multi-channel syringe pump (Cole-Parmer Ins. Co., model 74900-10), which guarantee that each syringe pump has the same flow rate. Seven different gauges of medical needles were used in the experiments to produce different size drops. Teflon pipe was used as connector between needles and syringes. A computerized video imaging system, consisting of a PC computer with a capture card, a video camera and a video tape recorder, was installed to record the movements of drops.

### Test System

The continuous phase is pure sulfolane. The dispersed phases are either multi-component mixture of benzene, toluene, xylene and n-heptane or binary mixtures benzene/n-heptane, toluene/n-heptane and xylene/n-heptane. The concentrations of each component in mixtures are always 10% (wt%). The physical properties of the components are shown in Table 1.

### Method of Analysis

The concentrations of samples are measured by gas chromatography. The instruments are HP5890 Series II GC connecting with HP3365 workstation, HP-1 quartz glass capillary (25 m × 0.2 mm × 0.33 μm), GCD-300 flame ionic detector(FID) and automatic hydrogen generator. The method of area normalization with calibration factor was applied in the calculation.

*Table 1. Physical properties of experimental systems.*

Component	$\rho$ (Kg · m <sup>-3</sup> )	$\mu$ (mPa · S)
benzene	872.5	0.596
toluene	862.3	0.547
p-xylene	859.9	0.605
n-heptane	680.5	0.396
sulfolane	1263.2	11.4

### Procedure

The column was filled with sulfolane. The whole column is airtight and does not have elastic parts, so an equal volume organic phase will leave from the top funnel when drop swarms enter the column. The interface of the two phases at the top funnel was controlled through injecting or sucking continuous phase by the syringe at the upper Plexiglass. The formation time of each drop was about 2 to 3 seconds. Drop size was calculated according to the flow rate of the pump and the time used to produce a certain number of drops. Assuming the overall mass transfer coefficient  $K_{od}$  of drop swarms doesn't change with time, it can be calculated by the following equations:

$$K_{od} = -\frac{d_p}{6t} \ln(1 - E) \quad (1)$$

$$E = (y_2 - y_1) / (y^* - y_1) \quad (2)$$

where  $y_1$ ,  $y_2$  are the samples concentration at 100 mm and 500 mm above the column bottom respectively, and  $y^*$  is the equilibrium concentration of continuous phase.

## EXPERIMENTAL RESULTS

### Multi-Component Mass Transfer Coefficients of Drop Swarm

The multi-component drop swarm mass transfer coefficients of benzene, toluene and xylene are shown in Figure 2. It is clear from the figure that the mass transfer coefficients of benzene are larger than those of toluene and much larger than those of xylene. The differences of mass transfer coefficients among benzene, toluene and xylene are significant. Therefore, it will cause huge error if the same mass transfer coefficients or tray efficiencies are used in design procedure according to the equilibrium stage model. On the other hand, the larger the drop diameter, the larger the mass transfer coefficients for all the components.

### Mass Transfer Coefficients of Drop Swarm in Binary Mixture

The drop swarm mass transfer coefficients of benzene, toluene and xylene in binary mixtures are shown in Figure 3. The effects of component and drop size on the mass transfer coefficients are similar with those of multi-component system. The mass transfer coefficients of benzene are about three times larger than those of xylene, and are about 50% larger than those of toluene.

### Comparison of Mass Transfer Coefficients between Multi-Component and Binary System

The comparison of toluene mass transfer coefficients between multi-component and binary system is shown in Figure 4. The mass transfer coefficients of toluene in multi-component system is slightly larger than those of in binary system and increased more quickly with the drop size.

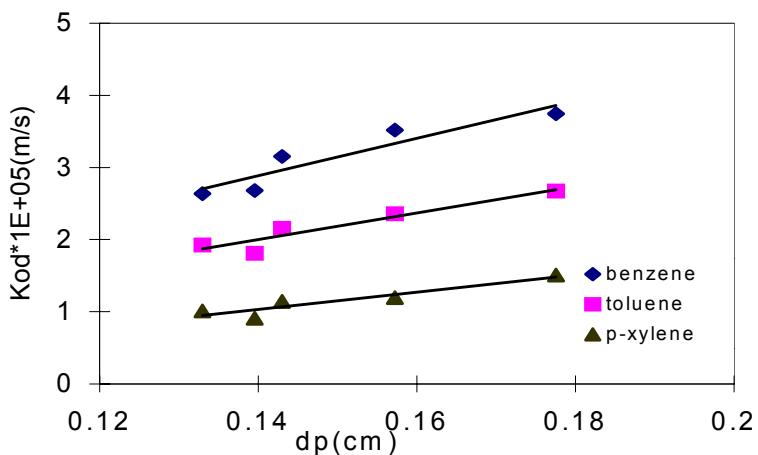

Figure 2. Mass transfer coefficients of drop swarms in multi-component mixture.

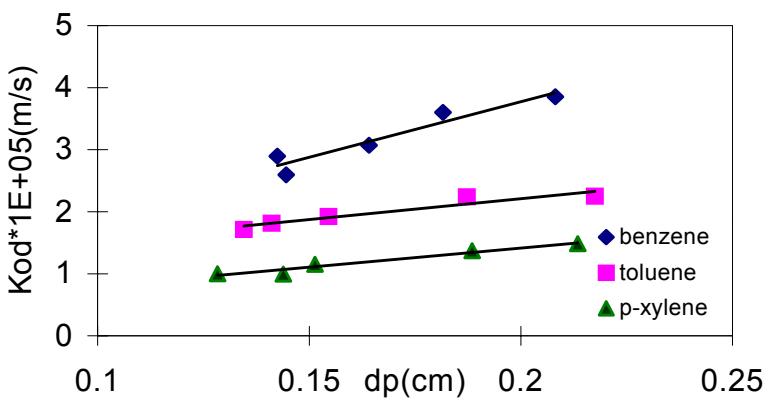

Figure 3. Mass transfer coefficients of drop swarms in binary mixture.

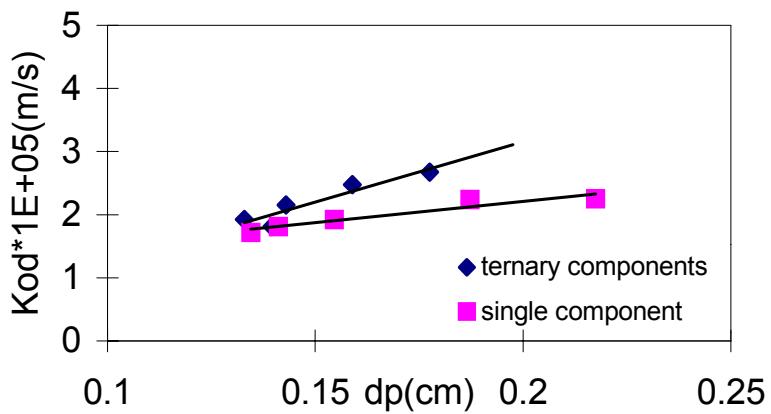

Figure 4. Mass transfer coefficients of toluene's drop swarms.

## DISCUSSION

There are many equations used to calculate the inside and outside drop mass transfer coefficients. These models can be classified into three categories, which are suitable for stagnant, circulating and oscillating drops respectively. Slater [3] and Kumar *et al.* [4] reviewed these models and proposed empirical correlations for the prediction of single drop mass transfer coefficient. However, most of them could not fit experimental data of this paper very well after extensive calculation and comparison [6]. It seems that the main reasons of this discrepancy are the difference between the mass transfer of single drop and drop swarm and the serious Marangoni effect during the mass transfer of test systems.

## CONCLUSIONS

1. It is shown from the multi-component mass transfer experiments of drop swarm that the mass transfer coefficients of benzene are about 50% larger than those of toluene and 200% larger than those of xylene.
2. According to the comparison between multi-component and binary system experiments the mass transfer coefficients of toluene in multi-component systems are slightly larger than those in binary systems.
3. The existing models could not fit experimental data of multi-component mass transfer experiments of drop swarm very well. Therefore, further study is necessary in this area.

## ACKNOWLEDGEMENTS

The authors wish to express their appreciation to the Solvent Extraction Laboratory, State Key Laboratory of Chemical Engineering, China, for its support.

## SYMBOLS

$d_p$	[m]	drop diameter
$E$	[‐]	fraction degree of extraction
$K_{od}$	[m s <sup>‐1</sup> ]	overall dispersed phase mass transfer coefficient
$t$	[s]	time
$y_1$	[mol l <sup>‐1</sup> ]	dispersed phase concentration at 100mm above the bottom
$y_2$	[mol l <sup>‐1</sup> ]	dispersed phase concentration at 500mm above the bottom
$y$	[mol l <sup>‐1</sup> ]	dispersed phase concentration

### Greek letters

$\mu$	[Pa S]	viscosity
$\rho$	[kg m <sup>‐3</sup> ]	density

## KINETIC STUDY OF NICKEL(II) EXTRACTION FROM CHLORIDE SOLUTIONS

A. Buch, D. Pareau , M. Stambouli and G. Durand

Laboratoire de Chimie et Génie des Procédés, Ecole Centrale Paris, Paris, France

The rate of nickel(II) extraction from aqueous chloride solutions by 2-ethylhexanal oxime (EHO) in dodecane has been studied as a function of the concentrations of extractant, metal and salt and of the equilibrium pH.

The extraction kinetics have been carefully studied and a mechanism in agreement with the experimental results has been proposed for pH > 4. The limiting step is an interfacial reaction between a neutral nickel adsorbed species and a molecule of EHO.

### INTRODUCTION

The extraction of nickel(II) by oximes is relatively slow [1-3]. For example, more than 1 hour is necessary for reaching equilibrium of nickel(II) extraction by 2-ethylhexanal oxime (EHO). Only a few authors have studied the kinetics of nickel(II) extraction by oximes, but a great number of them have investigated copper or nickel extraction by hydroxyoximes. All these systems involve an interfacial mechanism [4-6]. The limiting step of copper extraction by an hydroxyoxime (2-hydroxy-5-alkylbenzaldehyde oxime) is indeed often the complexation of an adsorbed species (containing one molecule of extractant and one atom of metal) with a second molecule of extractant as shown[4, 5]:

where the subscript, ad, denotes an interfacial adsorbed species and RH represents the acidic hydroxyoxime.

Another kind of limiting step has been determined for copper extraction by LIX 65N [6]:

In this case CuR<sup>+</sup> in the aqueous phase reacts with an adsorbed molecule of the extractant.

Chen [7] has however shown that in the case of nickel(II) extraction by dodecylsalicylaldoxime (HL), the rate-limiting step involves two reactions, one at the interface ( $\text{Ni}^{2+} + \text{HL} \rightarrow \text{NiL}^+ + \text{H}^+$ ) and one in the bulk aqueous phase ( $\text{Ni}^{2+} + \text{L}^- \rightarrow \text{NiL}^+$ ).

It can be seen that the kinetic interpretations of these systems are not simple. Our contribution is the determination of the limiting step of nickel(II) extraction by EHO, because of the interesting properties of this extractant in acid solutions.

EHO can adopt two configurations, known as (Z) and (E) [2,8,9]. As proposed by Kopczynski [8], the organic phase containing EHO was pre-equilibrated with the aqueous phase containing no metal, to ensure a pre-equilibrium condition with the (Z) and (E) configurations. Furthermore, the authors have reported the aggregation of this oxime previously [3]. EHO was found to form dimers and trimers. These results are used in this work to calculate the EHO monomer concentrations.

## EXPERIMENTAL

The principal reagent (EHO) was prepared by reaction of 2-ethylhexanal with hydroxyl ammonium chloride [3, 10]. The measured EHO purity was 98.5%. The diluent used was dodecane (Aldrich, 99%+). The aqueous solutions were prepared by dissolving nickel chloride salts (Fluka 99%) in water.

150 mL of aqueous nickel phase were contacted at 24°C in a homothetic cell with 150 mL of organic phase containing EHO. The pH was controlled using a specific calomel electrode.

Ni concentrations in the aqueous phase were measured by atomic absorption spectrometry (AA300 Varian). The metal contained in the organic phase was stripped with HNO<sub>3</sub> and its concentration in the aqueous stripping phase was measured by the same method.

The interfacial tension was measured by the drop volume method at 293 K.

## KINETIC STUDY OF NICKEL EXTRACTION BY EHO

This study was performed using a vigorously stirred cell. A homothetic cell (Rushton type) was designed in order to ensure a good reproducibility of the experimental results. In the previous thermo dynamical study [3], two different ranges of pH were considered. For pH > 4, the only range of pH considered in this study, the extracted complex was shown to be NiCl(Ox)(HOx)<sub>4</sub>.

By considering the global rate of extraction  $r = k_g (x - x_{eq})$  ( per surface unit), a kinetic model can be written as:

$$x(t) = x_{eq} + (x_0 - x_{eq}) \cdot \exp(-\alpha \cdot t) \quad (1)$$

where  $\alpha = \frac{ak_g V_t}{A}$ , A is the aqueous volume, V<sub>t</sub> the total volume of both phases, a the specific interfacial area (per total unit volume) (unknown but reproducible), and k<sub>g</sub> the kinetic constant. x<sub>0</sub>, x<sub>eq</sub>, x are respectively the concentrations of aqueous nickel at the initial time, at equilibrium and at time t. Experimental results (x, t) were fitted by the exponential expression of x (t) using the Microcal origin® program. The values for a.k<sub>g</sub> could then be determined.

### Influence of Hydrodynamic Parameters

The extraction rate of nickel(II) by EHO in a chloride solution is relatively low. If stirring is not sufficient, diffusion can be the rate limiting step. Experiments were performed with various stirring speeds and the experimental data was manipulated as described above. The calculated values of a.k<sub>g</sub> were found to be constant for a stirring speed greater than 650 rpm: diffusion was therefore not limiting in these conditions. In all further experiments a stirring speed of 700 rpm was used.

### Influence of Temperature

By varying temperature from 4 to 40°C, the different values of  $a.k_g$  were plotted versus  $1/T$ . A straight line was obtained for pH = 6.2 and the activation energy was calculated from the slope to be  $52.3 \pm 6.7$  kJ/mol. This value was greater than 40 kJ/mol, the range that represents the chemical nature of the kinetic regime.

### Influence of Chemical Parameters

Nickel concentration was varied between 2.5 to 9 mmol/L.  $a.k_g$  was found to be independent of Ni concentration and had the value  $(4.7 \pm 0.5).10^{-4}$  s<sup>-1</sup>. The reaction rate was therefore first order with respect to nickel. Other chemical parameters such as pH, EHO and NaCl concentrations were studied.

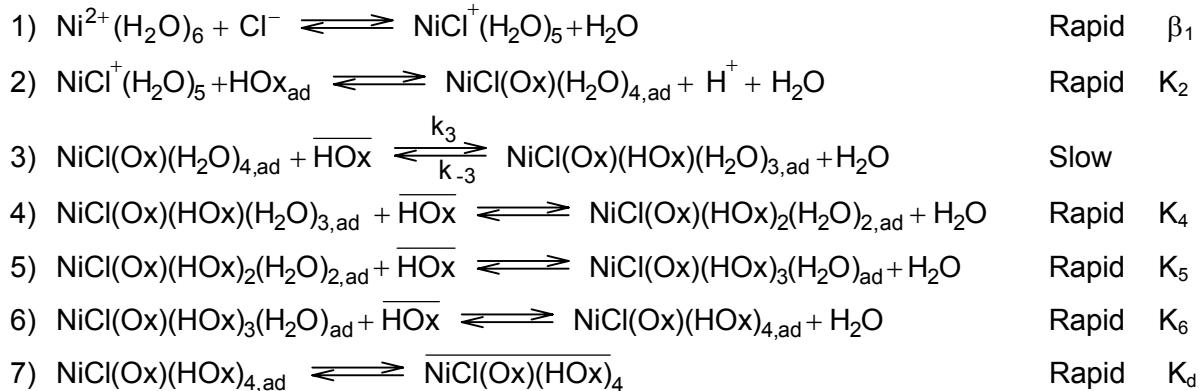

## EXTRACTION MECHANISM

Different experiments were performed to study the influence of EHO and NaCl concentrations and of pH under the following conditions:

- EHO concentration varying from 0.1 to 0.55 mol/L for pH 6.2 and NaCl 0.5 mol/L
- pH varying from 6 to 7 for NaCl 0.5 and 1 mol/L and EHO 0.295 mol/L
- NaCl concentration varying between 0.3 to 1 mol/L for pH 6.2 and EHO 0.295 mol/L.

The experimental data was manipulated using the model presented below.

The following mechanism was proposed and its accordance with the experimental results was tested.

where the overbar represents a species in the organic phase.

Activities were defined on the molarity scale, with reference to  $C_o=1$  mol/L. In the organic phase, the ionic strength was very low, so the activity coefficients could be considered to be constant. Furthermore,  $[\text{Ni}] = [\text{Ni}^{2+}] \cdot \alpha_{\text{Ni}}$ , with  $\alpha_{\text{Ni}} = 1 + \sum_{j=1}^m \beta_j \cdot a_{\text{Cl}^-}^j$ . where  $\beta_j$  is the associated complexation constant [11]. Only  $\beta_1$  is considered here. The activity coefficient of Ni was considered to be constant because nickel was present in trace amounts.

The apparent equilibrium constants can be written as :

$$\beta_1 = \frac{a_{\text{NiCl}^+(\text{H}_2\text{O})_5}}{a_{\text{Ni}^{2+}} a_{\text{Cl}^-}} = \frac{[\text{NiCl}^+(\text{H}_2\text{O})_5] \cdot \alpha_{\text{Ni}}}{[\text{Ni}] \cdot a_{\text{Cl}^-}} \quad (2)$$

$$K_2 = \frac{[NiCl(Ox)(H_2O)_4]_{ad} \cdot a_{H^+}}{[NiCl(H_2O)_5] \cdot [HOx]_{ad}} \quad (3)$$

$$K_4 K_5 K_6 K_d = \frac{[NiCl(Ox)(HOx)_4]}{[NiCl(Ox)(HOx)(H_2O)_3]_{ad} \cdot [HOx]^3} \quad (4)$$

The rate of the limiting step (reaction 3 in the mechanism proposed) is defined as:

$$r_3 = k_3 \cdot [NiCl(Ox)(H_2O)_4]_{ad} \cdot \overline{[HOx]} - k_{-3} \cdot [NiCl(Ox)(HOx)(H_2O)_3]_{ad} \quad (5)$$

or by replacing  $[NiCl(Ox)(H_2O)_4]_{ad}$  and  $[NiCl(Ox)(HOx)(H_2O)_3]_{ad}$  by their expressions:

$$r_3 = K_2 \cdot k_3 \cdot [HOx]_{ad} \cdot \frac{\overline{[HOx]}}{a_{H^+}} \cdot \frac{\beta_1 \cdot a_{Cl^-}}{\alpha_{Ni}} \cdot x - \frac{k_{-3}}{K_4 K_5 K_6 K_d \cdot \overline{[HOx]}^3} \cdot y \quad (6)$$

with  $y = \overline{[NiCl(Ox)(HOx)_4]}$

Introducing  $r_{3,eq} = 0$ :

$$r_3 - r_{3,eq} = K_2 \cdot k_3 \cdot [HOx]_{ad} \cdot \frac{\overline{[HOx]}}{a_{H^+}} \cdot \frac{\beta_1 a_{Cl^-}}{\alpha_{Ni}} (x - x_{eq}) - \frac{k_{-3}}{K_4 K_5 K_6 K_d \cdot \overline{[HOx]}^3} (y - y_{eq}) \quad (7)$$

This expression is correct only if  $\overline{[HOx]} = \overline{[HOx]}_{eq}$ ,  $a_{H^+} = a_{H^+,eq}$  and  $a_{Cl^-} = a_{Cl^-,eq}$ .

These hypotheses were justified because, for each experiment, only nickel concentrations varied. pH was kept constant and  $Cl^-$  and EHO were present in large excess.

The mass balance of nickel gives for equal volumes of both phases:  $(y - y_{eq}) = - (x - x_{eq})$

The kinetic constant  $a \cdot k_g$  is finally expressed as:

$$a \cdot k_g = K_2 \cdot k_3 \cdot [HOx]_{ad} \frac{\overline{[HOx]}}{a_{H^+}} \frac{\beta_1 a_{Cl^-}}{\alpha_{Ni}} + \frac{k_{-3}}{K_4 K_5 K_6 K_d \cdot \overline{[HOx]}^3} \quad (8)$$

The concentration of the adsorbed monomer (the only adsorbed EHO species) may be considered as constant when the total EHO concentration varies because of its excellent surfactant properties. The plot of the interfacial tension  $\chi$  versus  $\log[HOx]$  was indeed a straight line with  $\chi$  (N/m) =  $-7.9 \log [HOx] + 23.1$  ( $r^2 = 0.995$ )), showing that the interface was saturated with EHO monomers. This result is in a good agreement with previous findings that oximes are more interfacially active in aliphatic than in aromatic diluents [6].

From equation (8), the expressions of  $a \cdot k_g = f\left(\frac{\beta_1 a_{Cl^-}}{\alpha_{Ni}}\right)$ ,  $a k_g = f\left(\frac{1}{a_{H^+}}\right)$  and of  $a \cdot k_g \cdot [HOx]^3 = f\left(\overline{[HOx]}^4\right)$  were plotted and showed linear relationships (Figures 1, 2 and 3).

The model is therefore shown to be in good agreement with the experimental results.

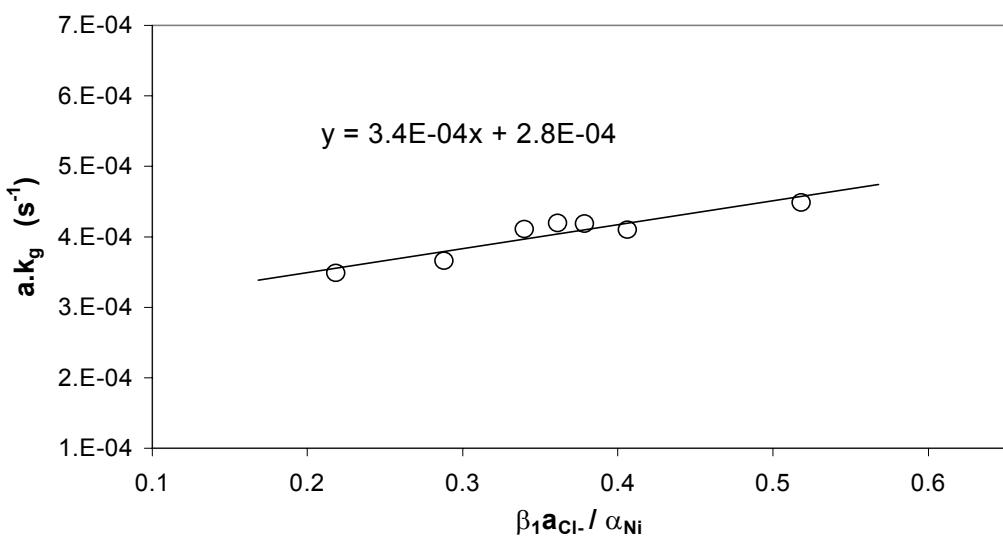

Figure 1. Plot of  $a.k_g$  versus NaCl activity,  $pH=6.2$ ,  $[EHO]_{\text{total}}=0.295 \text{ mol/L}$ .

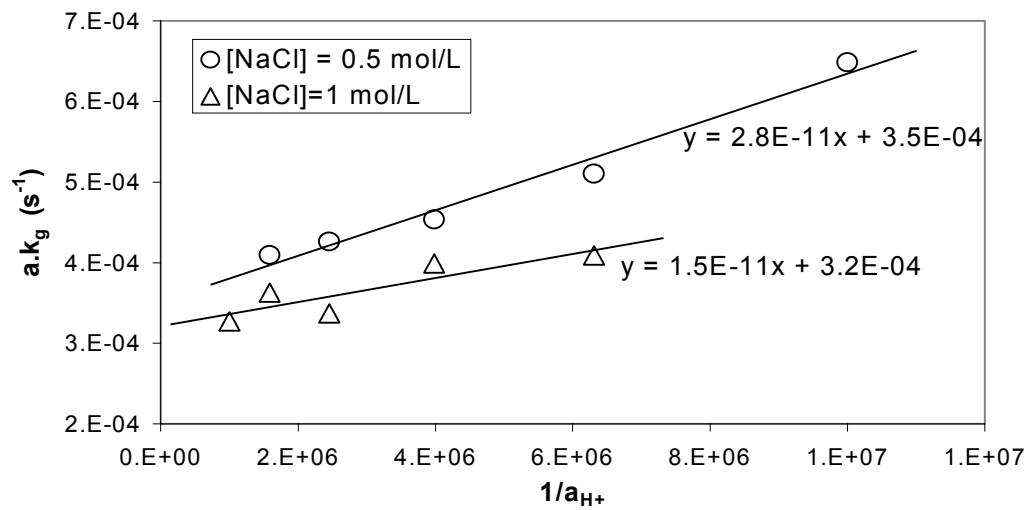

Figure 2. Plot of  $a.k_g$  versus  $a_{\text{H}^+}$ ,  $[EHO]_{\text{total}}=0.295 \text{ mol/L}$ .

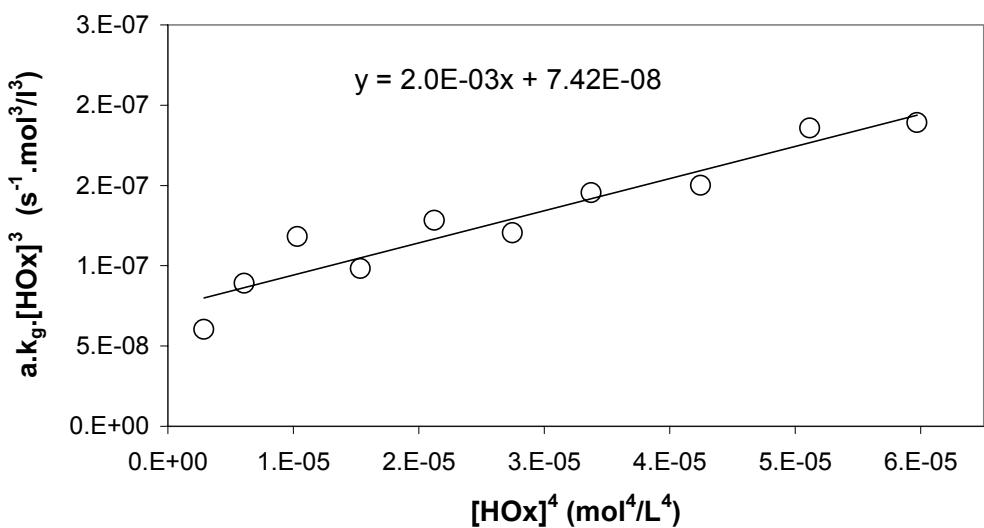

Figure 3. Validation of the model for EHO variations,  $pH=6.2$ ,  $[\text{NaCl}]=0.5 \text{ mol/L}$

The values of  $K_2 \cdot k_3 \cdot [HOx]_{ad}$  and  $\frac{k_{-3}}{K_4 K_5 K_6 K_d}$  were estimated from these three series of experiments. The values obtained were essentially constant, thus confirming the validity of the proposed mechanism:

$$K_2 \cdot k_3 \cdot [HOx]_{ad} = (2.4 \pm 0.3) \cdot 10^{-9} \quad \frac{k_{-3}}{K_4 K_5 K_6 K_d} = (9.0 \pm 0.7) \cdot 10^{-8}$$

## CONCLUSION

A kinetic mechanism proposed for the extraction of nickel by EHO was found to be consistent with experimental results. The limiting step was the first reaction of the solvation of the adsorbed neutral nickel species  $NiCl(Ox)(H_2O)_4$  by EHO. The slow reaction rate can be attributed to the solvation shell of this complex being very strong thus causing the substitution of a supplementary water molecule to be difficult. The further substitution reactions are then facilitated by the presence, in the solvation shell, of several EHO molecules.

The proposed kinetic mechanism is valid for pH greater than 4. When pH is lower, the nickel extraction reaction is not reversible and the kinetic mechanism is supposed to be fundamentally different, needing then another complete kinetic study.

## ACKNOWLEDGMENT

We gratefully acknowledge the support provided by Dr J.S. Preston for the synthesis of EHO.

## KINETICS OF RARE EARTH EXTRACTION WITH SEC-OCTYLPHENOXY ACETIC ACID

S. T. Yue\*, W. P. Liao, D. Q. Li and Q. Su

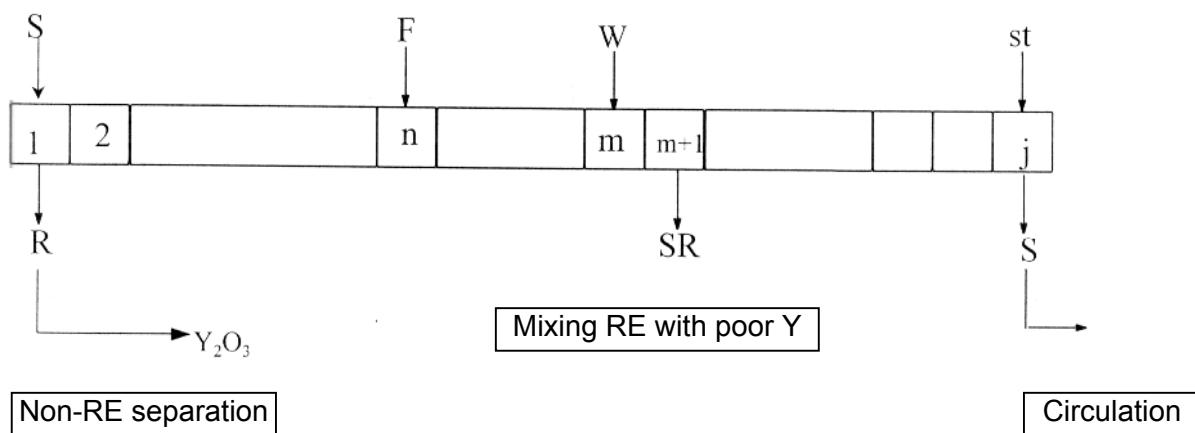

Laboratory of Rare Earth Chemistry and Physics, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun, P. R. China

\* Department of Chemistry, South of China Normal University, Guangzhou, P. R. China

The extraction kinetics of La(III), Gd(III), Er(III), Yb(III), and Y(III) with sec-octylphenoxy acetic acid in heptane have been investigated by using a constant interfacial area cell with laminar flow at 30°C. The results obtained have indicated that extraction rate is affected by the nature of the extracted species. For the extraction of Er(III), Yb(III) and Y(III), extraction rate is controlled by the reaction rate of M(III) and extractant molecules at the two-phase interface. For the extraction of Gd(III), extraction rate is decided by a mixed chemical reaction-diffusion. But, for the extraction of La(III), extraction rate is limited by diffusion. An interfacial extraction reaction model has also been derived.

### INTRODUCTION

It is well known that yttrium can be used in many fields, such as metallurgy, ceramics, lasers, and electronics, especially in fluorescent materials whose need for high purity yttrium oxide is always increasing. In China the resource of yttrium is very rich, and high purity yttrium has mainly been obtained by the process of naphthenic acid extraction [1-3]. However, there are some problems in the naphthenic acid extracting process. It is a very interesting project to develop a new process for extracting high purity yttrium, which is superior to the naphthenic acid.

S: HAB, F: feed, W: washings, st: stripping solution,  
S': HAB regeneration, R: raffinate, SR: stripped RE solution

Figure 1. Process scheme of separating yttrium by HAB extraction.

Ye *et al.* synthesized a carboxylic acid type of extractant, sec-octylphenoxy acetic acid (HA), whose composition is very simple. Under the same conditions, the natures of HA extraction are better than those of the naphthenic acid [4]. Li *et al.* [5,6] studied the mechanism of extracting rare earth(III) with HA and put forward HAB two solvent extraction system [two kinds of extractant system, HAB stands for HA+HB (another acidic extractant)]. Figure1 shows the process scheme of separating yttrium with HAB extraction system. But, the reports about the kinetics of rare earth extraction with HA have not been seen. It is very necessary to understand kinetics of the system. In this work, the extraction kinetics of Y(III), La(III), Gd(III), Er(III), Yb(III) with HA was examined following a thermodynamic study [5].

## EXPERIMENTAL SECTION

Interfacial tension measurements were performed as described in [7]. Apparatus and procedure employed in the study of extraction kinetics were described previously [8]. Both aqueous and organic phase volume were  $9.25 \times 10^{-5} \text{ m}^3$  ( $92.5 \text{ cm}^3$ ). Two phase interfacial area was  $2.1 \times 10^{-3} \text{ m}^2$  ( $21 \text{ cm}^2$ ). The pH in aqueous phase was adjusted by a NaAc-HAc buffer solution and the total concentration of NaAc and HAc was 0.2 mol/l. A Model 720 pH meter (Orion Co., America) was used to measure pH values in aqueous solutions.

Sec-octylphenoxy acetic acid (HA) was provided by Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences. Its purity was more than 93%. After dissolving in heptane, HA was washed in turn by sodium carbonate, hydrochloric acid, distilled water, and was then saponified with ammonia water. The extent of ammonia saponification was 57.3%. The stock solutions of rare earths were prepared by dissolving their oxides (which had purity of greater than 99.99%) in concentrated hydrochloric acid and evaporating the excess HCl.

## RESULTS

### Data Treatment

Experimental data were treated following Danesi [9]. Assuming that the mass transfer process could be formally treated as a pseudo-first-order reversible reaction with respect to the metal cation:

The rate equation can be written as:

$$-\frac{d[M]_{(o)}}{dt} = (Q/V) (k_{oa}[M]_{(o)} - k_{ao}[M]_{(a)}) \quad (2)$$

Integrating gives:

$$\ln (1 - [M]_{(o)} / [M]_{(o)}^e) = - (Q/V)(k_{oa} + k_{ao})t \quad (3)$$

At constant stirring speed, the pseudo-first-order rate constants,  $k_{oa}$  and  $k_{ao}$ , are function of the concentration of HA in the organic phase and the concentration of the hydrogen ion in the aqueous phase:

$$k_{ao} = f_1([HA]_{(o)}, [H^+]_{(a)}) \quad (4)$$

$$k_{oa} = f_2([HA]_{(o)}, [H^+]_{(o)}) \quad (5)$$

At equilibrium, equation (2) is equal to zero, then

$$Kd = [M]_{(o)}^e / [M]_{(a)}^e = k_{ao} / k_{oa} \quad (6)$$

Equation (6) is substituted into (3), i.e.

$$\ln (1 - [M]_{(o)} / [M]_{(o)}^e) = - (Q/V)(1 + Kd) k_{oa} t \quad (7)$$

The function  $\ln(1 - [M]_{(o)} / [M]^e_{(o)})$  vs. time was plotted for each experiment. The slopes of the plots were used to evaluate  $k_{oa}$  and  $k_{ao}$ . All plots were straight lines, indicating that the mass transfer process could be treated as a pseudo-first-order reversible reaction with respect to the metal cation.

### Interfacial Tension Measurements of HA

The interfacial excess of HA at the n-heptane-water interface was determined from the plot of the interfacial tension ( $\gamma$ , mN/m) vs  $\log c$ ,  $c$  being the concentration of HA. The plot is shown in Figure 2 and the interfacial excess  $\Gamma$  derived from the linear part of the plot according to the Gibbs equation (eq. (8)) is  $3.54 \times 10^{-6} \text{ mol} \cdot \text{l}^{-2}$ .

$$\Gamma = -\frac{1}{2.303RT} \left( \frac{\partial \gamma}{\partial \log c} \right)_T \quad (8)$$

Here,  $\gamma$  is interfacial tension (in mN/m),  $c$  is the bulk concentration (in mol/l),  $R = 8.314 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$ , and  $T$  is the absolute temperature. It is evident that HA possesses high interfacial activity.

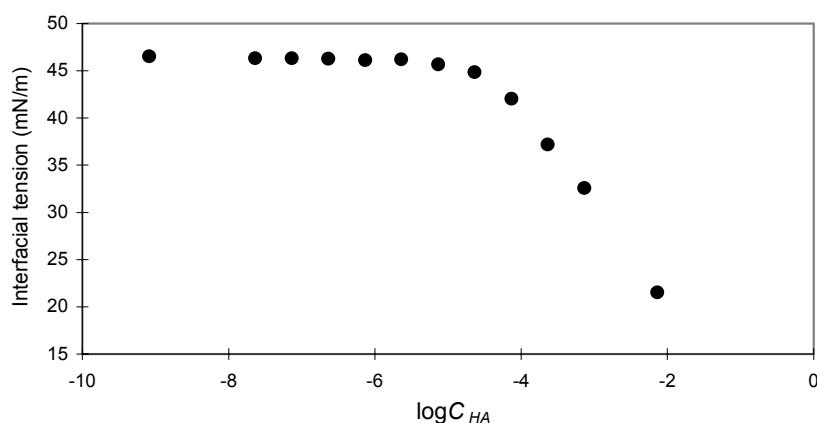

Figure 2. Interfacial tension of HA vs.  $\log c$ .

### Dependence of $\log k_{ao}$ on Stirring Speed

The apparatus used for the kinetic experiments is a constant interfacial area cell with laminar flow [8]. In a constant interfacial area cell, the thickness of the stationary interfacial film is thicker at a lower stirring speed and the diffusion limits the rate because of a relatively fast chemical reaction. With the increase of the stirring speed, the stationary diffusion film becomes thinner and the diffusion resistance smaller. At some value of the stirring speed, the extraction rate may be limited by the chemical reaction only, or the extraction rate is independent on the stirring rate and it is called "kinetics plateau". Hence, this kind of stirring cell allows an easy discrimination between limitation by diffusion or chemical reaction [10].

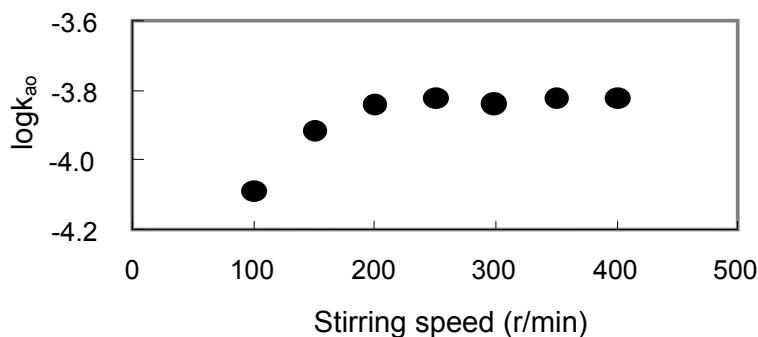

Figure 3. Dependence of  $\log k_{ao}$  vs. stirring speed.

Figure 3 shows the influence of the stirring speed on the extraction rate of yttrium(III) with sec-octylphenoxy acetic acid dissolved in heptane. When the stirring speed attained 200 r/min, the extraction rate was independent on the stirring speed. All other kinetic experiments were measured at 250 r/min in order to maintain same hydrodynamic conditions.

### Dependence of $\log k_{ao}$ on pH

In the pH range from 3.5 to 4.5, the effect of pH on extraction rate was studied. The orders of  $[H^+]$  for La(III), Gd(III), Er(III), Yb(III), Y(III) are  $-0.32$ ,  $-0.46$ ,  $-1.1$ ,  $-0.73$ ,  $-0.79$ , respectively. Because  $k_{ao}$  is function of the concentration of HA and  $H^+$ , for the extraction of La and Gd it is possible that the effect of the concentration of HA on the extraction rate is larger than that of  $[H^+]$ , which the order of  $[H^+]$  for the extraction of La and Gd is lower.

### Dependence of $\log k_{ao}$ on the Concentration of Extractant

The influence of extractant concentration on the extraction rate shows that with the increase of atomic weight from La to Yb the extraction rate decreases. The orders of extractant for La(III), Gd(III), Er(III), Yb(III), and Y(III) extraction with HA are  $1.2$ ,  $1.0$ ,  $1.2$ ,  $1.2$  and  $1.2$ , respectively.

### Dependence of $\log k_{ao}$ on Temperature

It was found that the extraction rate increased with temperature and the experimental data obeyed Arrhenius equation. The apparent activation energies for La(III), Gd(III), Er(III), Yb(III) and Y(III) extraction were calculated from the slope of  $\log k_{ao}$  versus  $1/T$  shown in Figure 4 and were  $18.4$  kJ/mol,  $30.0$  kJ/mol,  $46.2$  kJ/mol,  $55.2$  kJ/mol and  $49.9$  kJ/mol, respectively. Generally speaking [12], when an extraction activation energy ( $E_a$ ) is more than  $42$  kJ/mol, the extraction process is controlled by chemical reaction. When  $E_a$  is lower than  $20$  kJ/mol, species diffusion is rate-determining step. When  $E_a$  is in the range from  $20$  to  $42$  kJ/mol, the extraction rate is controlled by a mixed chemical reaction-diffusion. Thus, the extraction rate for Er(III), Yb(III) and Y(III) with HA is controlled by chemical reaction, Gd(III) is controlled by a mixed chemical reaction-diffusion, and La(III) is controlled by a diffusion.

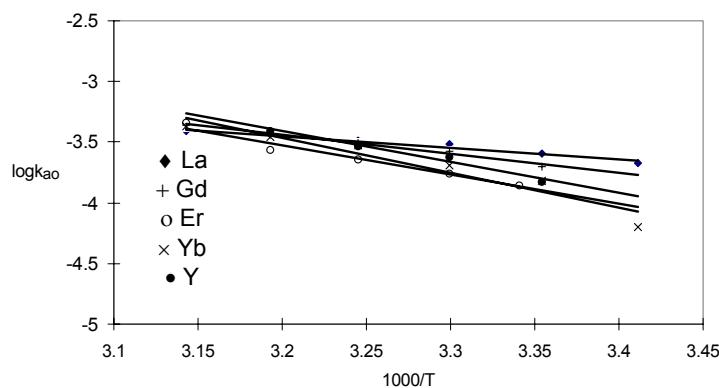

Figure 4. Dependence of  $\log k_{ao}$  vs.  $1/T$ .

## DISCUSSION

According to experimental results, the following rate equations are obtained:

$$-\frac{d[La^{3+}]_{(a)}}{dt} = k[La^{3+}]_{(a)}[H_2A_2]_{(o)}^{1.2}[H^+]_{(a)}^{-0.32} \quad (9)$$

$$-\frac{d[Gd^{3+}]_{(a)}}{dt} = k[Gd^{3+}]_{(a)}[H_2A_2]_{(o)}^{1.0}[H^+]_{(a)}^{-0.45} \quad (10)$$

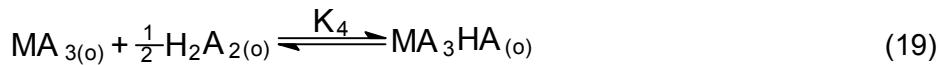

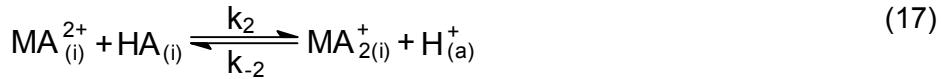

$$-\frac{d[Er^{3+}]_{(a)}}{dt} = k[Er^{3+}]_{(a)}[H_2A_2]_{(o)}^{1.2}[H^+]_{(a)}^{-1.1} \quad (11)$$

$$-\frac{d[Yb^{3+}]_{(a)}}{dt} = k[Yb^{3+}]_{(a)}[H_2A_2]_{(o)}^{1.2}[H^+]_{(a)}^{-0.73} \quad (12)$$

$$-\frac{d[Y^{3+}]_{(a)}}{dt} = k[Y^{3+}]_{(a)}[H_2A_2]_{(o)}^{1.2}[H^+]_{(a)}^{-0.79} \quad (13)$$

The molecules of HA can adsorb on the interface easily because of their surface activity and create a surface excess. Part of the molecules dissociates and diffuses, and interface double layer can result. Rare earth ions in aqueous solution can not easily enter the organic phase directly. Thus, it is more likely that the chemical reaction of extraction for rare earth ions with HA occurs at the two-phase interface. The previous thermodynamic study of rare earth extraction with HA [3] showed that the complex extracted into the organic phase for La(III), Gd(III), Er(III), Yb(III) was  $MA_3 \cdot HA$  and for Y was  $YA_3$ .

Based on the results of above kinetics and thermodynamics, the following extraction reaction mechanism for Er(III), Yb(III) and Y is put forward (there is no equation (19) for the extraction of Y(III)) :

From equations (14) and (15), one can obtain:

$$[HA]_{(i)} = K_1^{1/2} K_2 [H_2A_2]_{(o)}^{1/2} \quad (20)$$

If one assumes an instantaneous state and ignores the  $k_{-2}$  rate constant, the concentration of  $[MA^{2+}]_{(i)}$  can be easily calculated.

$$[MA^{2+}]_{(i)} = k_1 [M^{3+}]_{(a)} [HA]_{(i)} / (k_{-1} [H^+]_{(a)} + k_2 [HA]_{(i)}) \quad (21)$$

Assuming that equation (17) is the controlling-rate-step, one can write the following rate law:

$$R_f = k_2 [MA^{2+}]_{(i)} [HA]_{(i)} \quad (22)$$

Both equation (20) and (21) are substituted into equation (22), then:

$$R_f = k_1 k_2 K_1 K_2^2 [M^{3+}]_{(a)} [H_2A_2]_{(o)} / (k_{-1} [H^+]_{(a)} + k_2 K_2 K_1^{1/2} [H_2A_2]_{(o)}^{1/2}) \quad (23)$$

When  $k_{-1} [H^+]_{(a)} \gg k_2 K_2 K_1^{1/2} [H_2A_2]_{(o)}^{1/2}$ , equation (23) can be simplified as:

$$R_f = k [M^{3+}]_{(a)} [H_2A_2]_{(o)} [H^+]_{(a)}^{-1} \quad (24)$$

where  $k = k_1 k_2 k_{-1}^{-1} K_1 K_2^2$ .

The above mechanism is consistent with the experimental results.

# KINETICS AND MECHANISM OF METAL EXTRACTION ONTO A MICROCAPSULE CONTAINING ORGANOPHOSPHORUS EXTRACTANT

Eiji Kamio, Michiaki Matsumoto and Kazuo Kondo

Doshisha University, Kyotanabe, Japan

In this study, the adsorption behavior of gallium and indium onto a microcapsule containing 2-ethylhexylphosphonic acid mono 2-ethylhexyl ester is investigated by the shallow bed method. Firstly, the adsorption capacities were determined according to the Langmuir adsorption isotherm model. Subsequently, the adsorption rates of gallium and indium were measured and evaluated by homogeneous particle diffusion model. Furthermore, the initial extraction rates of the metals were evaluated for different metal concentrations. The resulted initial extraction rates were compared with those for the solvent extraction system measured using a stirred transfer cell, from which the adsorption behavior could be predicted.

## INTRODUCTION

In recent years, the need of more specific systems for metal recovery from both ecological and economic aspects has led to the development of new adsorbents such as solvent impregnated resins, polymer gels swollen with solvent, microcapsules containing extractant, and so on [1]. Among these new techniques, we have investigated the use of microcapsules as an effective method for recovery and separation of metals. In the previous study [2], we made the extraction equilibria clear and proposed a metal separation system using a column packed with microcapsules containing 2-ethylhexylphosphonic acid mono-2-ethylhexyl ester (abbreviated as EHPNA, trade name PC-88A). From the results, it was found that the microcapsules have a place in extraction chromatography at analytical application scale and are of potential application at an industrial scale. When we apply these microcapsules to industrial application, a fundamental study of transport phenomena of metal ions in a microcapsule is required for evaluating the extraction behavior. However, there are only few reports to evaluate the transport phenomena of metal ions into such adsorbents [3].

In our study, to make the extraction behavior clear, the kinetic experiments of gallium and indium for the microcapsule and solvent extraction systems are carried out.

## EXPERIMENTAL

### Reagents

The microcapsules containing EHPNA were prepared as was described previously [2]. The aqueous phase was prepared by dissolving gallium chloride ( $\text{GaCl}_3 \cdot 6\text{H}_2\text{O}$ ) or indium sulfate ( $\text{In}_2(\text{SO}_4)_3 \cdot 7\text{H}_2\text{O}$ ) in  $0.1\text{mol}/\text{dm}^3$  ( $\text{H, Na}_2\text{SO}_4$ ) solution. The pH of the solution was adjusted with a pH meter. The metal concentrations in the aqueous solutions were measured with an inductively coupled plasma spectrometer (ICPS).

### Adsorption Isotherm

The equilibrium adsorption isotherm of gallium or indium was measured under batch conditions. The aqueous solutions of pH 2.2 containing the metal ions at several concentrations and 0.1g of the microcapsules were contacted for over 1 day to attain equilibrium. Then the metal concentration in the aqueous solutions was measured. The amount of metal adsorbed into the microcapsule was determined by mass balance before and after equilibrium. All experiments were carried out at room temperature.

### Kinetic Study for Microcapsule System with Shallow Bed

Figure 1 shows the shallow bed used in this study. 0.05g of the microcapsules were packed into the bed. The bed was conditioned by feeding aqueous solution at pH 2.2 for 30 min. After 30 min, the aqueous solution containing 0.1 mol/m<sup>3</sup> of gallium or indium ion was introduced for appropriate periods. As soon as this time passed, a scrubbing solution of pH 3.0 was introduced into the bed at a fast flow rate to remove the feed solution remaining in the bed. Two minutes is enough to remove completely the metal ion remaining in the bed. Then the resulting microcapsules were collected and contacted with the stripping solution for 1 day.

### Experimental conditions

Flow rate : 70 cm<sup>3</sup>/min

Reynolds number of feed solution : 2.5

Microcapsules packed: 0.05g

pH of the feed : 2.20

pH of the scrubbing solution : 3.00

Stripping solution :

2.0 mol/dm<sup>3</sup> H<sub>2</sub>SO<sub>4</sub> for gallium

5.0 mol/dm<sup>3</sup> H<sub>2</sub>SO<sub>4</sub> for indium

Temperature : 313K

$$Re = d_p u \rho / \mu$$

$$d_p : \text{particle diameter} \\ = 1.5 \times 10^{-4} \text{ m}$$

$$u : \text{relative rate between fluid and particle} \\ = 10.1 \times 10^{-3} \text{ m/s}$$

$$\rho : \text{fluid density} \\ = 1.03 \times 10^6 \text{ g/m}^3$$

$$\mu : \text{fluid viscosity} \\ = 0.65 \text{ g/(m·s)}$$

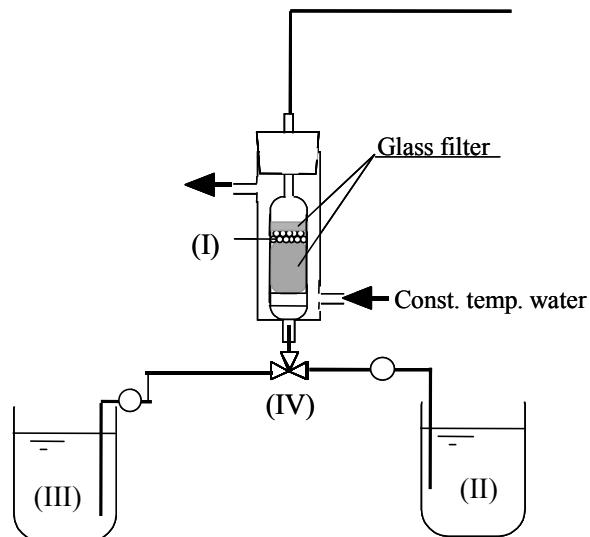

Figure 1. Experimental apparatus of shallow bed method; (I) shallow bed, (II) feed solution (pH = 2.20), (III) scrubbing solution (pH = 3.00), (IV) three-way cock.

### Kinetic Experiment for Solvent Extraction System

A stirred transfer cell was used to measure the rates of gallium and indium extraction by EHPNA at 313K. In this study, undiluted EHPNA was used as the organic phase. The solutions in the cell were stirred at 140 rpm. The aqueous solution containing no metal ion was contacted with the organic phase to attain equilibrium. Then the stock solution containing the metal ion was introduced into the lower compartment of the cell. Small samples were taken at intervals from both phases. The organic samples were treated with the stripping solution. The metal concentration was measured by ICPS.

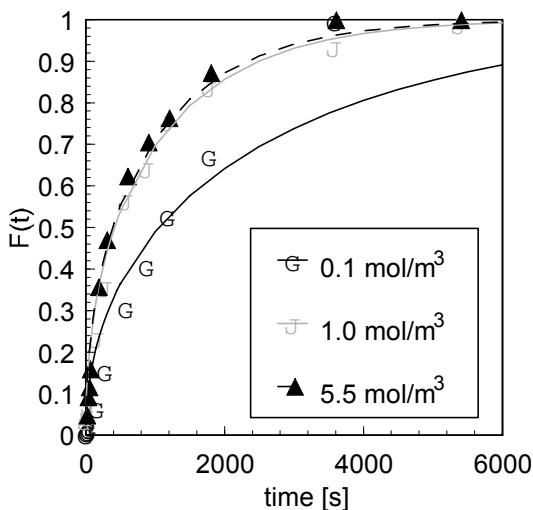

## RESULTS

### Adsorption Isotherms

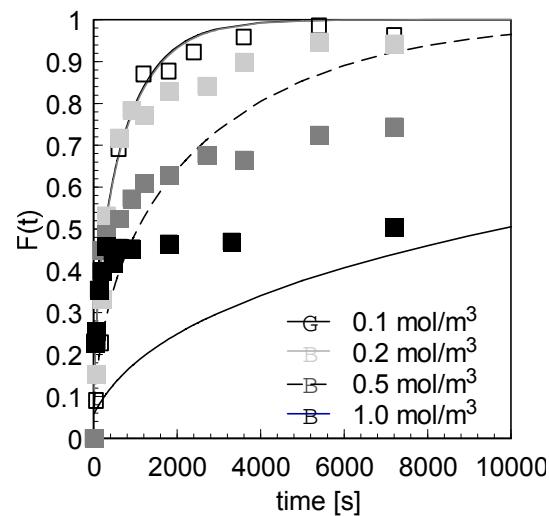

The experimental isotherm results for both metals correlated well with the calculated results based on Langmuir isotherm model. By the least-squares method, saturation capacities,  $q_\infty$ , and equilibrium constants,  $K$ , were determined.

### Kinetic Study for Microcapsule System with Shallow Bed

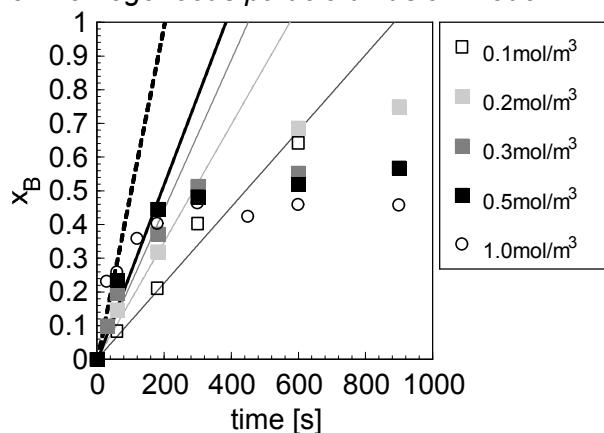

Figures 2 and 3 show the uptakes for gallium and indium adsorption, respectively. As shown in Figure 2, the adsorption rates of gallium increase with increasing the gallium concentration in the bulk. The extraction behavior was evaluated by a homogeneous particle diffusion model based on Fick's law. As a result, it was suggested that the extraction rate would be controlled by intraparticle diffusion of the metal-extractant complex. On the other hand, it is clear from Figure 3 that the adsorption rates of indium decrease with increasing the bulk concentrations. This is opposite tendency for general ion-exchanger or solvent extraction systems. However, at the early periods of the adsorption, the initial adsorption rates increase with increasing the bulk concentration as shown in Figure 4.

*Figure 2. Uptake for gallium adsorption. Solid and broken lines are theoretical result based on homogeneous particle diffusion model.*

*Figure 3. Uptake for indium adsorption. Solid and broken lines are theoretical result based on homogeneous particle diffusion model.*

*Figure 4. Uptakes for indium adsorption in early periods of adsorption.*

### Kinetic Experiment for Solvent Extraction System

Figures 5 and 6 show the relationship between initial extraction rate and metal concentration for gallium and indium, respectively. In these figures, the results for microcapsule systems were also shown. From the figures, it is clear that the calculated initial extraction rates for both systems are almost the same.

In the case of indium extraction, an interesting phenomenon was observed. As soon as the adsorption started, it was found that a white precipitation was formed in the aqueous phase at high metal concentration. This was collected and separated from the aqueous phase by centrifugation. Then, the precipitate was washed with 0.1 mol/m<sup>3</sup> (H, Na)<sub>2</sub>SO<sub>4</sub> solution of pH=2.2. Some was dissolved in 5 mol/m<sup>3</sup> H<sub>2</sub>SO<sub>4</sub> solution and the concentrations of indium and phosphorus were measured with ICPS. They were dried and its P=O bond was identified with FT-IR. From the result of measurement with ICPS, it was found that the molar ratio of In/P in the precipitate was 1.0. From the FT-IR spectrum, the characteristic peaks of EHPNA were observed at 1350 cm<sup>-1</sup> for P=O, 2925 cm<sup>-1</sup> for alkyl chain.

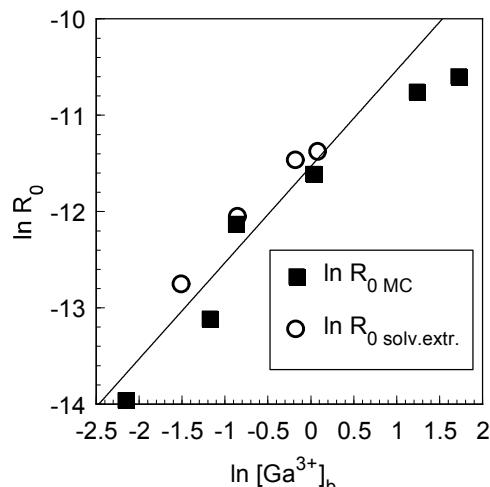

Figure 5. Effect of gallium concentration on initial extraction rate.

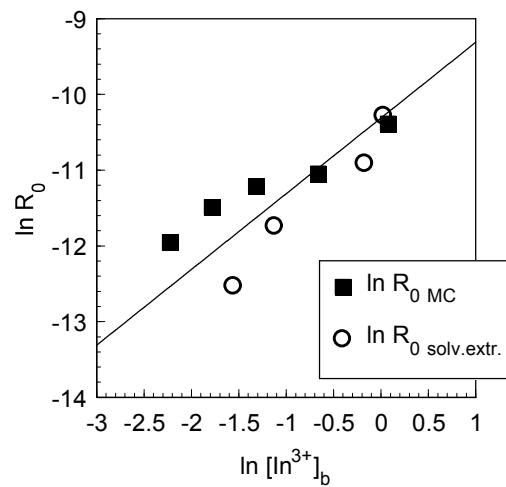

Figure 6. Effect of indium concentration on initial extraction rate.

### DISCUSSION

From the experimental results, it is suggested that the precipitate could be an aggregated indium-EHPNA complex. From this result, it is suggested that the pore in the microcapsule is closed with the indium-extractant precipitations.

We propose that the adsorption behavior occurring at the interface is as follows. At high metal concentration, one or two of the extractant molecule react with the metal ion and the metal-extractant complex ions ( $MR^{2+}$ ,  $MR_2^{+}$ ) are adsorbed at the interface. Only the metal-extractant complex ( $MR_3$ ) can diffuse toward the center of the microcapsules. If there are many metal ions in the liquid film, the metal-extractant complex ions would be mainly formed. Therefore, at early stage of the adsorption, the adsorption rate is fast because of the adsorption of metal ions onto the surface of the microcapsules. However, if the extractant has a high affinity with the metal ion, the aggregated precipitate would be formed at the interface and the exchange reaction of extractants between the complexes does not occur because the metal-extractant precipitate exists stably. As a result, the adsorption rate is considered to become low. On the other hand, if there is only a little metal ion in the bulk, a small amount of the metal-extractant complex ions are formed and no precipitate would be formed at the surface of the microcapsules. Therefore, the metal-extractant complex ions can be reacted with the active non-reacted extractant molecules, and the metal-extractant complex ( $MR_3$ ) will be easily formed. So the adsorption rate under low concentration condition will become faster than that under high concentration condition.

The calculated initial rates for both microcapsule and solvent extraction systems were almost the same. Therefore, it is suggested that chemical reaction controls the adsorption rate at the early periods.

## CONCLUSIONS

The kinetics of adsorption of gallium and indium were investigated in the microcapsule system and solvent extraction system in order to elucidate the adsorption mechanism. It was found that the adsorption of gallium into the microcapsule would be mainly controlled by intraparticle diffusion of metal complex. For indium adsorption, it was suggested that metal-EHPNA complex precipitation was formed at the surface of the microcapsules and it would prevent the diffusion of metal complex into the microcapsules. From the comparison of the results for both microcapsule and solvent extraction system, chemical reaction would control the adsorption at the early periods.

## NEW TYPES OF EXTRACTANT TO TRANSPORT METAL SULFATES IN BASE METAL RECOVERY PROCESSES

Donald M. Gunn, Hamish A. Miller, Ronald M. Swart\*, Peter A. Tasker,  
Lee C. West and David J. White

Department of Chemistry, The University of Edinburgh, Edinburgh, UK

Extractants to transport metal salts have been developed using components that are structurally related to the commercial phenolic oximes. The structures have been engineered to generate sulfate-binding sites so that both the metal cation and the sulfate counterion of divalent metal sulfates can be extracted without changing the pH or transferring any ions to an aqueous feed. Such extractants should be useful in opening up new flowsheets to recover base metals from sulfate streams when it is desirable to avoid any interstage pH-adjustment in solvent extraction or any neutralisation of effluent streams. Proof-of-concept has been established for systems to transport copper(II) sulfate or nickel(II) sulfate. Stripping the metal sulfate and recycling the extractants can be accomplished using pH-swing mechanisms, exploiting a key design feature of the extractants, that the metal sulfate is bound in a zwitterionic form.

### INTRODUCTION

This paper describes the design of novel reagents that are capable of transporting metals *salt*s in metal-recovery circuits (see Figure 1). A programme to develop ligands that bind both a metal cation and its attendant anion or anions was initiated in 1999 with “blue skies” funding from the UK’s Engineering and Physical Sciences Research Council. This was considered timely because developments in the area of supramolecular chemistry [1] have greatly improved our understanding of how to design organic complexing agents for anions [2] using a combination of electrostatic and secondary bonding forces. The programme aimed to exploit this new area of science to achieve high strength and selectivity of extraction of salts of base metals using “ditopic ligands” which have separated, tailor-made, binding sites for the cation and anion(s).

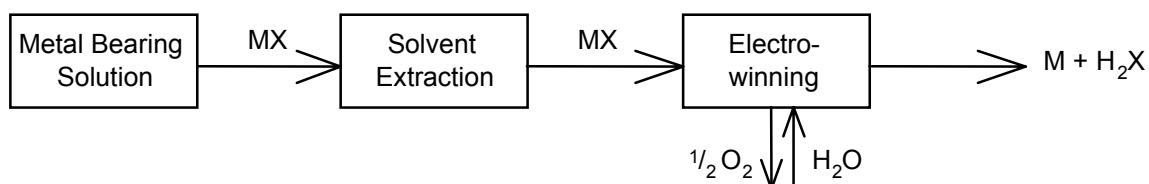

Figure 1. Transport of a metal cation and its attendant anion in a hydrometallurgical circuit.

The concept of transporting a metal salt across a hydrometallurgical circuit is well known for processes involving nitrate and chloride media. Copper recovery from chloride leaching of sulfidic ores has been proposed [3] by using extraction equilibria,

which are dependent on chloride ion concentrations and temperature. In such processes the transfer of the anion(s) to the organic phase is dependent on them being part of the coordination sphere of the metal cation to generate a neutral, organic-soluble, complex. Because the sulfate anion is a relatively poor ligand for base metal cations it is not easy to use this mechanism to transport metal sulfates and, partly as a consequence of this, ion-exchange reagents are generally used for the recovery of base metals from sulfate media. Most commonly in solvent extraction such ion-exchange reagents operate on a pH-swing mechanism,

releasing acid in the front end of a circuit. This is beneficial in primary metal recovery if the leaching step consumes acid and it leads to an almost ideal materials balance in the well established [4] processes to recover copper from oxidic ores *via* a heap leach/solvent extraction/electrowinning circuit as shown in Figure 2.

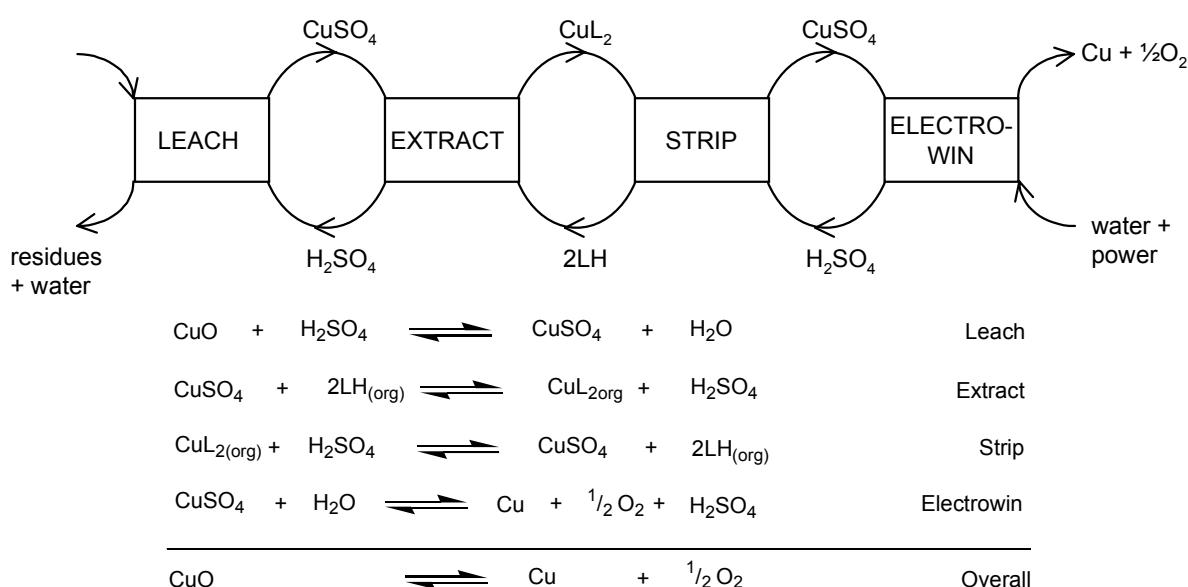

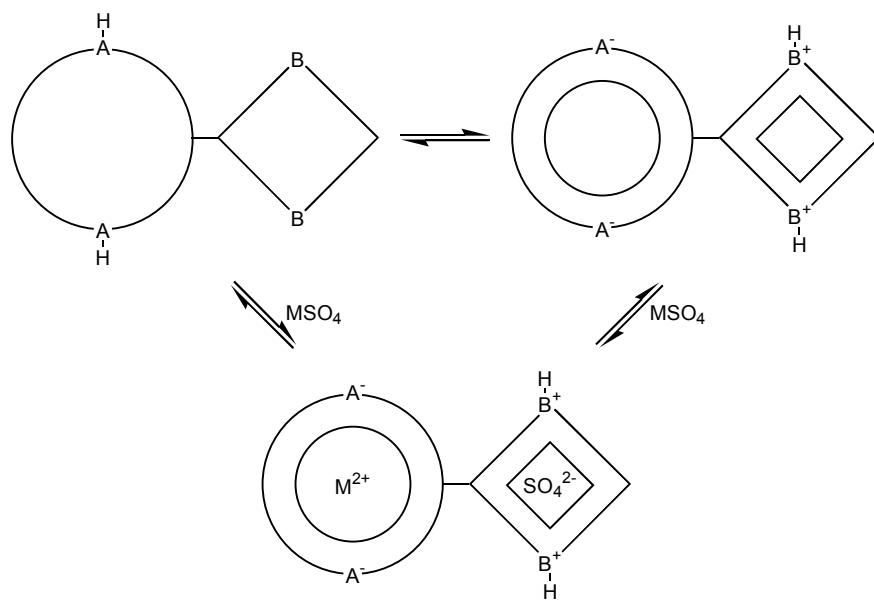

Figure 2. A simplified flowsheet and materials balance for the recovery of copper from oxidic and transition ores by heap leaching, solvent extraction and electrowinning.

Acidic cation-exchange extractants of this type are not so well suited to recovery from pregnant leach solutions where the leach process does not consume acid, or for recovery from secondary sources such as acidic tailings or acid main drainage streams because neutralisation of the acid released in raffinate will be required. For such situations a “subtractive” rather than exchange process is preferred in which the metal sulfate is removed from the aqueous feed.

In designing ligands to operate in this way it is important from the outset to address the following issues:

- (i) An effective mechanism to control loading and stripping must be defined which will allow us to generate an advance with high concentration of metal sulfate and to recycle the reagent efficiently. Whilst it is now possible in theory to design good binding sites for the metal cation and its attendant sulfate anion using relatively well established principles of co-ordination chemistry and supramolecular chemistry [5], it is not obvious how to reverse the complexation reactions. It was decided at the outset to tackle this problem by developing extractants which will bind the metal sulfate in a zwitterionic form of the ligand where the transfer of protons from one site to another creates two charged compartments, one to accommodate the metal cation and the other the sulfate dianion (see Figure 3). It is then possible to use “pH-swing” processes to remove the cation and sulfate anion from the ligand (see below).
- (ii) The metal-binding site, e.g., the dianionic compartment in the schematic ligand in Figure 3, will need to show high selectivity for the desired metal in the sulfate feed solution. It was proposed to tackle this design feature by incorporating other metal-ligating atoms into this compartment to generate a multidentate ligand with donor atoms types and dispositions to meet the preferences of the desired metal ion.
- (iii) For use in base-metal recovery the new extractants based on ditopic ligands must be relatively simple to manufacture and give good mass transfer efficiencies. This presents major challenges. Most of the complexing agents that have been developed recently for binding anions have high molecular weights and rigid, often macrocyclic, structures to pre-organise the functionalities which bind to the anion.

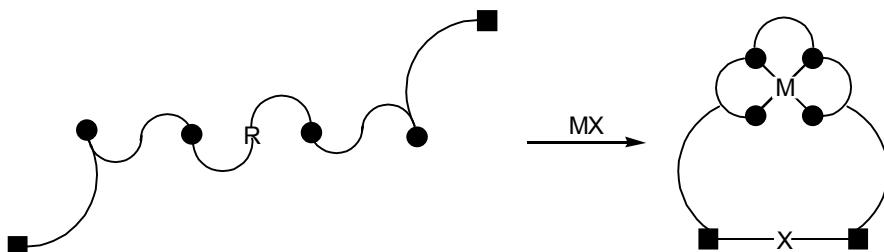

*Figure 3. Schematic representation of a ditopic ligand in which a divalent metal sulfate is bound in the charged “compartments” of a zwitterionic form of a diacidic/dibasic system.*

This paper describes the proof-of-concept of developing relatively simple ditopic ligands of the type shown in Figure 3 to bind metal sulfates and of exploiting the zwitterionic nature of these to establish convenient load/strip protocols to generate a concentrated advance electrolyte and to recycle the ligand. Details of the development and testing reagents to meet the requirements of specific nickel-recovery flowsheets will be presented orally at the meeting.

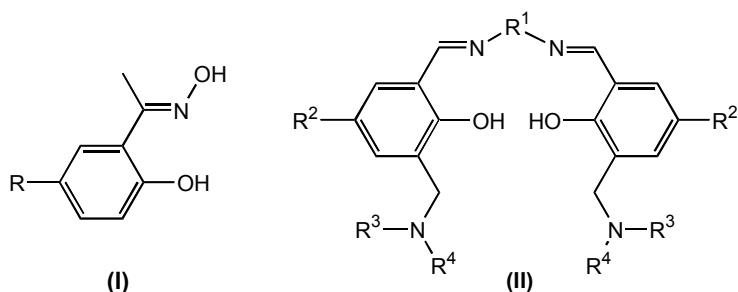

## PROTOTYPE DITOPIC LIGANDS

One of the simplest ways of incorporating the design features outlined in Figure 3 into a ligand superstructure is to use a linear molecule in which the central portion supplies the metal-binding site and the terminal groups the anion-binding site. Complexation of the metal cation can then be used to assist the preorganisation of the functionalities which are needed to bind the anion (see Figure 4).

*Figure 4. Metal-ion templating of the anion binding site in a linear multidentate ligand.*

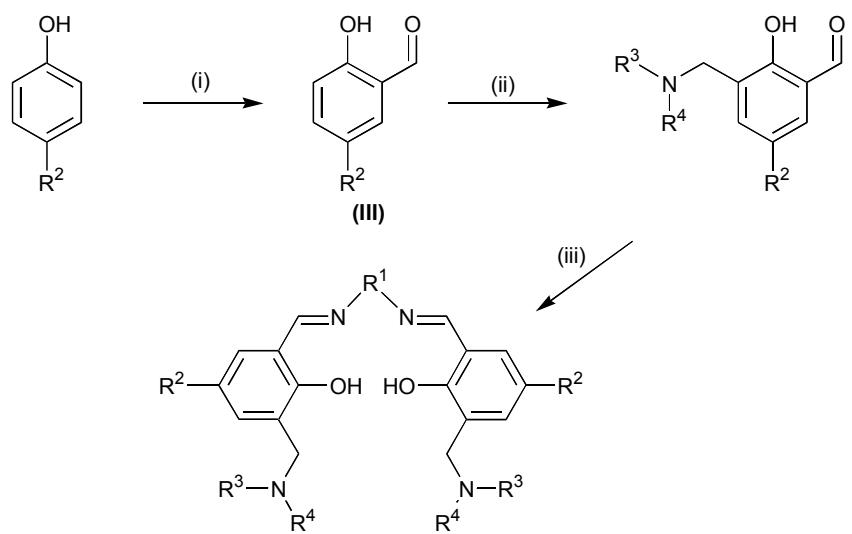

A donor set array as in Figure 4 can be constructed easily from phenolic aldehydes or ketones which are already in commercial production as precursors for the phenolic oxime extractants **I** used in copper recovery.

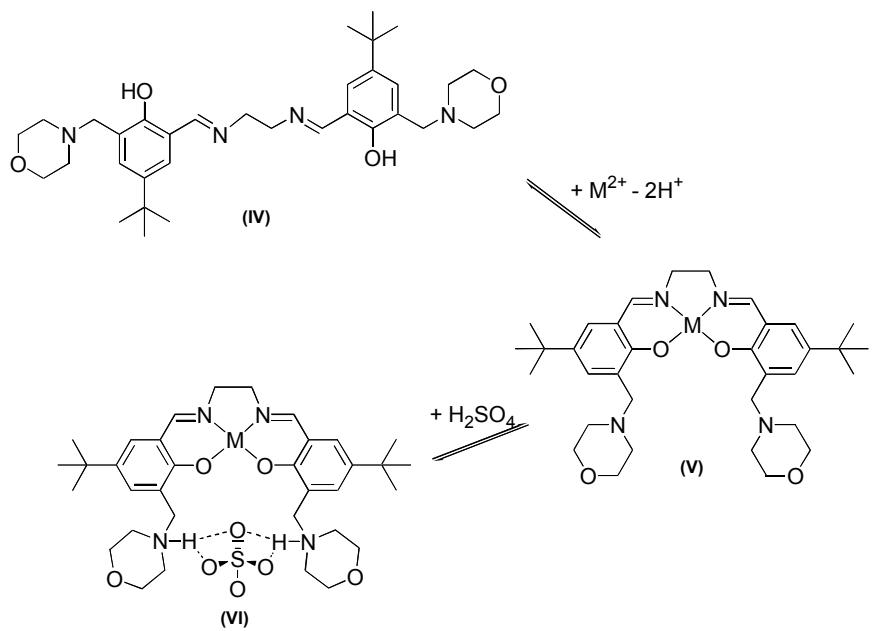

*Figure 5. The commercial oxime extractants **I** for copper and the prototype metal-salt extractants **II** described in this paper.*

The prototype ligands were prepared [6] from the parent phenolic aldehydes **III** in a two stage synthesis in yields approaching 95%, using the scheme outlined in Figure 6. Compounds with a solubilizing  $C_9H_{19}$  substituent  $R^2$  have been used in solvent extraction experiments and with  $CH_3$ - and  $^{13}C_4H_9$ -groups for characterisation and structure determination. Bis-imine ligands derived from salicylaldehyde, "salen-type" systems, have been much studied previously and the nature of the bridge  $R^1$  between the two imine nitrogen atoms has been extensively varied to "tune" metal binding. Appending amido groups in the sites *ortho* to the phenolic oxygen atoms has been used previously to provide hydrogen-bonding functionality [7].

The distinctive feature of the prototype ligands (Figure 6) is that their pendant tertiary amine groups allow formation of complexes of metal salts by incorporating the metal cation and its attendant anion into a zwitterionic form of the ligand which is created by transfer of the phenolic protons to the pendant amine groups. This process, and the templating of the sulfate-binding site are illustrated in Figure 7 for the system **IV** with a flexible  $-(CH_2)_2-$  bridge, and morphilino pendant arms.

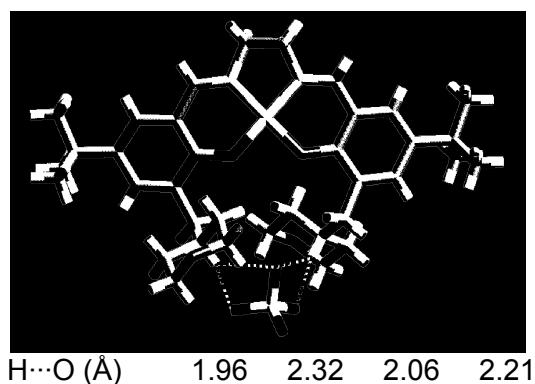

**Figure 6.** The synthesis of the “salen”-type prototype metal-salt ligands: (ia) MgOMe, MeOH-toluene, reflux 3 h; (ib) paraformaldehyde, distillation; (ii) secondary amino-ethoxymethane, MeCN, N<sub>2</sub>, reflux 66 h; (iii) diamine, Et<sub>2</sub>O-EtOH (1:1), r.t. 24 h.

**Figure 7.** The templating of the sulfate binding site in the prototype ligands showing formation of the “nickel-only” complex **V** and the nickel sulfate complex **VI**.

## CHARACTERISATION OF METAL-SALT COMPLEXES

An X-ray structure (Figure 8) determination of the nickel(II) sulfate complex **VI** of the *t*-butyl-substituted ligand indicates clearly that in the solid state the sulfate dianion is located between the protonated morpholinium units forming strong bifurcated hydrogen bonds.

*Figure 8. The solid-state structure of the nickel sulfate complex VI, with the morpholinium-NH to sulfate hydrogen-bonding dimensions.*

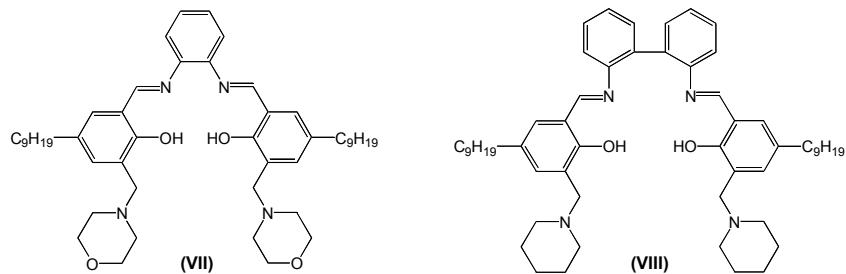

The importance of the “metal-templating” of the pendant tertiary amine groups is illustrated by comparing the distances [8,9] between the morpholino nitrogen atoms in the free ligand with those in the “nickel-only” complex (**V** in Figure 8). The “metal-only” complexes can be formed by carrying out the complex formation at relatively high pH (see below). The morpholino nitrogen atoms are separated [8] by 16.2 Å in the free ligand **IV** compared with 5.17 Å in the “nickel-only” complex **V**. This distance is very similar to that (5.16 Å) in the nickel sulfate complex **VI**.

A wide range of solid-state metal salt complexes of the “salen” prototype ligands has been characterised in our laboratories using X-ray crystallography and other methods. An interesting feature of this chemistry is that “metal only” complexes analogous to **V** in Figure 7 can be treated with diacids to generate polymeric structures with unusual dianion-bridged three-dimensional arrays of complex units [8].

In addition to establishing the viability of metal complex formation using the ligand zwitterions, the solid state structures provide some insight into the design features that are likely to prove important in the development of reagents to be used in liquid phase transport processes. In particular, the geometry of the sulfate-binding site will be dependent on both the “templating” properties of the metal cation and the nature of the bridging unit R<sup>1</sup> in the ligand structure. These will greatly influence the “strength” and selectivity of reagents. Also the solubility of the ligand:metal salt assembly will be very dependent on using functionalities in the pendant tertiary amines which envelop the sulfate group, restricting the formation of intermolecular H-bonded assemblies which will lead to polymeric (insoluble) materials.

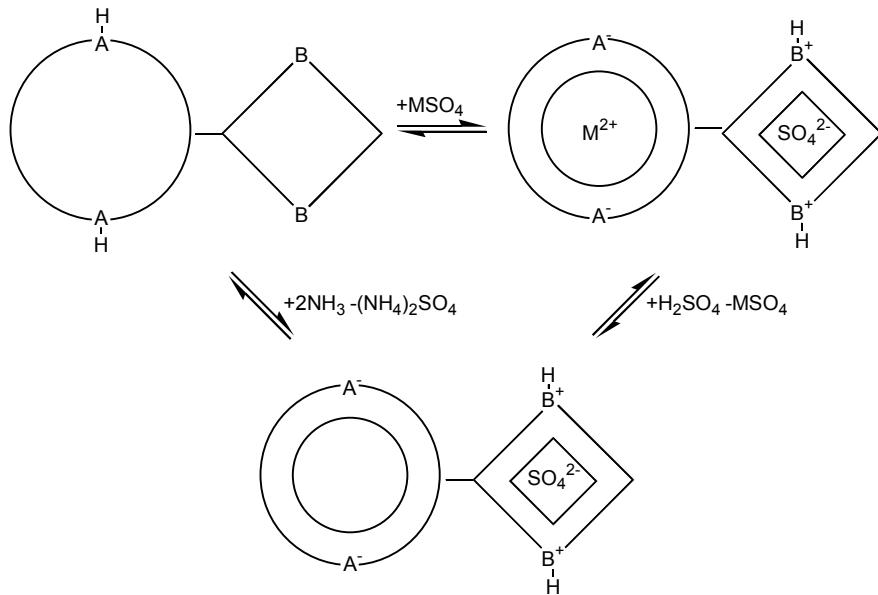

#### **EXTRACTION STUDIES – PROOF OF CONCEPT WITH TRANSPORT OF COPPER(II) SULFATE**

Initially proof-of-concept was established by contacting a 0.01 M solution of the o-phenylene-bridged ligand (**VII** in Figure 9) with an excess of copper(II) sulfate at room temperature. At equilibrium (with no pH-adjustment) a 95-100% loading of copper and sulfate was confirmed by ICP OES analysis. It proved impossible to strip copper from ligand **VII** without using acids of such a concentration that significant decomposition of the ligand resulted.

*Figure 9. "Salen-type" ligands used in extraction experiments.*

One of the strategies envisaged to recover metal salts from these new types of extractants exploits their zwitterionic nature and is illustrated in Figure 10. Because the charges on the binding sites result from protonation/deprotonation reactions we can envisage controlling loading and stripping using “pH-swing” processes. Ideally the system needs to show a pH-profile which has a high stability of the metal-sulfate complex (top right, Figure 10) at a pH close to that of the aqueous feed. The  $\text{pH}_{1/2}$  for reprotoonation of the metal-cation binding site needs to be accessible for stripping with 1-5 M  $\text{H}_2\text{SO}_4$  to yield the sulfate salt of the ligand (bottom, Figure 10). The  $\text{pK}_{\text{a}}$ s of the pendant groups binding the sulfate need to be such that the free ligand (top left, Figure 10) can be easily regenerated with base (ammonia is shown in Figure 10).

*Figure 10. Exploiting the zwitterionic binding sites in the prototype ligands to recycle the extractant and recover metal and sulfate.*

In order to establish the viability of this load(strip protocol for copper sulfate it was clear that the "strength" of the binding site for Cu(II) needs to be "de-tuned" from that in the *o*-phenylene-bridged ligand **VII**. This was approached by incorporating a bridging unit R<sup>1</sup> which will distort the N<sub>2</sub>O<sub>2</sub><sup>2-</sup> donor set of the "salen-unit" away from the planar arrangements preferred by copper(II). Several approaches to this were tried, but the most successful appeared to be the incorporation of a 2,2'-biphenyl-linkage (**VIII** in Figure 9). The solubility of this extractant and its metal complexes was also enhanced by replacing the morpholino units in the pendant arms by piperidino groups. This extractant again showed 95-100% loading of copper from copper(II) sulfate without pH adjustment, but could be stripped to  $\leq 5\%$  copper loading with sulfuric acid pH 1.0 (see Figure 11). The results presented in Figure 11 were obtained [10] by contacting preloaded 0.01M solutions of **VIII** in chloroform with aqueous H<sub>2</sub>SO<sub>4</sub>/Na<sub>2</sub>SO<sub>4</sub>.

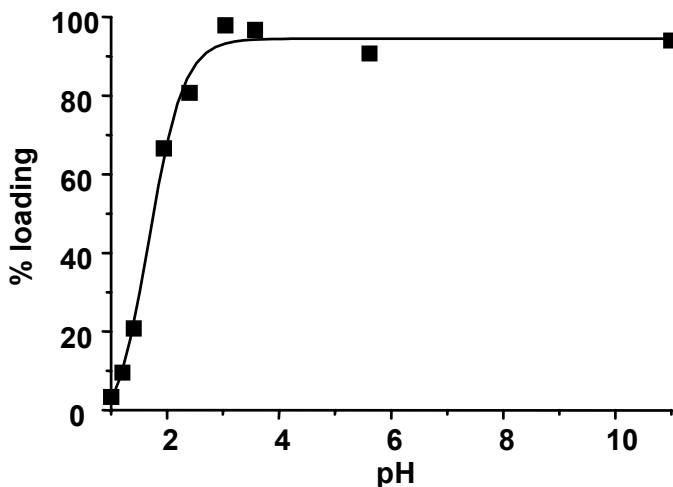

Figure 11. Copper loading of ligand **VIII** as a function of pH.

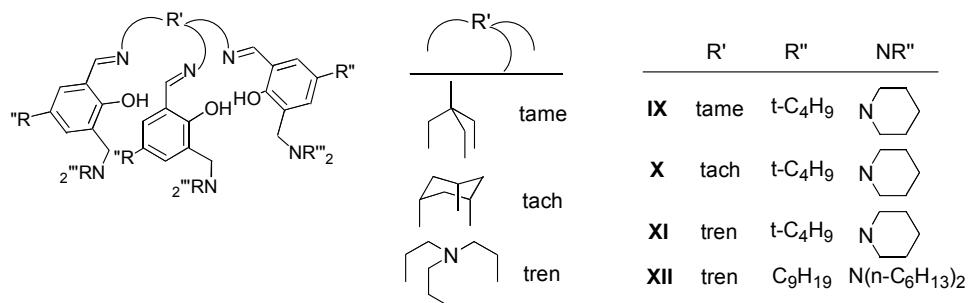

Ammonia solutions can be used very effectively to strip sulfate from the morpholinium binding site of **VIII**. After contracting either a fully CuSO<sub>4</sub>-loaded, or the copper-stripped solution of **VIII** in chloroform referred to above, with aqueous ammonia (pH  $\geq$  11.0) the sulfate loading, as judged by ICP OES, falls to <1%. The reagent **VIII** is robust, and when taken through a cycle of loading with CuSO<sub>4</sub>, copper-stripping with 2 M H<sub>2</sub>SO<sub>4</sub> and sulfate-stripping with ammonia it can be reloaded with CuSO<sub>4</sub> to the same level (>95% of theory) which was observed initially. If the sequence of operations outlined above were to be coupled with conventional electrowinning of copper from sulfate the materials balance would be given by

CuSO <sub>4</sub> + L <sub>org</sub> = [CuLSO <sub>4</sub> ] <sub>org</sub>	Extract
CuLSO <sub>4</sub> + H <sub>2</sub> SO <sub>4</sub> = CuSO <sub>4</sub> + [LH <sub>2</sub> SO <sub>4</sub> ] <sub>org</sub>	Strip 1
[LH <sub>2</sub> SO <sub>4</sub> ] <sub>org</sub> + 2NH <sub>3</sub> = L <sub>org</sub> + [NH <sub>4</sub> ] <sub>2</sub> SO <sub>4</sub>	Strip 2
CuSO <sub>4</sub> + H <sub>2</sub> O = Cu + ½ O <sub>2</sub> + H <sub>2</sub> SO <sub>4</sub>	Electrowin
<hr/>	
CuSO <sub>4</sub> + H <sub>2</sub> O + 2NH <sub>3</sub> = Cu + ½ O <sub>2</sub> + [NH <sub>4</sub> ] <sub>2</sub> SO <sub>4</sub>	Overall

These “shake-out” experiments establish the proof-of-concept of transporting a metal sulfate across a hydrometallurgical circuit and illustrate that the prototype “salen” extractants can be tailored to show strength, pH-profiles for loading and stripping, and solubility characteristics which would allow them to be applied in a wide range of operations. The practicalities of their use in primary copper recovery from sulfate media using a flowsheet involving the material balance outlined above would give some cause for concern in terms of the consumption of ammonia and generation of ammonium sulfate as a by product. It is timely to review with potential end-users how and where the new reagents could be most effectively used in developing flowsheets for base metal recovery. In order to facilitate such discussions, we have focused recently on identifying reagents for the recovery of nickel-from-sulfate media. Results are given below and will be presented in more detail in the context of circuit design at the forthcoming meeting.

## RECOVERY OF NICKEL FROM SULFATE FEED SOLUTIONS

The development [11] of a number of new leaching processes for the recovery of nickel potentially provides opportunities for reagents to transport nickel(II) sulfate. Preliminary work using the “salen-type” extractants (Figure 9) showed that while these readily form  $\text{NiSO}_4^-$ -complexes, the kinetics of loading and stripping are very poor (>24 hours is often needed to approach equilibrium) and the “strength” of the  $\text{N}_2\text{O}_2^{2-}$  binding site is often not sufficient to give high loadings. Consequently we considered extending the design concept to ligands related to this prototype but with the metal cation binding site having six donor atoms to favour the formation of octahedral complexes. The systems which will be described here have trifurcated structures (Figure 12) and provide trianionic and tricationic sites to bind the metal salts. An important feature of such systems is that when binding divalent metal sulfates the overall charge on the metal sulfate complex is zero and good solubility in low polarity organic solvents is possible. Also on the grounds of electrostatic contributions to bonding the “strength” of these trifurcated reagents is expected to be greater than the analogous bifurcated systems. Both of these features have been realised for  $\text{NiSO}_4$ -complex formation with the reagents outlined in Figure 12. Other types of metal salt-ligands containing *pseudo*-octahedral binding sites will be described [12] elsewhere.

*Figure 12. Trifurcated ligands providing tricationic sulfate-binding and trianionic six co-ordinate metal-binding sites.*

These trifurcated reagents can be prepared in high yields by adaptations of the route outlined in Figure 6. The reagents shown in Figure 12 all form nickel complexes readily under conditions analogous to those used for the “salen-type” ligands and spectroscopic and magnetic data support the formulation of these as *pseudo*-octahedral high spin systems. The six co-ordinate geometry of  $\text{Ni}^{2+}$  in these systems has been confirmed by X-ray crystallography for the  $\text{NiSO}_4$  complex of **IX**.

For the development of nickel-recovery processes based on sulfate transport, the reagents will be required to have a high solubility in commercial hydrocarbon solvents, good kinetics of extraction and convenient stripping protocols to allow the SX-based recovery to be interfaced with conventional nickel reduction processes. In the context of the latter it was found that  $\text{NiSO}_4$ -loaded forms of all the ligands **IX-XII** (Figure 12) can be directly stripped by aqueous ammonia to generate nickel ammonium sulfate. This can be used as a feedstock for the conventional Sherrit-reduction process from which the ammonia can be recycled as in the flowsheet based on:

$\text{NiSO}_4 + \text{L}_{\text{org}} = [\text{NiLSO}_4]_{\text{org}}$	Extract
$[\text{NiLSO}_4]_{\text{org}} + 6\text{NH}_3 = \text{L}_{\text{org}} + [\text{Ni}(\text{NH}_3)_6]\text{SO}_4$	Strip
$[\text{Ni}(\text{NH}_3)_6]\text{SO}_4 + \text{H}_2 = \text{Ni} + [\text{NH}_4]_2\text{SO}_4 + 4\text{NH}_3$	Sherrit reduction
$[\text{NH}_4]_2\text{SO}_4 + \text{Ca}(\text{OH})_2 = 2\text{NH}_3 + \text{CaSO}_4 + 2\text{H}_2\text{O}$	Ammonia regeneration
$\text{NiSO}_4 + \text{H}_2 + \text{Ca}(\text{OH})_2 = \text{Ni} + \text{CaSO}_4 + 2\text{H}_2\text{O}$	Overall

Good solubility in hydrocarbons and phase disengagement are shown by the bis-hexylamine-functionalised reagent **XII**. Shake-out work defining loading/stripping isotherms, kinetics measurements and the results of minirig trials will be reported at the forthcoming meeting.

## CONCLUSIONS

An understanding of the principles of “supramolecular chemistry” allows us to design receptors for anions by incorporating functionalities which use secondary bonding to generate stable complexes. One of the potential advantages of incorporating anion-binding sites into metal extractants is that the processes can function without changing the pH or transferring any ions to an aqueous feed.

Having established that it is possible to synthesise such reagents easily from commercially available components, and that they can be tailored to transport metal sulfates in solvent extraction-based circuits, it is timely to review the best areas for their exploitation. It is envisaged that these would involve processes to recover base metals from sulfate streams when it is desirable to avoid any interstage pH-adjustment in solvent extraction or any neutralisation of effluent streams, but other possibilities should be explored. Developing extractants to meet the needs of a particular flowsheet would be best undertaken in collaboration with potential end-users, suppliers of the engineering and a reagent manufacturer.

## ACKNOWLEDGEMENTS

This work has been supported by the Engineering and Physical Sciences Research Council under a ROPA grant and by the Scottish Higher Education Funding Council under a POC award. Bryn Harris, Hatch International (B.Harris@hatch.ca), and Geoff Seward, Hydromet Services International (gseward@25kingfisher.fsnet.co.uk), are thanked for their contributions to defining areas of application of the new reagents which will be described more fully at the meeting. We are also grateful to Avecia for providing access to equipment, expertise and materials for the project and to Edinburgh Research and Innovation, in particular Tom Higgison, for support.

## PHYSICO-CHEMICAL PROPERTIES OF CYANEX® 301

Gerard Cote, Jean-Valéry Martin\*, Denise Bauer\*\* and Yves Mottot\*

Ecole Nationale Supérieure de Chimie de Paris, Paris, France

\* Rhodia Recherches, Aubervilliers, France

\*\* Ecole Supérieure de Physique et de Chimie Industrielles de Paris, Paris, France

This paper gives a rapid overview of the physical and chemical properties of Cyanex® 301. In particular, it is shown that purified bis(2,4,4-trimethylpentyl)dithiophosphinic acid, the active substance of Cyanex® 301, has a weak tendency to dimerize in non-polar organic diluents. The dimerization constant  $K_2$  is close to 5 ( $M^{-1}$ ) in *n*-heptane equilibrated with an aqueous phase of ionic strength of 0.02 M. The aqueous pKa and the logarithm of the partition ratio ( $K_D = [HL] / [HL]$ ) of the monomeric form of bis(2,4,4-trimethylpentyl)dithio-phosphinic acid were estimated to be close to 1.7 and 4.8 (at low ionic strength), respectively. Other properties of Cyanex® 301 such its chemical stability and resistance to  $\gamma$ -irradiation, as well as the nature of the metal species extracted into the organic phases are discussed.

### INTRODUCTION

The organothiophosphorus compounds have attracted a great attention in solvent extraction over the last three decades and their properties have been extensively investigated [1]. Cyanex® 301 is an organothiophosphorus extractant which is commercially available from Cytec and contains about 80% (in weight) of bis(2,4,4-trimethylpentyl)dithiophosphinic acid [denoted hereafter either HL or R<sub>2</sub>PSSH] as the active substance. Originally, Cyanex® 301 was developed for the selective extraction of zinc from effluent streams containing calcium, such as those generated in the manufacture of rayon by the viscose process, but it was found that this reagent is also capable to extract a great number of metal and metalloid species in a large range of acidity [2]. Some possible fields of applications of Cyanex® 301 reported in the recent literature include the treatment of spent catalysts and electroplating baths (removal of Ni) [3], the purification of wet-phosphoric acid (removal of Cd by Solvent Impregnated Resin technology) [4], the treatment of phosphoric acid process liquors [5], the management of tannery waste [6] and the production of separated rare earths [7]. It was also recently discovered that Cyanex® 301 and its analogues are capable of separating actinides(III) from lanthanides(III) in nitric acid media, which is of high strategic importance for the development of advanced nuclear waste reprocessing schemes [8-15]. It has been demonstrated that the high actinides(III)/lanthanides(III) separation factors obtained with such extractants are due to a covalent effect in the M(III)-S bond, which is greater for actinides(III) (e.g., Am<sup>3+</sup>) than for lanthanides(III) (e.g., Eu<sup>3+</sup>). However, despite numerous studies dedicated to Cyanex® 301, and more generally to the organodithiophosphinic acids, some physical and chemical properties of such compounds are not yet very well known or even remain controversial.

The purpose of the present paper is to give a rapid overview of the properties of purified and non-purified Cyanex 301®. Properties such as self-association in the organic phases, acidic dissociation ( $pK_a$ ), distribution between aqueous and organic phases, adsorption at the liquid-liquid interfaces, chemical and radiolytic stabilities are considered. Some crystallographic data of crystallized bis(2,4,4-trimethylpentyl)dithiophosphinic acid are also given. Finally, the nature of the extracted species is discussed.

## PHYSICO-CHEMICAL PROPERTIES

### Chemical Composition

In earlier works, Cyanex® 301 was used as delivered by Cytec (or previously by Cyanamid). Recently, Zhu *et al.* have proposed a method based on the formation, isolation and recrystallization of ammonium bis(2,4,4-trimethylpentyl)dithiophosphinate and regeneration of the acidic form with 4 M HCl, for purifying Cyanex® 301 [16]. Alternatively, El Aouni has proposed a derived method based on the formation of sodium bis(2,4,4-trimethylpentyl)dithiophosphinate [17]. The composition of purified and non-purified Cyanex® 301 has been investigated by various authors with different techniques. The results are summarized in Table 1.

*Table 1. Composition of purified and non-purified Cyanex® 301 (HL).*

Samples	Species and concentrations (R = 2,4,4-trimethylpentyl)	Analytical methods	Ref.
Non-purified Cyanex® 301	R <sub>2</sub> PS <sub>2</sub> H 75 - 83 %      R <sub>3</sub> PS 5 - 8 % R <sub>2</sub> PSOH 3 - 6 %      unknown ≈ 2 %	GC-MS <sup>31</sup> P-NMR	[18]
Non-purified Cyanex® 301	R <sub>2</sub> PS <sub>2</sub> H 78 %      R <sub>3</sub> PS 14 % R <sub>2</sub> PSOH 0.8 %      R <sub>2</sub> PO <sub>2</sub> H 3.5 % unknown ≈ 3.6 %	GC	[19]
Purified Cyanex® 301	R <sub>2</sub> PS <sub>2</sub> H > 99% (up to 99.8 %)	Potentiometric titration <sup>31</sup> P-NMR	[16] [8]
Purified Cyanex® 301	R <sub>2</sub> PS <sub>2</sub> H ≈ 98 %	GC Metal loading at saturation	[17]

Examination of Table 1 mainly shows that the composition of Cyanex® 301 varies from one sample to another, and that the purification method proposed by Zhu *et al.* is efficient.

### Some Physical and Spectrometric Characteristics of Purified Cyanex® 301

At room temperature, purified Cyanex® 301 is a greenish liquid. Some of its physical and spectrometric characteristics are given in Table 2. When purified Cyanex® 301 is left at 0°C, white needle shaped crystals (typically 5-15 μm width x 100 - 200 μm length) of pure bis(2,4,4-trimethylpentyl)dithiophosphinic acid slowly form. These crystals were found to belong to the monoclinic system with  $a = 1.784 \pm 0.003$  nm,  $b = 0.4849 \pm 0.0006$  nm,  $c = 1.127 \pm 0.005$  nm and  $\alpha = \beta = 90^\circ$ ,  $\gamma = 125.1 \pm 0.2^\circ$ . Examination of Table 2 shows that pure bis(2,4,4-trimethylpentyl)dithiophosphinic acid exhibits only a low interfacial activity at the 0.1 M H<sub>2</sub>SO<sub>4</sub> / *n*-decane interface as its Critical Adsorption Concentration is close to 0.03 M.

Table 2. Some properties of purified Cyanex® 301.

Properties	Data		Ref.
Density at 24°C (kg dm <sup>-3</sup> ) Viscosity at 24°C (mPa s)	0.946 18.1		[20]
Interfacial tension at the 0.1 M H <sub>2</sub> SO <sub>4</sub> / <i>n</i> -decane interface, at 25°C (mN m <sup>-1</sup> )	43.7 (C = 0.0001 M) 43.7 (C = 0.001 M) 41.0 (C = 0.01M)	39.3 (C = 0.1 M) 30.1 (C = 1 M)	This work
Proton decoupled <sup>31</sup> P-NMR spectrum (in CDCl <sub>3</sub> )	Only 2 peaks at 67.0 and 67.1 ppm (85% H <sub>3</sub> PO <sub>4</sub> as external standard)	The presence of two peaks in the spectrum is due to the existence of diastereoisomers as each of the two 2,4,4-trimethylpentyl chains contains one stereogen center	This work [2]
Some characteristic absorption bands in the IR spectrum (cm <sup>-1</sup> )	S-H stretching : 2580 P-CH <sub>2</sub> bending : 820	C-P-C bending : 805 P=S stretching : 611	This work

### Self-Association in the Organic Diluents, Distribution between Aqueous and Organic Phases and Aqueous Acidic Dissociation Constant

Although the self-association of purified and non-purified Cyanex® 301 in the organic diluents has been investigated by various authors and various techniques, the subject is still a matter of controversy (Table 3). Indeed, on the one hand, three independent studies based on vapour pressure osmometry and a very recent work based on SANS (small angle neutron scattering) unambiguously indicate that Cyanex® 301 exists as a monomer in toluene (or deuterated toluene), benzene and heptane, at least up to about 0.1 - 0.2 M (0.4 M in toluene), regardless it is purified or not [21-23]. On the second hand, distribution ratio measurements between aqueous and organic phases at pH 3.66 suggest that purified bis(2,4,4-trimethylpentyl)dithiophosphinic acid is dimeric in *n*-heptane, when its total concentration ranges between 0.2 and 1.0 M [20]. These two diametrically opposed conclusions have their unconditional followers and some extraction mechanisms proposed in the literature from metal distribution measurements may be not operative since they have been established considering that bis(2,4,4-trimethylpentyl)dithiophosphinic acid is either monomeric or dimeric, without any further evidence. Thus, the question is of importance.

In inert diluents, the self-association of the dialkyldithiophosphinic acids is possible only through the formation of S – H … S hydrogen bonds. Allen *et al.* have investigated this phenomenon by infrared spectroscopy and found that diethyldithiophosphinic acid and diphenyldithiophosphinic acid in carbon tetrachloride, chloroform and cyclohexane exhibit a very sharp νSH band at 2550 – 2560 cm<sup>-1</sup> (due to the monomeric form of the studied acids) and a broad νSH band at about 2400 cm<sup>-1</sup> (due the dimeric form), whose relative intensities and areas greatly vary with the dithiophosphinic acid concentration: at 0.1 M the IR spectra show mainly the sharp νSH band at 2550 – 2560 cm<sup>-1</sup>, whereas above 2 M the broad νSH band at about 2400 cm<sup>-1</sup> is dominant [25]. Such observations suggest that the two studied dithiophosphinic acids are mainly monomeric in dilute solutions (*i.e.*, up to about 0.1 M), but dimeric in concentrated solutions, which is in a rather good qualitative agreement with the results reported in Table 3 for bis(2,4,4-trimethylpentyl)dithiophosphinic acid.

If equilibria (1-3) are considered, the distribution coefficient D<sub>Cyanex® 301</sub> of bis(2,4,4-trimethylpentyl)dithiophosphinic acid is given by Eq. (4) and Eq. (5) :

Table 3. Aggregation of Cyanex® 301 in organic diluents.

Techniques	Experimental conditions	Aggregation number found ( <i>n</i> )	Ref
Vapour pressure osmometry	0.2 M and 0.4 M non-purified Cyanex® 301 in toluene	<i>n</i> = 1.05 (0.2 M) <i>n</i> = 1.04 (0.4 M)	[21]
Vapour pressure osmometry	About 0.1 M non-purified Cyanex® 301 in benzene at room temperature	<i>n</i> = 0.90 (i.e., <i>n</i> ≈ 1)	[22]
Vapour pressure osmometry	0.016 to 0.16 M non-purified Cyanex® 301 in heptane at 28°C	<i>n</i> = 1 (no detectable deviation from the standard)	[23]
SANS (small angle neutron scattering)	0.1 M purified Cyanex® 301 (99%) in deuterated toluene	<i>n</i> = 1.07	[24]
Distribution ratio measurements between aqueous and organic phases	0.2 M to 1.0 M purified Cyanex® 301 in <i>n</i> -heptane at 25°C (pH = 3.66)	<i>n</i> ≈ 2	[20]

$$D_{Cyanex\text{®}301} = 2K_2 \left( \frac{K_D}{(1+K_a/[H^+])} \right)^2 [Cyanex\text{®}301] + \frac{K_D}{(1+K_a/[H^+])} \quad (4)$$

$$\log D_{Cyanex\text{®}301} = \log K_D - \log 2 + \log \left\{ 1 + (1 + 8K_2 C_{Total})^{0.5} \right\} - \log (1 + K_a / [H^+]) \quad (5)$$

where overbars refer to the species in organic phases,  $[Cyanex\text{®}301] = [HL] + [L^-]$  (i.e., total aqueous concentration) and  $C_{Total} \approx \overline{HL} + 2\overline{H_2L_2}$ .

Examination of Chen's data in *n*-heptane [20] obtained at an ionic strength of 0.02 M shows both a linear dependence of  $D_{Cyanex\text{®}301}$  vs  $[Cyanex\text{®}301]$  and a linear dependence of  $\log D_{Cyanex\text{®}301}$  vs pH :

$$D_{Cyanex\text{®}301} = 5.44 \times 10^6 [Cyanex\text{®}301] + 7.17 \times 10^2 \quad \text{at pH} = 3.66 \quad (R^2 = 0.983) \quad (6)$$

$$\log D_{Cyanex\text{®}301} = 6.98 - 0.997 \text{pH} \quad (R^2 = 0.996) \quad (7)$$

By identifying Eq. (4) and Eq. (6), one obtains  $K_D/(1+Ka/[H^+]) = 7.17 \times 10^2$  and  $2K_2(K_D/(1+Ka/[H^+]))^2 = 5.44 \times 10^6$  (at 25°C, pH = 3.66 and I = 0.02 M), and as a result  $K_2 \approx 5$  ( $M^{-1}$ ) in *n*-heptane. Furthermore, comparison of Eq. (5) and Eq. (7) indicates that  $Ka/[H^+] \gg 1$  in the range of pH investigated (i.e., 2.4 – 4.0) and thus that  $pKa < 2.4$ . Then, at pH = 3.66 and I = 0.02 M,  $K_D [H^+]/Ka \approx K_D/(1+Ka/[H^+]) = 7.17 \times 10^2$ , which leads to  $\log(K_D/Ka) \approx 6.5$ . Finally, by identifying Eq. (5) and Eq. (7), it comes also  $\log(K_D/Ka) - \log 2 + \log(1+(1+8K_2C_{\text{Total}})^{0.5}) = 6.98$ , which gives  $\log(K_D/Ka) \approx 6.6$ , as  $C_{\text{Total}} = 0.4$  M, and thus corroborates the previous determination.

The value of about 5 estimated above for the dimerization constant of bis(2,4,4-trimethylpentyl)dithiophosphinic acid in *n*-heptane, at 25°C, is in a good agreement with the established order of aggregation [23] : alkylphosphinic ( $\log K_2 = 3$  in kerosene [26] and 2.3 in CHCl<sub>3</sub> [27], for Cyanex® 272) > alkylthiophosphinic ( $\log K_2 = 1.3$  in heptane for Cyanex® 302 [H]) > alkylidithiophosphinic acid ( $\log K_2 = 0.7$  in *n*-heptane for Cyanex® 301 [this work]).

The pKa values of organophosphorus acid can be predicted from appropriate statistical relationships [28]. For the XYPSSH dithiophosphinic acids in water containing 7% ethanol, Eq. (8) was established [28,29]:

$$pKa = 1.74 + 0.01\sigma^\phi \quad (8)$$

where  $\sigma^\phi = -1.21, -1.44, -1.21$  and  $-1.11$  for X (or Y) =  $-(CH_2)_4CH_3, -CH_2-C(CH_3)_3, -(CH_2)_5CH_3$  and  $-(CH_2)_7CH_3$ , respectively. The coefficient 0.01 in Eq. (8) suggests that the nature of the substituent X and Y in XYPSSH has only a little influence on the pKa values. Thus, the pKa of bis(2,4,4-trimethylpentyl)dithiophosphinic acid can be estimated to be close to 1.7 in aqueous 7% ethanol, but also in water as the presence of a moderate concentration of ethanol has only a little effect on the pKa values [29,30]. Such a value is indeed lower than 2.4, as stated above. If the value of 1.7 is retained for aqueous pKa at low ionic strength, thus  $\log K_D$  can be estimated to be close to 4.8, which is credible. In summary, the following values can be proposed for bis(2,4,4-trimethylpentyl)dithiophosphinic acid in the system water / *n*-heptane, at low ionic strength :  $pKa \approx 1.7$ ,  $\log K_D \approx 4.8$  and  $\log K_2 \approx 0.7$ . Obviously, such estimates are rough.

However, a value of 5 for the dimerization constant  $K_2$  means that about 40 % of bis(2,4,4-trimethylpentyl)dithiophosphinic acid is already under its dimeric form at  $C_{\text{Total}} = 0.1$  M and it is surprising that the presence of this form was not detected by vapour pressure osmometry, especially in heptane (Table 3). The presence of impurities when non-purified Cyanex® 301 was used, as well as the possible use of dry diluents in which the tendency for aggregation could be weaker than in organic phases equilibrated with water may explain such a discrepancy [31]. Nevertheless further investigations based on the coupled use of various techniques (e.g., VPO, SANS, distribution ratio measurements, etc.) are necessary to elucidate all the involved phenomena.

Finally, it is of interest that in oxygenated diluents such as diethylether or in inert diluents modified by long chain alcohols, the S – H … O hydrogen bonding becomes predominant and the dimerization of the dithiophosphinic acids, including Cyanex® 301, can be ignored, even at high concentration [25,31,32], as assumed in our previous works [33-35].

## **Chemical Stability and Resistance towards Radiolysis**

The dithiophosphorus acids can be easily oxidized into disulphides according to Eq. (9) :

For similar alkyl chains, it was found that the dialkyldithiophosphinic acids are slightly more easily oxidable than their dithiophosphoric analogues (e.g.,  $E^\circ = 0.13$  V for  $X = Y = i\text{-C}_4\text{H}_9$ , whereas  $E^\circ = 0.23$  V for  $X = Y = i\text{-C}_4\text{H}_9\text{O}$ ) [36]. The strong reductive properties of phosphorus dithioic acids determine the instability of their complexes with some metals. In particular, it is known that copper(II) dithiophosphate complexes are converted in polar media into polynuclear copper(I) compounds having a 1:1 metal : ligand stoichiometry [36]. More recently, Sole *et al.* have confirmed the 1:1 stoichiometric ratio between copper and Cyanex® 301 and postulated a structure for the oligomeric complex [22]. It is of interest that the reduction of copper(II) into copper(I) may be intermolecular rather than intramolecular in nature (*i.e.*, the molecules of Cyanex® 301 which act as reducing-agent against copper(II) are not those engaged in the copper(II) complex, but the free Cyanex® 301 molecules in excess) [17]. Evidence of such a behaviour is that the organic solutions of purified Cyanex® 301 loaded with copper(II) at saturation do not undergo transformation, whereas the reduction takes place in the presence of free Cyanex® 301.

Logically, Sole *et al.* found that contact with nitric acid solutions which are oxidizing causes rapid destruction of Cyanex® 301, even at low acid strength and for short periods of time [19]. Even under milder conditions, the dithiophosphorus acids are prone to oxidation with the formation of disulphides in the organic solvent phases. However, they can be regenerated by reduction with metal powders (e.g., Ni, Co, Zn, etc.) [37,38].

Another commonly cited problem with earlier generation of dithiophosphoric acid extractants was their poor hydrolytic and thermal stabilities [39]. Such difficulties are largely overcome with Cyanex® 301 as the latter exhibits no significant degradation when subjected to prolonged periods of exposure to sulphuric acid solutions, even under severe conditions (e.g., 3 M  $\text{H}_2\text{SO}_4$ , 60°C, 3000 hours) [19].

Finally, due to the interest of dithiophosphinic acids for separating actinides(III) from lanthanides(III), the radiolytic stability of non-purified and purified Cyanex® 301 was investigated by Chen *et al.* [40]. It was found that Cyanex® 301 is severely damaged by  $\gamma$ -irradiation, but that purified Cyanex® 301 is more resistant than the non-purified reagent. For instance, the damage percentage of  $\text{R}_2\text{PSSH}$  in purified and non-purified Cyanex® 301 in xylene amounts to 54% and 94%, after a dose of  $10^5$  Gy, respectively. Dialkylmonothiophosphinic acid, dialkylphosphinic acid and various other phosphorus compounds form under  $\gamma$ -irradiation.  $\text{H}_2\text{SO}_4$  also forms after a dose of  $10^6$  Gy.

## **Extracted Species**

From the analysis of metal distribution data by the slope analysis method, various types of extracted complexes have been identified :  $\text{ML}_2$ ,  $\text{ML}_2\text{HL}$ ,  $\text{ML}_2(\text{HL})_2$ ,  $\text{M}(\text{HL}_2)_2\text{.}(\text{HL})_2$ ,  $\text{ML}_3$ ,  $\text{ML}_3\text{.HL}$ ,  $\text{ML}_3\text{.}3\text{HL}$ , etc. Generally, the dithiophosphinates behave as chelating or bridging (in polynuclear complexes) ligands, whereas the non-dissociated dithiophosphinic acid molecules can contribute to the formation of auto-adducts. However, in some cases the formulas proposed for the species extracted in the organic phases may be erroneous as they have been established by assuming that Cyanex® 301 is either totally monomeric or totally dimeric in the organic phases, regardless the actual situation. Thus, considering that purified Cyanex® 301 is totally dimeric in kerosene, Zhu *et al.* found that the plot  $\log D_{\text{Am}}$  vs.  $[\text{H}_2\text{L}_2]_{\text{free}}$  is linear with a slope of 2 (curve 1 in Figure 1) and concluded that  $\text{Am}^{3+}$  is extracted by Cyanex® 301 by formation of  $\text{ML}_3\text{.HL}$  according to Eq. (10) [16] :

However, if one considers that Cyanex® 301 is not totally dimerized in kerosene in the range of concentration investigated (i.e., 0,2 – 1,0 M) and that its dimerization constant is equal to 4 (which is close to 5 as estimated in the preceding paragraph for *n*-heptane), one obtains a plot  $\log D_{Am}$  vs.  $\overline{HL}_{free}$  which is also linear, but whose slope is equal to 3 (curve 2 in Figure 1), which leads to the conclusion that  $Am^{3+}$  is extracted merely as  $AmL_3$  according to Eq. (11) :

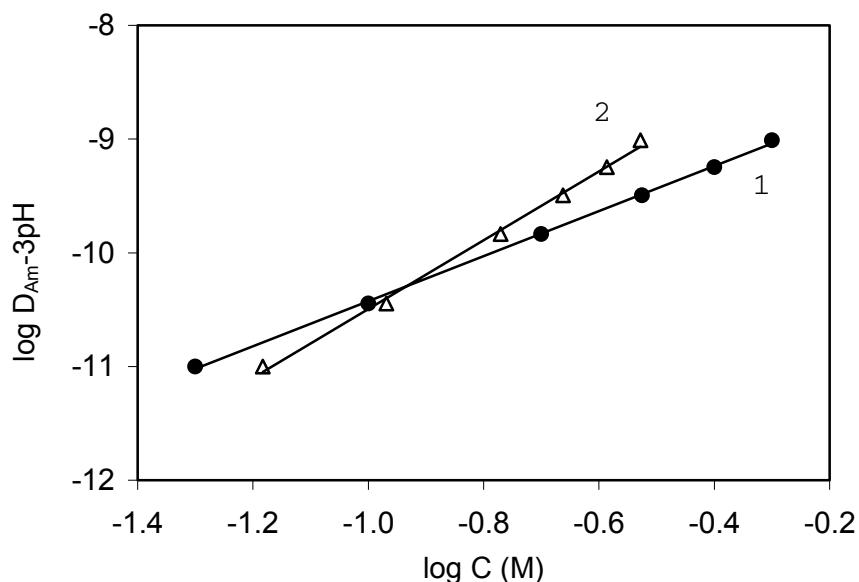

Figure 1. Plot  $\log D_{Am} - 3pH$  vs  $\log C$ . (1) Cyanex® 301 is assumed to be totally dimerized and  $C = [H_2L_2]$ ; slope = 1.98 ( $R^2 = 0.999$ ) [16]; (2) Cyanex® 301 is assumed to be partly dimerized with  $\log K_2 = 0.6$  and  $C = [HL]$ ; slope = 3.02 ( $R^2 = 0.997$ ).

Thus, most equations proposed in the literature for the extraction of metals under experimental conditions where Cyanex® 301 can distribute more or less equally between its monomeric and dimeric forms should be considered critically.

Another interesting phenomenon related to the extracted complexes is the formation of mixed ligand complexes for producing synergistic effects [7,14,15]. We point out that in the presence of O-bearing co-extractant, the formation of S – H  $\cdots$  O hydrogen bonds should be favoured and that the tendency of Cyanex® 301 to dimerize should be depressed.

## TOWARD RECOGNITION OF THE ANION IN THE EXTRACTION OF ALKALI METAL SALTS BY CROWN ETHERS AND CALIXARENES

Bruce A. Moyer, Peter V. Bonnesen, Lætitia H. Delmau,

Recent results are reviewed concerning major factors that govern selectivity for monovalent anions when host-guest chemistry is employed in the extraction of salts from aqueous solution. Such factors include solvation, ion-pairing, and anion binding by anion receptors. From these considerations, we may begin to anticipate the ability to control the selectivity for the anion as well as the cation in salt extraction by designed receptors.

### INTRODUCTION

Despite the attractive selectivity that crown ethers, calixarenes, and other host molecules offer toward *cations*, the role of the anion has not been fully understood nor controlled by design. In recent years, research in this laboratory has focused on ion-pair extraction employing cation and anion receptors for alkali metal salts. Interest in such systems stems in part from the desire to strip extracted salts with water, resulting in processes that yield a pure salt product stream with little secondary waste. Examples include processes for nuclear-waste treatment that produce aqueous streams of cesium nitrate [1] or sodium pertechnetate [2] suitable for vitrification and disposal. These processes respectively employ calixcrown and crown ether extractants to bind the cation, leaving the co-extracted anion to be solvated by diluent, modifier, and water molecules. Solvation principles [3] may thus be used to gain a modest degree of control over the selectivity toward the anion. For univalent anions, extractability tends to increase with increasing anion thermochemical radius. This monotonic selectivity trend has been referred to as "bias," the steepness of which may be manipulated by judicious selection of diluent and any modifier [4]. Exploiting such considerations, the extractability of trace pertechnetate anion from a sodium nitrate waste matrix by a crown ether is possible because pertechnetate is the largest anion in the system. On the other hand, the extractability of trace cesium from a nitrate matrix is more challenging, owing to the difficulty associated with extraction of a small, hydrated anion. Extraction in this case is possible because nitrate has a high concentration and is overwhelmingly the most abundant anion in many nuclear wastes.

In the context of ion-pair extraction by neutral cation receptors like crown ethers, the question naturally arises as to how one can gain better control of the anion co-extraction and escape from reliance upon ion-solvation effects. In this paper, the major effects governing anion selectivity in ion-pair extraction are examined from the point of view of systems studied in this laboratory. Results reflect both solvation and ion-pairing effects in simple systems involving crown ethers. Novel approaches involve the use of separate anion hosts in synergistic combination with cation hosts. Ultimately, such research is aimed at improving processes for the extraction of certain cations such as cesium or sodium by increasing the strength of the extraction and by minimizing matrix effects. A practical benefit would be increased net

strength of extraction of salts from aqueous matrices that contain high concentrations of chloride, nitrate, or other hydrated anions common in hydrometallurgy. Second, one may possibly disrupt the bias-type of selectivity favoring large anions to gain true anion recognition. Third, given the availability of extractants that are each specific to a given salt, one may then possibly combine such extractants without mutual interference. Thus, processes may be envisioned in which one or more targeted salts may be extracted by design from a complex salt mixture.

### SYSTEMS EMPLOYING ONLY A CATION RECEPTOR

In a low-polarity diluent system, the simplest mechanism for the extraction of an alkali metal salt with a univalent anion may be written as:

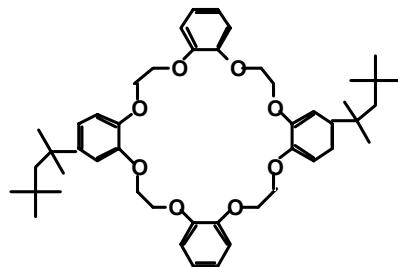

where Crown is any lipophilic neutral metal ion receptor. Many extraction reactions involving crown ethers or calixarenes in fact follow such a stoichiometry [5]. To evaluate how the net driving force depends on anion interactions, it is instructive to examine this reaction in terms of its component thermochemical steps. A particularly useful thermochemical scheme comprises Gibbs energy changes associated with a) partitioning of the individual metal ion  $M^+$  from water to the solvent phase [ $\Delta G_p^\circ(M^+)$ ], b) partitioning of the individual anion  $X^-$  from water to the solvent phase [ $\Delta G_p^\circ(X^-)$ ], c) complexation of the metal ion by the cation receptor CE in the solvent phase [ $\Delta G_{\text{cpx}}^\circ(CEM^+)$ ], and d) ion pairing in the solvent phase [ $\Delta G_{\text{ip}}^\circ(CEM^+X^-)$ ]. The standard Gibbs energy change  $\Delta G_{\text{ex}}^\circ$  associated with the net extraction may be expressed as sum of the four component steps:

$$\Delta G_{\text{ex}}^\circ = \Delta G_p^\circ(M^+) + \Delta G_p^\circ(X^-) + \Delta G_{\text{cpx}}^\circ(CEM^+) + \Delta G_{\text{ip}}^\circ(CEM^+X^-) \quad (2)$$

Generally, the tetraphenylarsonium tetraphenylborate (TATB) extrathermodynamic assumption is employed for evaluating the ion-partitioning terms [3]. Under this reasonable assumption, the values of  $\Delta G_p^\circ$  are set equal for tetraphenylarsonium and tetraphenylborate, thus allowing the evaluation of  $\Delta G_p^\circ$  values for individual ions.

In cases where ion-pairing is weak or effectively does not occur, anion selectivity can be understood entirely on the basis of the behavior of the anion-partitioning term  $\Delta G_p^\circ(X^-)$  [4]. Many such values have been reported in the form of standard Gibbs energies of transfer  $\Delta G_{\text{tr}}^\circ(X^-)$ , which for simplicity are not distinguished here from  $\Delta G_p^\circ(X^-)$  [6]. Unfortunately, quantitative tools for predicting ion partitioning are rather imprecise. Electrostatic theory agrees qualitatively with the general observation that the extractability of anions of a given charge type increases with increasing anionic thermochemical radius ( $r_-$ ). One may say that extraction is "biased" toward larger anions, as distinct from peak selectivity or recognition. Often electrostatic relationships are expressed in terms of  $1/r_-$ , and certain thermodynamic quantities such as standard Gibbs energies of ion hydration or transfer often plot nearly linearly with this variable. From tabulated  $\Delta G_{\text{tr}}^\circ(X^-)$  values [6], it may be seen that values of  $\Delta G_{\text{tr}}^\circ(X^-)$  for a range of anions with a given diluent indeed correlate with  $1/r_-$ , and the slope of the fitted line depends upon the diluent. Toward understanding this effect, electrostatic theory distinguishes among diluents mainly in terms of the dielectric constant, which has unfortunately turned out to be a poor parameter for correlating diluent effects in ion partitioning. Rather, statistical analysis has shown that the most important diluent property governing partitioning of anions is the diluent's ability to donate a hydrogen bond relative to that of water [7]. It follows from this statistical analysis that the slope of plots of  $\Delta G_{\text{tr}}^\circ(X^-)$  vs.  $1/r_-$  correlates with the diluent hydrogen-bond-donor (HBD) strength. By way of a simple conclusion, the closer the diluent is to water in donating hydrogen bonds, the less anion discrimination or bias is possible. To maximize anion discrimination, the diluent should therefore be chosen to have no HBD ability.

A practical example is the extraction of trace pertechnetate ( $\text{TcO}_4^-$ ) as a sodium salt by a crown ether from a concentrated sodium nitrate matrix [2]. In this case, one requires the maximum discrimination or bias in favor of the larger pertechnetate ( $r_- = 0.252 \text{ nm}$  [4]) vs. nitrate ( $r_- = 0.196 \text{ nm}$  [4]). It follows that one should choose a diluent system with low HBD strength, as a hydrogen-bond donor would bind more strongly to the smaller nitrate ion and thereby lower selectivity for pertechnetate. Accordingly, 1-octanol in comparison with non-HBD solvents such as 2-octanone gave poor extraction of pertechnetate [8].

4,5"-bis(*tert*-octylbenzo)dibenzo-24-crown-8

To quantify the thermochemical terms in eq. 2 by way of a specific example, Figure 1 shows the stepwise extraction of cesium nitrate and perchlorate salts by a representative cesium-selective crown ether, 4,5"-bis(*tert*-octylbenzo)dibenzo-24-crown-8 (see structure at right) [9]. Through equilibrium analysis of liquid-liquid distribution data, it has been possible to evaluate these component steps in terms of their standard Gibbs energies with use of 1,2-dichloroethane as a model (as opposed to a process-suitable) diluent. The use of this diluent was helpful in this regard, as a) values of  $\Delta G_p^\circ$  are available [6], b) extraction behavior is simple, and c) the intermediate dielectric constant (10.4) permits examination of the ion-pairing step. It may be seen in Figure 1 that partitioning of the individual ions into the solvent is highly unfavorable, but the favorable complexation of the cation by the crown ether more than compensates, drawing the cesium ion into the solvent phase. Ion pairing provides additional stabilization. The overall process, corresponding to eq. 1, is favorable for each salt, whence  $\Delta G_{\text{ex}}^\circ = -1.7 \text{ kJ mol}^{-1}$  for  $\text{CsNO}_3$  extraction and  $-18.0 \text{ kJ mol}^{-1}$  for  $\text{CsClO}_4$  extraction.

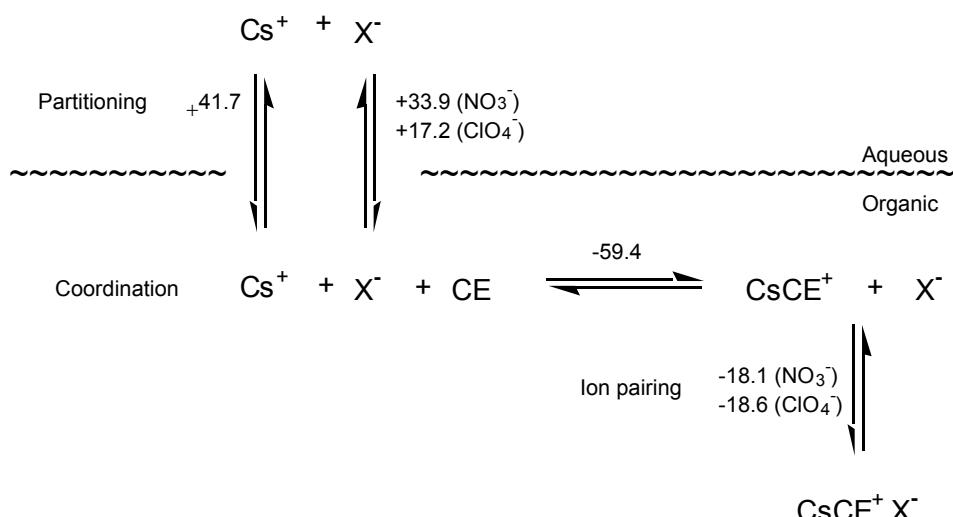

Figure 1. Thermochemical scheme for the extraction of cesium salts by 4,5"-bis(*tert*-octylbenzo)dibenzo-24-crown-8 (CE) in 1,2-dichloroethane at 25 °C. The numbers associated with the equilibria are standard Gibbs energies in  $\text{kJ mol}^{-1}$ .

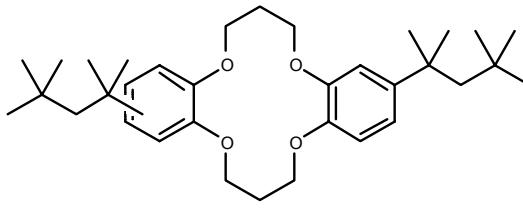

By reference to Figure 1, it may be appreciated that two processes govern anion selectivity: anion partitioning and ion-pairing. In the example shown, the overall extraction of the perchlorate salt of cesium is favored over nitrate by 16.3 kJ mol<sup>-1</sup>, consistent with the thermochemical radii (0.196 nm and 0.250 nm for nitrate [4] and perchlorate [6], respectively). Moreover, it is clear that almost all of the selectivity comes from the anion-partitioning process and is thus governed essentially by solvation. Ion pairing in this case has almost no effect on anion preference, attributable to the fact that the ion-pair is ligand-separated as a consequence of the efficient encapsulation of the Cs<sup>+</sup> ion by the crown ether [9]. Maximal anion discrimination is thus achieved, as ion-pairing is minimized.

Thermochemical measurements corresponding to the system shown in Figure 1 have been made for a large series of anions under the same conditions. The standard Gibbs energy change for the process in which the ions are completely dissociated in the solvent phase may be defined:

$$\Delta G_{\text{ex}\pm}^\circ = \Delta G_p^\circ(M^+) + \Delta G_p^\circ(X^-) + \Delta G_{\text{cpx}}^\circ(\text{CEM}^+) \quad (3)$$

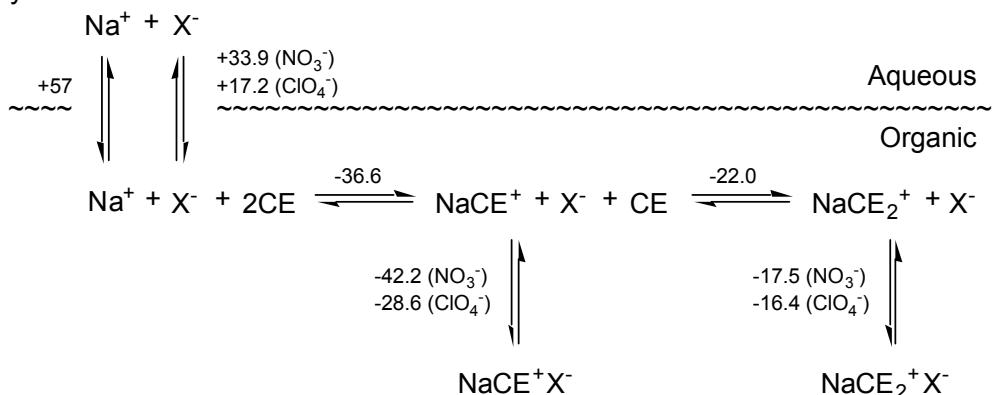

As expected, linear plots of the corresponding constant  $\log K_{\text{ex}\pm}$  vs.  $\Delta G_p^\circ(X^-)/(2.303RT)$  were obtained. This has allowed the determination of values of  $\Delta G_p^\circ(X^-)$  for anions not yet reported in the literature(kJ mol<sup>-1</sup>): picrate (3.4), MnO<sub>4</sub><sup>-</sup> (12.4), CF<sub>3</sub>SO<sub>3</sub><sup>-</sup> (20.5), CF<sub>3</sub>COO<sup>-</sup> (34.9), CH<sub>3</sub>SO<sub>3</sub><sup>-</sup> (48.1), and CH<sub>3</sub>COO<sup>-</sup> (56.5).

By contrast, Figure 2 illustrates a case where ion-pairing does have a significant impact on anion selectivity. The system shown involves the extraction of sodium salts by bis(*tert*-octylbenzo)-14-crown-4 (structure at right) in 1,2-dichloroethane at 25 °C [10]. This crown ether was shown to bind Na<sup>+</sup> ion as a 1:1 metal:ligand open-face sandwich and a 1:2 metal:ligand sandwich complex in the same system. In the formation of the open-face sandwich complex NaCE<sup>+</sup>X<sup>-</sup>, the ion-pairing step favors nitrate by 13.6 kJ mol<sup>-1</sup>, owing to the ability of the anion to engage in contact ion-pairing with the Na<sup>+</sup> cation. As a result, the ion-pairing interaction nearly cancels the perchlorate selectivity of the ion-partitioning step, and the net reaction favors perchlorate by just 3.1 kJ mol<sup>-1</sup>. On the other hand, sandwich formation prevents contact ion-pairing, and the result is reminiscent of the case in Figure 1. Namely, the ion-pairing step discriminates weakly between the anions, because the charge-separation is large in the ligand-separated ion-pair. Consequently, the ion-partitioning step controls the selectivity, and perchlorate is favored in the net reaction by 15.6 kJ mol<sup>-1</sup>, in fairly good agreement with the results obtained in Figure 1 with an entirely different system.

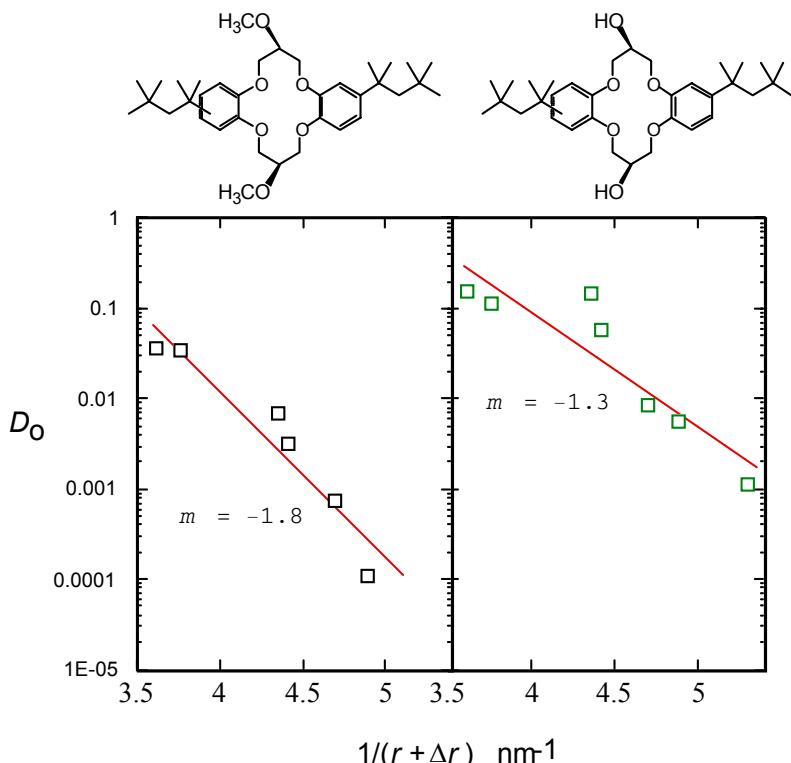

Another way to modulate anion selectivity through the ion-pairing interaction entails modifying the cation-receptor molecule by adding HBD groups. Figure 3 illustrates such an example, in which the *syn*-bis(methoxy) and *syn*-dihydroxy derivatives of bis(*tert*-octylbenzo)-14-crown-4 are compared [11]. In the experiment, each crown ether was used to extract aqueous solutions containing single sodium salts, and <sup>22</sup>Na tracer techniques were employed to determine the distribution ratio of each salt. From largest to smallest, the anions tested include ReO<sub>4</sub><sup>-</sup>, ClO<sub>4</sub><sup>-</sup>, SCN<sup>-</sup>, I<sup>-</sup>, NO<sub>3</sub><sup>-</sup>, Br<sup>-</sup>, and Cl<sup>-</sup>. Sodium chloride extraction was too feeble for reliable measurement in the case of the *syn*-bis(methoxy) derivative and could not be determined. A correction for loading was applied to the distribution data, and the corrected distribution ratio  $D_0$  is shown plotted vs. the reciprocal of the anionic thermochemical radius augmented by a small correction term ( $\Delta r_- = 0.017$  nm). The size correction  $\Delta r_-$  is that which linearizes plots of Gibbs energies of anion hydration vs.  $1/(r_- + \Delta r_-)$

[12]. As shown in Figure 3, both crown ether systems exhibit a strong bias toward large anions, as indicated by the arbitrary lines drawn with negative slope. If one refers to the slope ( $m$ ) as a measure of bias, then it may be concluded that the effect of the hydroxy groups is to attenuate this bias. The hydrogen-bond donation provided by the hydroxy groups would be expected to boost extraction of all anions. However, the hydrogen-bonding interaction would be strongest with the smallest anions and would thereby enhance their extraction to a greater degree than that of the larger anions. The net effect is to make the negative slope of the line less steep. It may be noted that some recognition may be exhibited in the case of the  $\text{SCN}^-$  ion, which lies somewhat above the line in the case of the *syn*-dihydroxy crown.

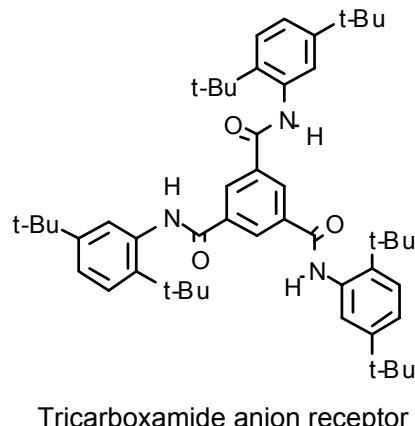

*Figure 2. Thermochemical scheme for the extraction of sodium salts by bis(tert-octylbenzo)-14-crown-4 in 1,2-dichloroethane at 25 °C. The numbers associated with the equilibria are standard Gibbs energies in kJ mol<sup>-1</sup>.*

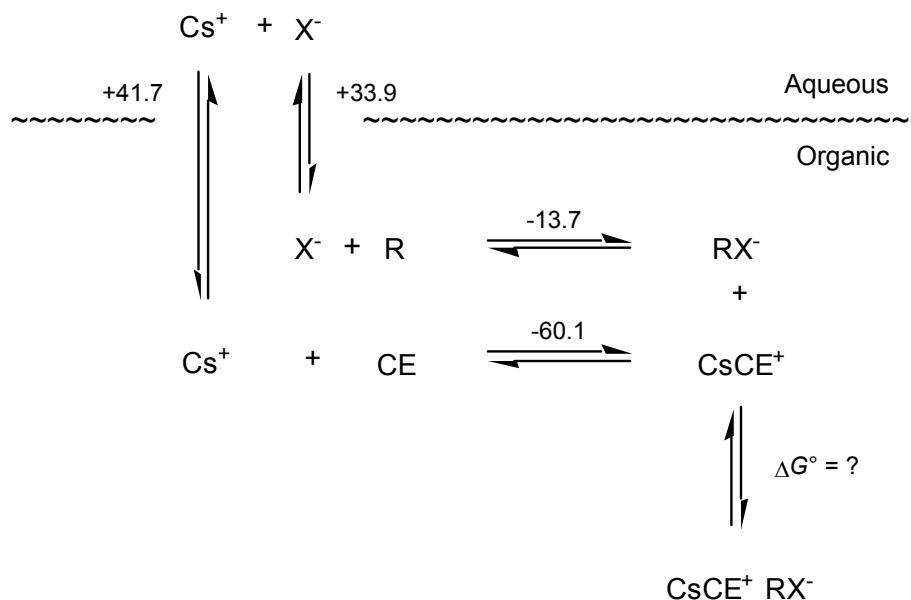

*Figure 3. Extraction of individual sodium salts at 0.5 M by two derivatives of bis(tert-octylbenzo)-14-crown-4 at 50 mM in 1,2-dichloroethane at 25 °C. From left to right, points in the plots each correspond to the anions  $\text{ReO}_4^-$ ,  $\text{ClO}_4^-$ ,  $\text{SCN}^-$ ,  $\text{I}^-$ ,  $\text{NO}_3^-$ ,  $\text{Br}^-$ ,  $\text{Cl}^-$ ; chloride was not determined in the left plot and was omitted.*

## DUAL-HOST SYSTEMS

As illustrated in Figure 4, it is possible to fundamentally alter the extractability of the anion in ion-pair extraction of alkali metals by the addition of an anion receptor [13]. By combination of a tripodal tricarboxamide-type anion receptor with 4,5"-bis(*tert*-octylbenzo)dibenzo-24-crown-8 in 1,2-dichloroethane, the extraction of cesium nitrate at 25 °C is synergistically enhanced. According to the equilibrium constant for nitrate binding measured independently by  $^1\text{H}$  NMR, the enhancement in driving force is potentially as much as -13.7 kJ mol<sup>-1</sup> in this case. Electro-spray mass-spectrometry results confirmed the 1:1 binding of the nitrate anion by the receptor. Comparable results were obtained with tripodal triamide receptors based on tris(2-aminoethyl)amine (tren) [14]. Synergistic enhancements in the distribution experiments were comparable to, though somewhat less than, the values expected from the NMR binding constants. Detailed equilibrium analyses remain to be performed, including determination of the ion-pairing constants and intermolecular association between the two receptors. Ion-pairing may be weak, as conditions were chosen to favor dissociation, and the complexation of the anion is likely to decrease the stability of the ion pair by increasing charge separation. Likewise, intermolecular association as judged from vapor-phase-osmometry data is weak in these systems, though not absent.

Tricarboxamide anion receptor

*Figure 4. Scheme showing stepwise extraction of cesium nitrate into an organic solvent containing 4,5"-bis(*tert*-octylbenzo)dibenzo-24-crown-8 and a tripodal tricarboxamide-type anion receptor in 1,2-dichloroethane at 25 °C.*

In experiments using more powerful disulfonamide anion receptors combined with a calixcrown  $\text{Cs}^+$  ion receptor, the synergistic enhancement in the extraction of cesium salts was found to increase with decreasing anion size [15].  $^{137}\text{Cesium}$  tracer distribution experiments shown in Figure 5 were performed using aqueous phases containing 0.10 M  $\text{NaX}$  (inextractable) and  $5 \times 10^{-6}$  M  $\text{CsX}$  [in order of increasing  $\Delta G_p^\circ(\text{X}^-)$ ,  $\text{X}^- = \text{ClO}_4^-$ ,  $\text{I}^-$ ,  $\text{NO}_3^-$ ,  $\text{Br}^-$ ,  $\text{Cl}^-$ ]. Organic phases contained 0.010 M of calix[4]arene-bis(benzo-18-crown-6) **1** either alone or with 0.035 M of sulfonamides **2**, **3**, or **4** in 1,2-dichloroethane at 25 °C. Based on previous results [16], these experimental conditions are expected to minimize ion-pairing and

its role in anion selectivity. Control experiments performed with organic phases containing sulfonamides alone gave negligible extraction relative to the calixarene used alone. The results in Figure 5 show that receptors **2** and **3** dramatically enhance Cs<sup>+</sup> ion extraction by the calixcrown for small anions. In general, the degree of enhancement agreed with that expected from independently measured anion-binding constants measured by NMR titrations. As follows from eq. 3, the cesium distribution ratio using the calixcrown alone varies linearly with  $\Delta G_p^\circ(X^-)$ . Remarkably, the combined systems also give linear plots, indicating that there is no special recognition for any of these anions. The effect of the anion receptors is apparently to attenuate the bias for the large anions. As discussed above, such behavior resembles that expected for hydrogen-bond donor diluents.

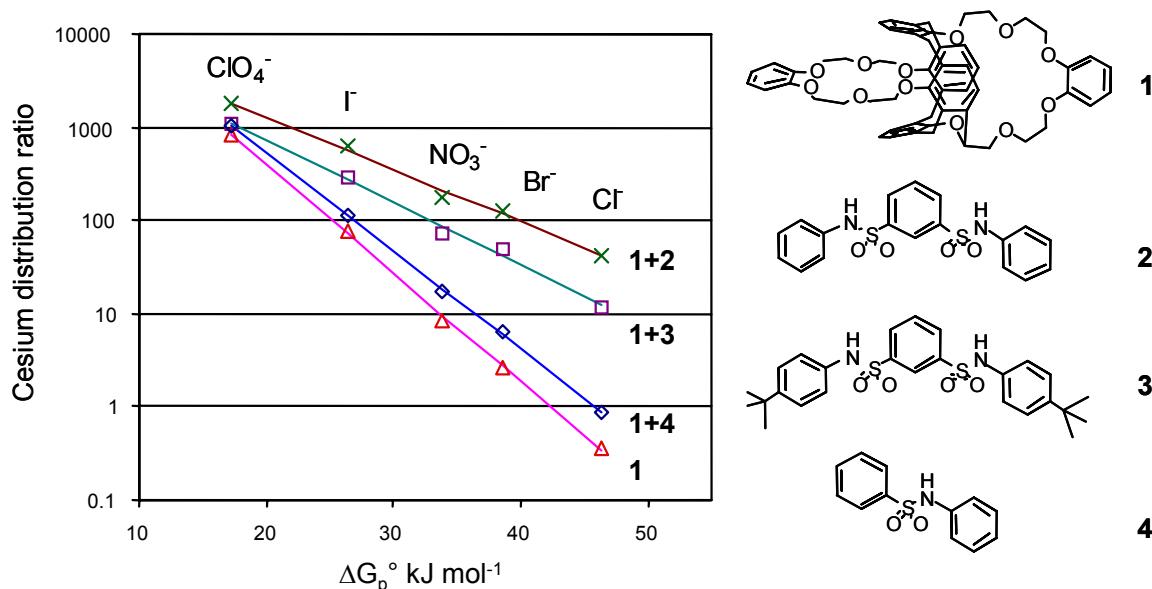

Figure 5. Plot showing the synergistic effect involving combinations of calixcrown **1** with sulfonamide anion receptors **2** - **4** in 1,2-dichloroethane in the extraction of trace Cs<sup>+</sup> ion from 0.1 M sodium salt solutions at 25 °C.

## CONCLUSIONS

Recent results show how one may manipulate interactions involving the co-extracted monovalent anion in ion-pair extraction systems involving neutral cation and anion receptors. In the absence of other specific interactions, solvation effects govern anion selectivity in systems involving only the cation host. A persistent dependence on the reciprocal anion thermochemical radius has been linked to the often-observed bias-type selectivity favoring large anions. Diluent effects are pronounced, though limited mainly to influencing the steepness of this bias effect. Ion-pairing interactions attenuate this bias, but if the cation is fully encapsulated so as to prevent contact ion-pairing, minimal attenuation occurs. Contact ion-pairing is a strong effect and was observed to nearly cancel the bias due to solvation alone. Hydrogen-bonding groups on the cation receptor may also interact with the anion to attenuate bias.

A promising novel approach entails the combination of cation and anion receptors. Significant synergistic effects are observed that can be definitely attributed to anion binding. However, systems so far investigated exhibit only attenuated bias with little or no evidence for true anion recognition. Future efforts are focusing on use of anion receptors possessing multiple hydrogen-bond donor groups and sufficient constraints so as to foster anion

recognition. Detailed equilibrium models are needed to understand the net process in terms of discrete thermochemical steps. One interaction not yet well characterized entails interaction between the two hosts. This potentially antagonistic effect has not proved strong in the case of the tricarboxamide hosts but remains an open question with sulfonamide and pyrrole-type receptors under current investigation.

Ditopic hosts combining cation and anion receptors into a single molecule offer incentives for future study but represent a particular challenge. Such ion-pair receptors must discourage intra- and inter-molecular interactions between hydrogen-bond donor and acceptor groups while maintaining maximal preorganization for the incoming ion-pair. Given that such systems may be found, a key advantage may lie in efficient encapsulation of the ion-pair as a unit, minimizing the role of the diluent and perhaps permitting use of aliphatic diluents with little or no modifier. It therefore seems possible that practical processes may be devised for selective salt extraction from a complex aqueous mixture. Additionally, for particular purposes in which it would be advantageous to target multiple salts simultaneously, well-designed ditopic hosts could be combined without antagonistic interaction.

### ACKNOWLEDGMENTS

This research was sponsored by the Division of Chemical Sciences, Geosciences, and Biosciences, Office of Basic Energy Sciences, U.S. Department of Energy, under contract DE-AC05-00OR22725 with Oak Ridge National Laboratory, managed and operated by UT-Battelle, LLC. The participation of T.G.L. and K.K. was made possible by an appointment to the ORNL Postgraduate Program administered by the Oak Ridge Associated Universities.

<sup>c</sup> Freie Universität Berlin, Berlin, Germany

The design of extractants for noble metal ions, especially Au(III), which are based on the concept of ion recognition is reported. The structure of extractants that recognize  $[\text{AuCl}_4]^-$  was optimized with respect to extraction efficiency, high selectivity, complete back extraction and fast kinetics. For that purpose, functional groups were attached to a macrocyclic backbone which places them in suitable positions to match the metal coordination sphere. The most useful of these calixarenes are nitrogen- and sulfur-containing ones having a cavity which is large enough to wrap around the desired metal ion. The study also includes the comparison with extractants of similar structure but different donor atoms, e.g., amides instead of thioamides. The synthesis of such new ligands is straightforward and proceeds in good yields. The extraction equilibria were characterized in terms of concentration and pH-dependency. Quantitative extraction from hydrochloric acid solutions ( $> 0.01 \text{ M}$ ) is achieved with ligands **1** and **3**. Ligands **2** and **4** extract  $> 99\%$  Au(III) at  $\text{HCl} \geq 1 \text{ M}$ , where they exist in their protonated forms. A 99.9% recovery in one step is possible by stripping with diluted thiourea/HCl (ligands **1**, **3**) or thiourea/H<sub>2</sub>O (ligands **2**, **4**). In the latter cases, stripping is also possible by deprotonating the ligand. The equilibria were reached in less than 5 minutes of overhead shaking. The selectivity over the metals accompanying gold in ores, especially iron at excess concentrations, is promising.

### INTRODUCTION

A type of macrocyclic ligand with the name calix[n]arene enjoys a remarkable interest in various fields of chemistry in recent years, which is highlighted by several books [e.g., 1-3]. Over 50 reviews concerning their synthesis, properties and applications were published, including their use in solvent extraction studies [4-8].

The interest in this class of compounds, which consists of a large number of derivatives results mainly from the possibility of designing 3-dimensional ligand structures in order to match the coordination sphere of the ion or molecule to be extracted. Based on the previous studies, it is now possible to derive some design principles concerning, for example, the size of the cavity, the molecular flexibility, and the arrangement of ionophilic functional groups. Other important factors for the application in extraction are (i) the inexpensive starting materials, (ii) the chemical stability, and (iii) the insolubility in water thanks to branched alkyl chains. The extractant can be imagined as a macrocyclic skeleton onto which various functional groups are attached and the hydrophobic and ionophilic properties are kept in balance.

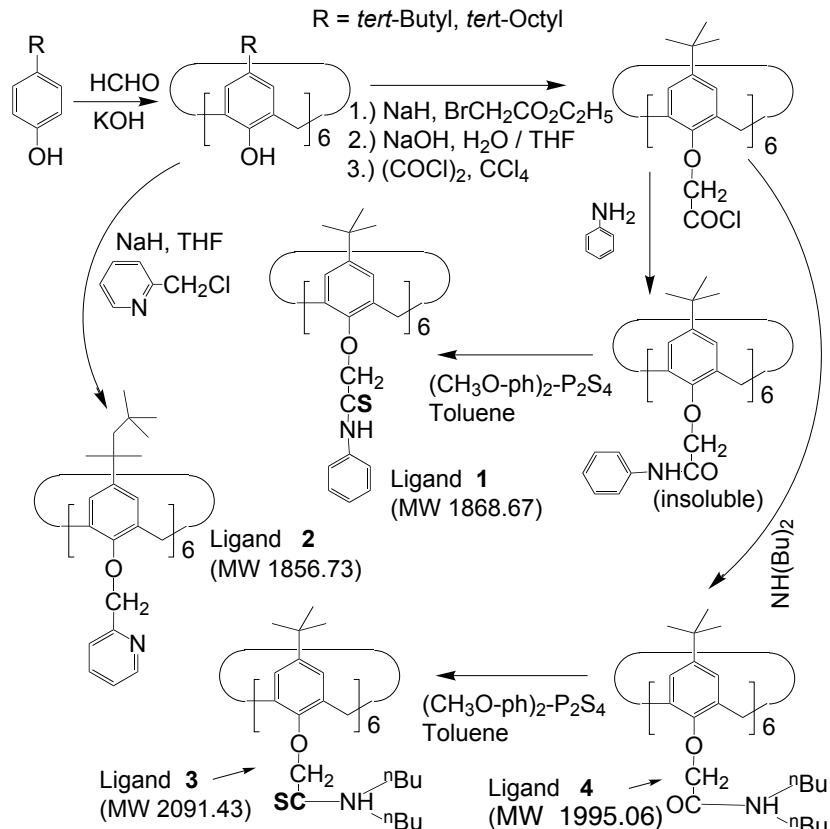

In this work we report on the design, synthesis and extraction properties of calixarenes with the aim of examining their usefulness for the extraction of gold from HCl leaching of Algerian ores. Previously, we investigated the noble metal extraction by calix[4]arenes bearing amide groups [9] and the current work was undertaken to improve the extraction behaviour.

## LIGAND DESIGN AND EXPERIMENTAL

In order to discriminate between the anionic  $[\text{AuCl}_4]^-$  and other metal ions, which exist predominantly as cations in 1 M HCl, we considered various structural features, especially:

- The ligand should have a cavity large enough to include the gold complex. Calix[6]arenes with a flexible, ca.  $0.3 \times 0.76$  nm cavity appear suitable.
- The ligand must be able to participate in coordination and should therefore contain donor atoms such as sulphur and/or nitrogen.
- These donor atoms should be allowed to arrange themselves into the optimum position around the metal, thus a certain degree of molecular flexibility is to be balanced with the degree of molecular pre-organization.
- The desired high extraction yield must be balanced with stability of the extracted complex in order to allow easy backextraction. One approach to this goal are the protonation / deprotonation equilibria of ligands **2** and **4**.

The synthesis of the ligands is outlined in Scheme 1. Each step proceeds in reasonably high chemical yield. The products were identified on the bases of their NMR- and mass-spectra, by elemental analysis and chromatographically. Details of the synthesis will be reported in a subsequent paper.

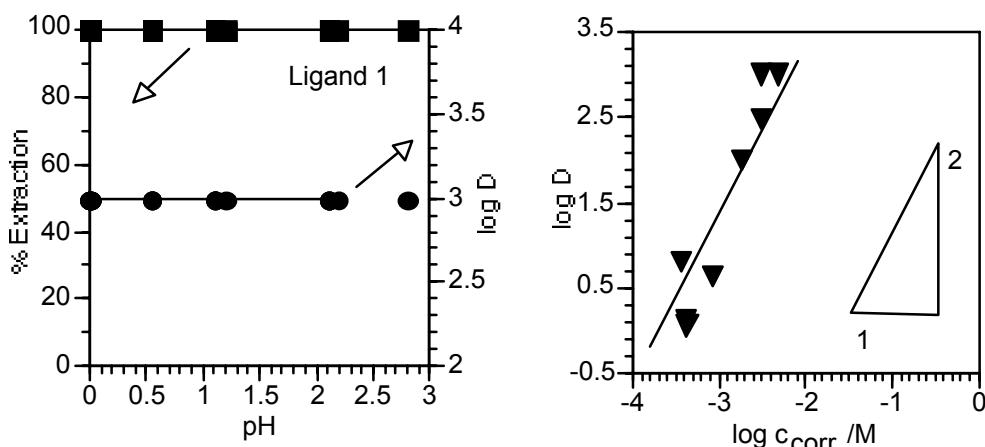

Scheme 1. Extractants used for this work, and their synthesis.

Metal extraction was carried out batchwise with equal volumes at 298K.  $\text{CHCl}_3$  saturated with water served as solvent. Metal contents before and after extraction were analyzed by means of atomic absorption spectrophotometry after dilution with 1 M HCl. Quantitative stripping was done with 10 mM thiourea dissolved in water (ligands **2**, **4**) or 1 M HCl (ligands **1**, **3**) and a 100% mass balance was obtained. Using thiourea in water or diluted HCl, partial stripping is possible in one step as tested for ligands **1** and **2**, respectively. The agitation speed was 54 rpm in an overhead shaker. Solutions were prepared by handling  $\text{AuCl}_3$  under  $\text{N}_2$  in a glove bag and dissolving in HCl. For the pH-dependent extraction, the pH was adjusted by adding ammonia or HCl to 0.1 M HCl solutions. Equilibrium pH values were measured with a combination glass electrode. The concentration of uncomplexed ligand (corrected) was calculated by taking into account the complexation. Selectivity studies were done as competitive extraction. The chemical stability was tested by repeated extraction and stripping cycles, in the course of which no degradation was observed.

## RESULTS AND DISCUSSION

### Extraction Equilibria

Figure 1 shows the results for the extraction of Au(III) by ligand **1**. The term '% Extraction' is defined as the percentage of extracted metal into the organic phase with respect to the overall metal concentration. The extraction is quantitative above 3 mM ligand concentration within the investigated pH range. From the  $pK_a$  of the parent [aniline $\cdot\text{H}^+$ ] (4.5), it is concluded that ligand **1** can exist in a mono-protonated form under these conditions. Due to the high  $D$ -values, a variation with the pH cannot be measured, while higher pH-values were not applied in order to avoid metal hydrolysis. The extracted species is assumed to be  $[(\text{AuCl}_3)\cdot\text{LH}^+\cdot\text{L}]$ .

Figures 1a and 1b. Effect of pH (left) and of concentration (right) on the extraction of gold by ligand **1**. Aq. phase: 14 mg/l Au(III) (0.07 mM) in HCl, pH 2.8 (right figure), Org. phase:  $\text{CHCl}_3$  containing ligand **1** (3.3 mM in left figure).

Figure 2 shows the extraction data obtained with the pyridine derivative **2**. Quantitative extraction from 1 M HCl is achieved with 5 mM ligand solution. In contrast to ligand **1**, the stoichiometry of metal:ligand in the extracted complex is 1:1. The pH-dependency is attributed to the protonation of the ligand. Due to electrostatic interactions within one ligand molecule, we assume mono-protonation under the conditions applied. The following equations were applied to calculate the extraction constant  $K_{\text{ex}}$  according to the equilibrium (1), the acid constant  $K_a$  of ligand **2**, and the line in the plot of  $\log D$  vs. pH:

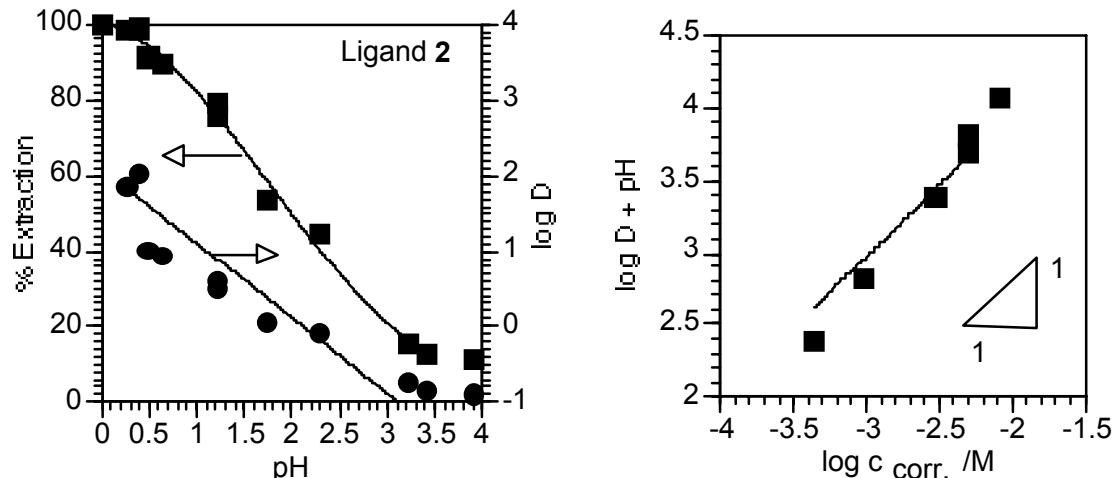

$$K_{\text{ex}} = \frac{D}{[\text{LH}^+]_{\text{org}}} = \frac{D}{\left( \frac{[\text{H}^+] \cdot c^0}{[\text{H}^+] + K_a} \right)}$$

with  $K_a = \frac{[\text{L}] \cdot [\text{H}^+]}{[\text{LH}^+]}$

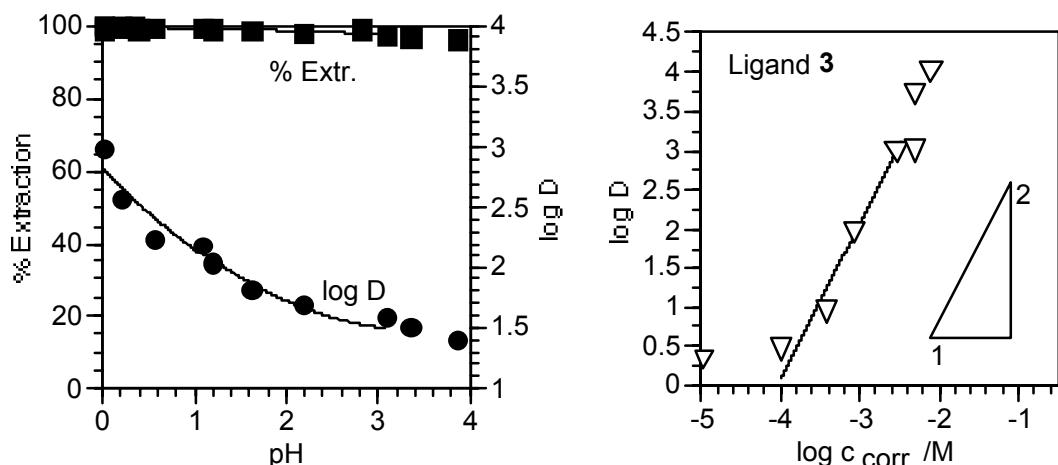

$$\log D = \log K_{\text{ex}} - \text{pH} + \log \left( \frac{c^0}{(\text{H}^+ + K_a)} \right) \quad \text{with } c^0 \text{ as the initial concentration}$$

$$\log K_{\text{ex}} = 6.064, \text{p}K_a = -1.65$$

Figures 2a and 2b. Extraction of Au(III) by pyridine derivative 2. Aq. phase: 14 mg/l Au(III) in HCl,  $c_{\text{HCl}} = 1 \text{ M}$  (right figure), Org. phase:  $\text{CHCl}_3$  containing ligand 2 (5 mM in left figure).

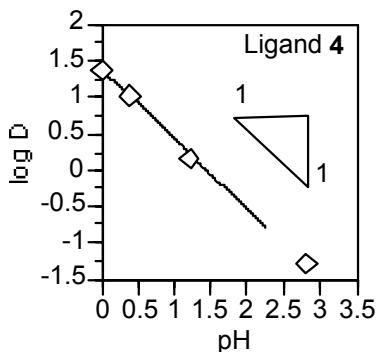

Figures 3a and 3b. Extraction data for thioamide derivative 3.  
The experimental conditions are the same as in Figure 2.

The thioamide derivative 3 is characterized by very high extraction of Au(III) as seen in Figure 3. The high extractability and the stoichiometry are comparable with the behaviour of ligand 1. The extraction depends on the pH, but not on the chloride concentration (*vide infra*). The mechanism is interpreted as protonation of the ligand and extraction of  $([\text{AuCl}_4]^- \cdot \text{LH}^+ \cdot \text{L})$ . However, the slope of  $\log D$  vs. pH is less than  $| -1 |$ , therefore only an apparent extraction constant was estimated for pH = 0 according to equation (2):  $\log K_{\text{ex}} = 8.08$ .

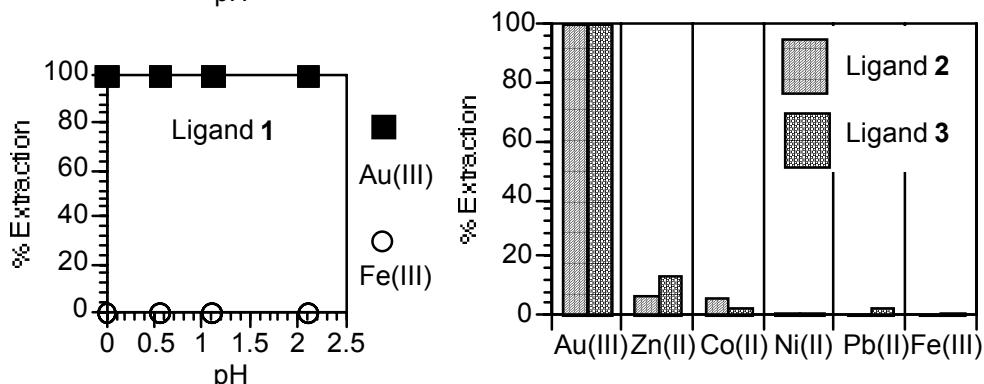

$$\log D = \log K_{\text{ex}} + 2 \log [\text{L}] \quad \text{at pH} = 0$$

Finally, ligand **4** has a structure resembling that of **3**, but carbonyl oxygen atoms replace the thiocarbonyl sulphur atoms. The distribution ratios are lower compared with **3**, which proves the important role of the sulphur atoms in the complexation. Upon protonation of one nitrogen atom, ligand **4** nearly quantitatively extracts Au(III). The occupation of the ligand cavity by the chloro complex of Au(III) probably contributes to the good extraction.

*Figure 4 (on the left):*  
pH-Dependent extraction of Au(III) by amide **4**.  
Aq. phase: 14 mg/l Au(III) in HCl,  
Org. phase: CHCl<sub>3</sub> contg. 5 mM ligand.

*Figures 5a and b: Selectivity data for ligands **1**, **2** and **3** in competitive extraction.*  
Aq. phase: 14 mg/l Au(III) in 1 M HCl, 2 mM Fe(III) (Fig. 5a, left) or 0.1 mM each of Zn<sup>2+</sup>, Co<sup>2+</sup>, Ni<sup>2+</sup>, Pb<sup>2+</sup>, Fe<sup>3+</sup> (Fig. 5b, right side), Org. phase: CHCl<sub>3</sub> containing 5 mM ligand.

### Selectivity

The selectivity of ligands **1** to **3** for gold over metals which are present in excess in Algerian ore was examined by competitive extraction. Figure 5a shows that (i) the quantitative extraction of gold by ligand **1** is maintained in the presence of excess Fe(III), and (ii) iron is not extracted from the aqueous solutions of various acidity.

The selectivity data for ligands **2** and **3** are shown in Figure 5b. The quantitative extraction of gold from 1 M HCl is not affected by the presence of other metals at comparable concentrations. Among these metals, zinc is extracted to the highest extent with 7% and 13%, respectively. We interpret the good selectivity as the result of the ligand design: The metal cations, even if they have an affinity towards nitrogen or sulphur atoms in the ligands, are much smaller than the cavity of calix[6]arenes and are therefore unable to interact with all donor atoms in order to match their coordination sphere.

## Extraction Kinetics

The time necessary to reach distribution equilibrium was examined in batch experiments. The results in Table 1 show that the equilibria are reached very fast for all extractants. We attribute this to the remaining molecular flexibility of the ligand. Thus steric crowding as well as slow conformational equilibria, which can occur in the smaller calix[4]arenes or in tautomeric equilibria for example, are avoided. The stripping equilibria were established fast as well, which is attributed to fast decomplexation and deprotonation equilibria.

Table 1. Kinetics of Au(III) extraction (0.1 mM in 1 M HCl) into CHCl<sub>3</sub> containing 5 mM ligand at 54 rpm overhead shaking at 298 K

%Ex / t, min	1	3	5	10	20	30	70	100
Ligand 1	99.61	>99.99	>99.99	>99.99	>99.99	>99.99	>99.99	>99.99
Ligand 2	98.36	98.86	99.24	99.92	>99.99	>99.99	>99.99	>99.99
Ligand 3	98.25	98.46	98.53	98.91	99.86	99.97	99.98	>99.99
Ligand 4	98.78	98.61	99.28	99.28	99.44	99.44	99.78	>99.99

## Influence of Chloride Salt Concentration

Increasing the concentration of chloride ions by adding up to 5 M NaCl to 0.1 M HCl solutions results in slightly higher distribution ratios with ligand **2**, while the near quantitative extraction by ligand **3** remained unaffected. The small increase of log  $D_{\text{Au}}$  in case of ligand **2** is interpreted as change in activity coefficients (salting out), because the [AuCl<sub>4</sub>]<sup>-</sup>-complex predominates already at low concentrations of Cl<sup>-</sup>.

## CONCLUSIONS

High distribution ratios of Au(III) are observed when the ligand contains both sulphur and nitrogen as donor atoms, resulting in quantitative extraction from HCl solution. Ligands containing only nitrogen as donor atoms extract Au(III) quantitatively when they are protonated. The oxygen atoms of the ligands are considered to play only a minor role in gold complexation. The results on selectivity and kinetics are further proof that this type of macrocyclic ligands have the potential for application in recovery of valuable metals from dilute solutions.

## SEPARATION OF PALLADIUM(II) WITH IMMOBILIZED MALEONITRILE-DITHIOCROWN ETHERS

W. Mickler, H. Bukowsky and H-J. Holdt

Universität Potsdam, Institut für Anorganische Chemie und Didaktik der Chemie,  
Potsdam, Germany

As extractants for the selective separation and recovery of palladium (II) from industrially spent liquors crowned dithiomaleonitriles are proposed. These macrocyclic chelate ligands extract palladium (II) at sufficient rate in very good yields. The synthesis of the immobilized ligands proceeds from the 2-allyloxy-1, 2-propanediol. The silylated macrocycle is immobilized by a spacer onto activated silica gel. By modification of the cavity of the macrocycle the extraction rate can be optimised. The best results were observed with the maleonitrile-dithio-12-crown-4. The composition of the extracted compounds has to be found as 1:1. The separation is unsatisfactory in the case of Ag(I), Hg(II), Tl(I) and of the most 3d-elements.

### INTRODUCTION

Especially in the last few years the recovery and separation of palladium(II) from spent autocatalysts or industrial wastes has become increasingly important [1]. For the technical realisation of such processes commercial extractants as di(n-alkyl)sulfide ((Hex)<sub>2</sub>S) [2, 3, 4] were widely used. Recently an extraction process on the basis of substituted amines in presence of LIX 63 as accelerator[5] has been described. More classical separation technologies for the platinum group metals have been reported [6]. Moreover substituted acylpyrazolones [7], calix[4]arenes [8], hydroxyquinolines [9] or phenyloximes [10] are proposed for the separation of palladium.

Generally, ligands containing sulphur as donor atoms are particularly well suited for the separation of thiophilic palladium (II) by liquid-liquid-extraction [11]. This quality we advantageously used in the case of crowned dithiomaleonitrile [12]. For the accumulation and separation of small concentrated cations from diluted solutions the utilization of ion exchangers is helpful. In this case the selectivity of the anchor groups of the resin and the advantage of a continuous operation are usefully associated.

As supporting material for immobilizing ligands especially silica gel is used frequently because both the hydrosilylation of the extractant and the reaction following with the matrix are performed easily. Additionally, the mechanical stability of the ion exchanger and its hydrophilic surface, cause rapid kinetic of the exchange process and have advantages over the commercial liquid ion exchangers.

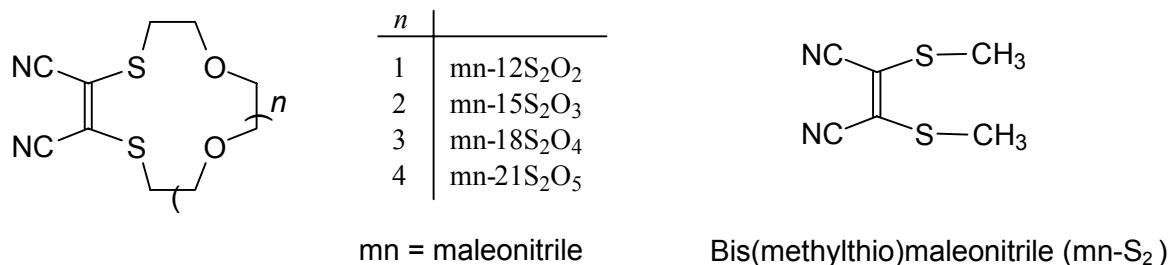

## EXPERIMENTAL

To allow a comparison with the commercial extractant di-n-hexylsulphide the extraction behaviour of the selected macrocyclic compounds was studied with the free ligand dissolved in chloroform. The liquid-liquid-extractions were performed as single experiments in separation funnels at room temperature. The metal concentration was generally in the range of  $10^{-4}$  mol•L<sup>-1</sup>, in nitric acid 0.01 mol•L<sup>-1</sup>. All chemicals were of analytical grade. The metal stock solutions were prepared by dilution of a Merck-standard solution with bidistilled water. Generally, the concentration of the ligands was adjusted to  $10^{-2}$  mol•L<sup>-1</sup> in a phase ratio to the model solution of 1+1 (1 mL).

A mechanical shaker performed each extraction cycle within 120 minutes. After re-extraction of the organic phase with an aqueous thiourea solution (2 mol•L<sup>-1</sup>) the metal concentration was determined by AAS (AAS 1100 B, Perkin Elmer). The distribution coefficient:  $D = \frac{C_{M^{n+}}^{(org)}}{C_{M^{n+}}^{(aq)}}$  was calculated from the metal concentration in the aqueous phase before extraction and from the organic phase after re-extraction. The slope  $n$  of the function  $\log D = f(c_L)$  corresponds to the number of coordinated ligands.

### Extractants

As extractants were used a series of maleonitrile-dithiocrown ethers with different lengths of the oligo(oxyethylene)unit [13,14,15]. For comparison the acyclic compound bis(methylthio)maleonitrile ( $mn\text{-S}_2$ ) and the commercial extractant di(n-hexyl)sulfide [ $(\text{Hex})_2\text{S}$ ] were used.

The scheme of the syntheses of the allylsubstituted maleonitrile-dithio-12-crown-4 ( $mn\text{-}12\text{S}_2\text{O}_2\text{-allyl}$ ) is given in Figure 1.

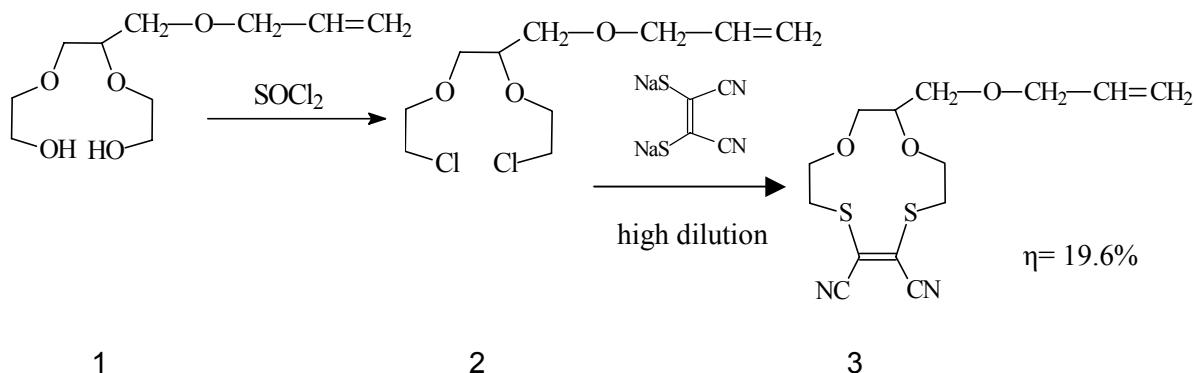

Figure 1. Synthesis of the allylsubstituted maleonitrile-dithio-12-crown-4.

By the reaction of 2-allyloxy-1,2-propanediol with potassium t-butoxide and chloracetic acid the dicarbon acid was formed and subsequently changed by a reduction to the diole (1). With the help of thionylchloride the dichloro compound (2) was synthesized which, together with a dithiolate ((Z)-disodium-1,2-dicyanethene-1,2-dithiolate), under high dilution conditions formed the macrocycle (3). Then the allylsubstituted maleonitrile-dithio-12-crown-4 can be silylated and the resulting alkoxy silane is immobilized onto activated silica gel. The substituent forms in the same time a spacer and should be modified in the future. All compounds were purified by distillation *in high vacuo*. The macrocycle (3) was isolated in a good overall yield (19.6 %).

## RESULTS AND DISCUSSION

In Figure 2 the results of the extraction of palladium (II) with the examined extractants are shown. The function  $\log D = f(c_{\text{ligand}})$  illustrates the influence of different structural parameters on the extraction behaviour. The time needed to reach the extraction equilibrium was determined in preceding experiments to 120 minutes. From the slope of the curves the expected composition of the extracted species as (PdL) has to be found.

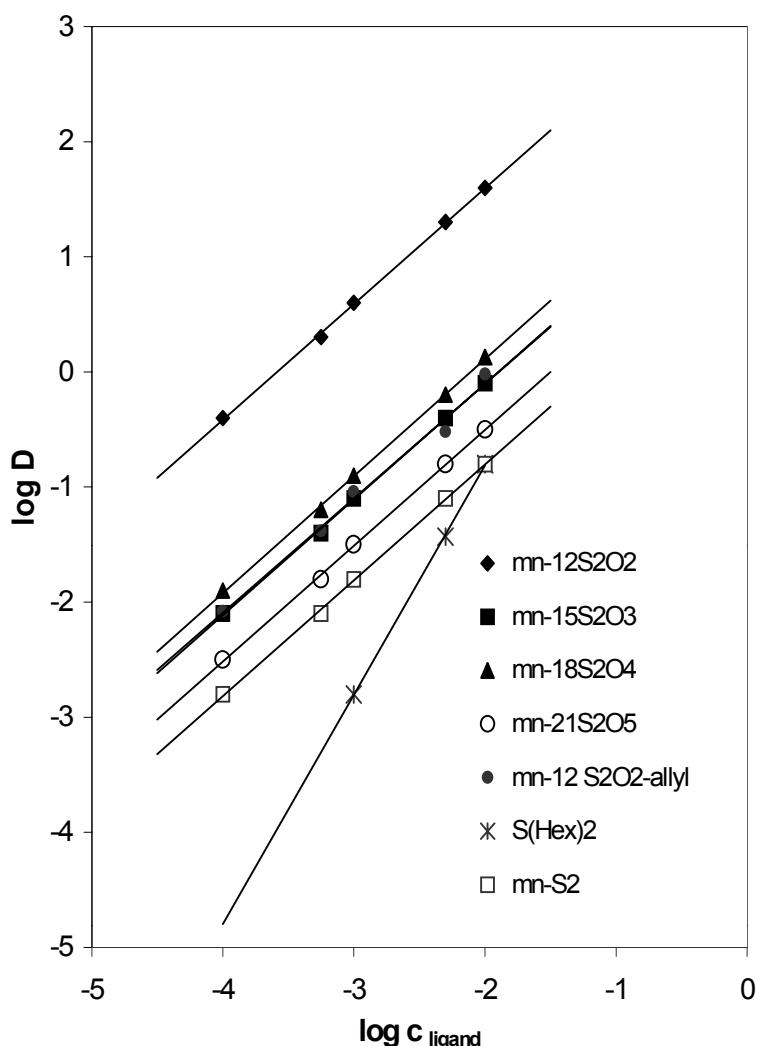

Figure 2. Extraction of Pd(II) with maleonitrile-dithiocrown ethers and di(*n*-hexyl)sulfide.

In the case of the commercial extractant di(n-hexyl)sulfide the expected slope of the function has to be found and leads to the composition of the extracted chelate as 1:2. Generally, it can be seen that all the tested maleonitrile-dithiocrown ethers show better distribution coefficients than the frequently used commercial extractant di(n-hexyl)sulfide and the acyclic compound mn-S<sub>2</sub>. The reason for the low palladium (II) extractability of mn-S<sub>2</sub> is the free rotatability of the methyl groups hindering the chelation of the palladium (II) with the sulphur atoms.

Furthermore, the extraction behaviour can be discussed by the fact that 1,2-dithioethenes are weak chelate-forming ligands [16] and in the case of bis(methylthio)maleonitrile [17] the donor power of both of the sulphur atoms is further decreased by the electron withdrawing effect of the cyano groups. This quality is advantageously used in the case of crowned dithiomaleonitrile. By macrocyclic fixing the dithio unit is available for the complex formation without any hindrance and so the transfer of palladium (II) into the organic extraction phase is possible, as is illustrated by the increasing distribution coefficients. The best results for the extraction of palladium (II) were observed in the case of maleonitrile-dithio-12-crown-4 (mn-12S<sub>2</sub>O<sub>2</sub>). In comparison to this, the increasing length of the oligo(oxyethylene) unit from mn-12S<sub>2</sub>O<sub>2</sub>, mn-15S<sub>2</sub>O<sub>3</sub>, mn-18S<sub>2</sub>O<sub>4</sub> to mn-21S<sub>2</sub>O<sub>5</sub> cause a decreasing separation coefficient. One reason for this unsatisfying result is the reduced availability of the sulphur atoms for the complex formation by the increased flexibility of the macrocycle. The differences between mn-12S<sub>2</sub>O<sub>2</sub> and its allylsubstituted derivative (mn-12S<sub>2</sub>O<sub>2</sub>-allyl) are caused by the steric hindrance of the allyl-chain of the chelate formation. The separation of palladium (II) is disturbed because the free rotatable substituent covers the donor atoms of the macrocycle. The chelate formation and also the stability of the palladium complex would be improved by fixing the maleonitrile-dithiocrown ether with its substituent on a matrix.

*Table 1. Formation constants of PdCl<sub>2</sub>-chelates in methanolic solutions.*

Complex	log K <sub>a</sub>
[PdCl <sub>2</sub> (mn-12S <sub>2</sub> O <sub>2</sub> )]	6.20 ± 0.30
[PdCl <sub>2</sub> (mn-18S <sub>2</sub> O <sub>4</sub> )]	4.70 ± 0.10
[PdCl <sub>2</sub> (mn-21S <sub>2</sub> O <sub>5</sub> )]	4.67 ± 0.02
[PdCl <sub>2</sub> (mn-15S <sub>2</sub> O <sub>3</sub> )]	3.90 ± 0.01
[PdCl <sub>2</sub> (mn-S <sub>2</sub> )]	3.60 ± 0.50

In Table 1 the formation constants of the complexes determined by UV spectroscopy in methanol are given. The order of log K<sub>a</sub> is in good agreement with the results found by liquid-liquid-extraction so that the relatively high complex stability of the palladium complex of mn-12S<sub>2</sub>O<sub>2</sub> may be regarded as an important reason for its good extractability.

The extraction behaviour of the tested dithiocrown ethers towards palladium (II) and some competition elements is summarized in Figure 3. As it can be seen from Table 2, especially palladium is extracted selectively with a good yield. The separation coefficient towards nickel was about 1.4·10<sup>3</sup>.

*Table 2. Extraction rate (E %) and selectivity (S) of the extraction of palladium, lead and different 3d-elements with mn-12S<sub>2</sub>O<sub>2</sub>.*

element	chromium	iron	nickel	copper	cadmium	zinc	lead	palladium
E %	0.00	0.56	2.75	1.60	1.78	2.45	1.03	97.3
S (towards Pd)	--	1.3·10 <sup>4</sup>	1.4·10 <sup>3</sup>	2.4·10 <sup>3</sup>	2.2·10 <sup>3</sup>	1.6·10 <sup>3</sup>	3.9·10 <sup>3</sup>	--

One of the reasons for this behaviour may be the coordination structure of the formed complexes. In opposite to most of the 3d-elements palladium (II) favours a square-planer coordination geometry. For that reason the relatively inflexible structure of the macrocycles supports especially those elements which prefer a planar structure.

This fact could be also verified by its extraction behaviour with 4-acylpyrazolones. These ligands prefer spatial geometries. In the case of the 3d-elements almost stable octahedral complex structures are formed so that a high extraction rate could be found [18]. The extraction of palladium (II) with 1-phenyl-3-methyl-4(2-ethylhexanoyl)-5-pyrazolone at pH 2.3 shows only a rate of 34 %. This could mainly be due to the unfavourable geometrical structure of the extracted chelate.

Especially a good selectivity of the palladium (II) extraction with maleonitrile-dithiocrown ethers was also observed towards silver and mercury, so that interesting applications to the separation of noble metals should be possible. A comparison of the extraction behaviour of the various elements showed slightly better results for the soft and thiophilic elements such as nickel or lead, against chromium and iron.

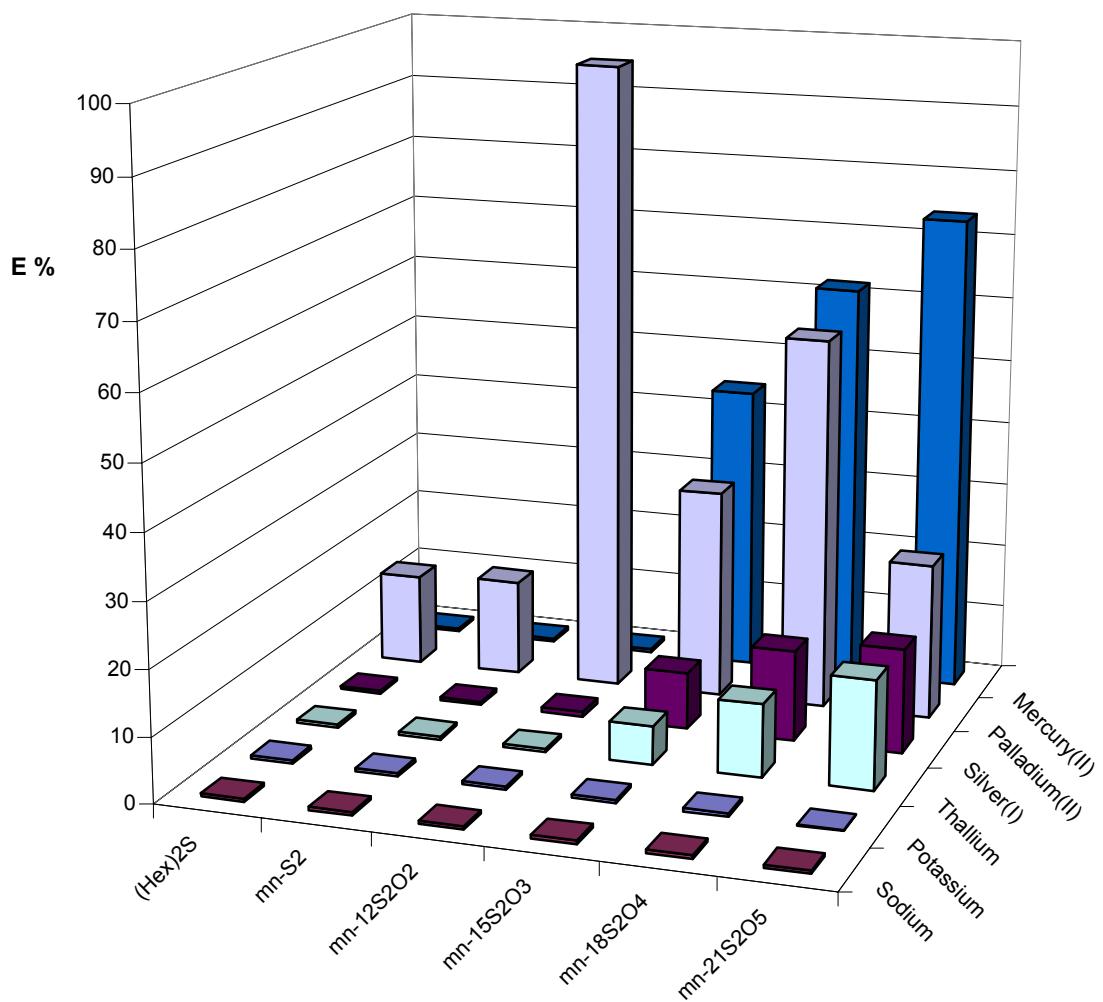

Figure 3. Extraction of different metals with maleonitrile-dithiocrown ethers and  $(\text{Hex})_2\text{S}$ .

## SEPARATION OF PALLADIUM FROM PLATINUM

Jan G. H. du Preez, Eric C. Hosten and Shimoné E. Knoetze

Research Unit for Metal Ion Separation, University of Port Elizabeth,  
Port Elizabeth, South Africa

In this paper it is shown how the basic coordination chemistry of Pd, Pt and contaminants can be applied to suggest possibilities for the development of separating agents which can preferentially extract Pd(II). The method is applied and illustrated by the synthesis of pyrazole derivatives in both the form of extractants and a resin. It is shown how Pd(II) can be selectively extracted from Pt(IV) from dilute HCl solutions contaminated with base metals. The durability of the agents is also illustrated.

### INTRODUCTION

The platinum group metals are found in a very complex ore body. They appear together with gold, silver and some base metals like iron, cobalt, nickel and copper. They are mainly found in the same matrix in the form of their sulfides, arsenides, selenides and tellurides. The separation and isolation of the metals are thus formidable tasks since the process is further complicated by the kinetic stability of the various complex species. A number of separating schemes are employed industrially, however, systems which utilise HCl media seem to be most important, especially as far as separation of palladium from platinum is concerned.

In our laboratory we have for many years directed efforts to develop improved or novel separating agents for metal ions. The method followed was always to first study those aspects of the coordination chemistry of the relevant metal ions in order to determine their preferences and those of possible contaminants. Information thus obtained is then applied to investigate possible avenues for improved separation.

When this approach was applied to the above problem two types of methods emerged:

Type I: Separation of chloro-anionic complexes present in the HCl feed solutions, namely  $\text{PtCl}_6^{2-}$ ,  $\text{PdCl}_4^{2-}$  and also  $\text{Pd}_2\text{Cl}_6^{2-}$ . Differences in ion pairing and/or phase transferability are exploited by using suitable cationic species. The lower charge density of the  $\text{PtCl}_6^{2-}$  complex results in the preference of the latter over  $\text{PdCl}_4^{2-}$  for most cations, especially those which also have low charge densities like quaternary ammonium cations. Conditions which favour formation of  $\text{Pd}_2\text{Cl}_6^{2-}$ , however, should be avoided. This separation can be achieved by employing the cationic site in the form of a precipitant, an extractant or an active site on a resin. Since the basis of this separation is ion pairing, the kinetics of the reaction are relatively fast.

These reactions can be represented by equations 1(a) and 1(b).

Apart from the above reactions, it must be borne in mind that the HCl effect of the above species is not the same; normally it is smaller for  $\text{PtCl}_6^{2-}$  than for  $\text{PdCl}_4^{2-}$  when quaternary ammonium cations are used. Further interference via the reaction of  $\text{Pd}_2\text{Cl}_6^{2-}$  species is only experienced when very bulky low charge density cations and low  $\text{Cl}^-$  concentrations are used.

A very large variety of cations has been applied by researchers in this area. These can be divided into two main categories (i) low charge density cations, e.g., quaternary ammonium [1], phosphonium [2] and arsonium species [3,4], and (ii) "protonic" cations obtained by protonation of neutral donor species. These can be described as relatively high charge density cations. This group can be subdivided into two categories: firstly those containing neutral donor atoms like oxygen for which these metals have very low affinities. A large variety of such oxygen donor extractants has been applied for the extraction of the above chloro complexes, e.g., C-O compounds like alcohols [5,6], ketones [7,8], ethers [6], esters [6] and P-O compounds [9-11]. In all of the above cases, the extraction occurs via the formation of an oxonium counter cation.

Secondly, "protonic" cations formed by protonation of neutral donor atoms having the potential to coordinate to these metals as such, e.g., amines, i.e., primary, secondary and tertiary amines. Such amines include aliphatic amines, e.g., tri-n-octylamine [12] and triisobutylamine [13].

Type II: Separation by using the differences in the kinetic stability of  $\text{PtCl}_6^{2-}$  and  $\text{PdCl}_4^{2-}$  through the application of a suitable soft donor ligand/extractant, which will replace the  $\text{Cl}^-$  from  $\text{PdCl}_4^{2-}$ , but not from  $\text{PtCl}_6^{2-}$ . These ligands are ones with good covalent capability for which the palladium has a high affinity. This type are, almost without exception, also reducing agents which have low protonation constants.

The reactions are represented in equation (2).

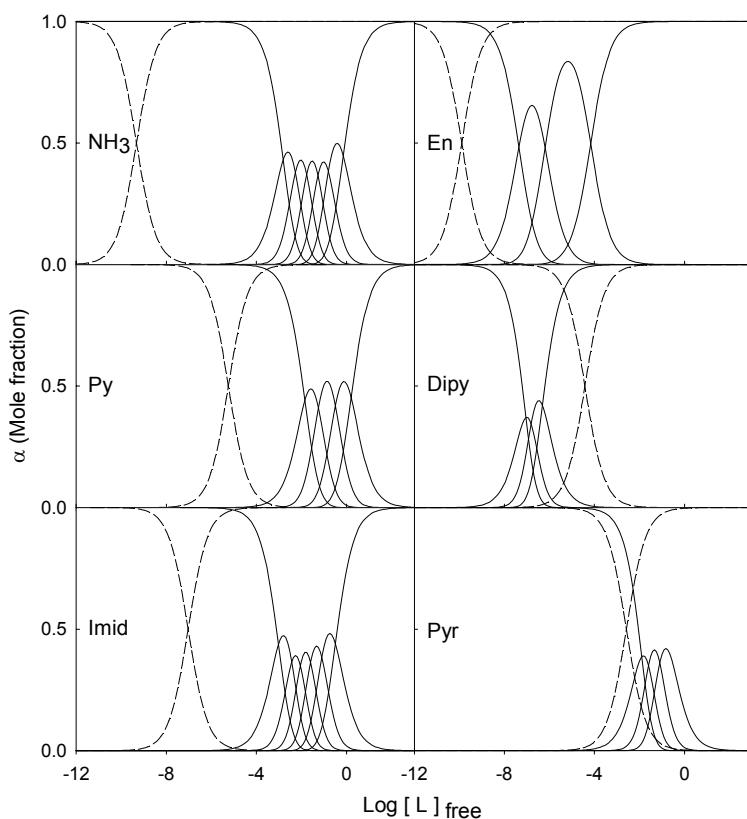

With reference to type II, the most important compounds are sulfur donor atom ligands, in particular thioethers. Di-n-octylsulfide is a typical example [14]. This extractant reacts by replacing the  $\text{Cl}^-$  in  $\text{PdCl}_4^{2-}$  through the formation of  $\text{PdCl}_2\text{L}_2$  where L = extractant. In contrast to the extraction of type I, this process is kinetically controlled and equilibrations occur normally slowly. Back extraction can only be achieved by another ligand exchange process.

Thioethers are reducing agents. At the redox potential required to obtain Pt as Pt(IV), some oxidation of the thioether to sulfoxides occurs leading to the destruction of the separating agent thus shortening its lifetime. A great advantage of the thioethers however, is their very low protonation constants which is required to avoid cation formation leading to extraction of  $\text{PtCl}_6^{2-}$ .

## SELECTION OF ACTIVE CENTRE FOR SEPARATING AGENT

In our previous studies with amines as potential separating agents for base metals, we recognised promise for the application of some of these for Pd/Pt separation. At the basis of the potential application of these as separating agents lies their affinity for the specific metal ion ( $\text{Pd}^{(\text{II})}$ ) relative to the affinity for protons as well as the affinity for contaminants (e.g., base metals).

As a first-order approximation for the potential application of amines in terms of the above arguments, species distribution curves using published [15] formation constants of their complexes with  $\text{Ni}^{2+}$  (a  $3d$  transition metal ion) as formed in aqueous solution were compiled (see Figure 1). The dotted curves are the species formed with  $\text{H}^+$ . These curves clearly suggest that amine complexes of aliphatic amines with  $\text{Ni}^{2+}$  will not be formed in acidic media, although the difference in stability between the  $\text{H}^+$  and  $\text{Ni}^{2+}$  gets smaller upon chelation (compare results of  $\text{NH}_3$  with ethylene diammine (en) for  $\text{Ni}^{2+}$  (Figure 1 (top))).

*Figure 1. Species distribution curves for  $\text{Ni}^{(\text{II})}$  complexes with some amines.*

In the case of the corresponding aromatic N donor ligands (compare results of py and dipy with  $\text{Ni}^{2+}$  - Figure 1 (middle)), it is clear that the difference in complexing capability becomes even smaller (py) and is reversed with the bidentate aromatic ligand (dipy). In the latter case it will be very difficult to "strip"  $\text{Ni}^{2+}$  from such an extracted phase by pH control if such a ligand is used as extractant.

In the case of the diazines imidazole and pyrazole (Figure 1 (bottom)) it is indicated that imidazole has an intermediate behaviour when compared to ammonia and pyridine. Pyrazole, on the other hand, poorly coordinates to both  $\text{Ni}^{2+}$  and  $\text{H}^+$ .

In considering the above data to determine the separation potential of these amines it must be borne in mind that the curves represent formation of complexes in a single phase (aqueous). For effective separation, two-phase systems will be required. Phase transfer of the H<sup>+</sup> with its counter anion will provide a barrier towards protonation in a nonpolar organic phase. It has been indicated that derivatives of imidazole and pyridine can extract base metal ions from slightly acidic aqueous solutions via coordination (pH values > ~2) [16,17].

The great difference in behaviour between the 3d and 4d transition metals should also be considered if these data are to be applied to palladium(II). The amine complexes of Pd(II) are much more stable than those of Ni<sup>2+</sup> (its 3d analogue – dotted lines) (see the species distribution curves for the NH<sub>3</sub> complexes of Pd(II) in Figure 2). Palladium(II) is already completely in the form of Pd(NH<sub>3</sub>)<sub>4</sub><sup>2+</sup> at a free NH<sub>3</sub> concentration of 1x10<sup>-5</sup> M whereas the first NH<sub>3</sub> complex, of Ni<sup>2+</sup>, i.e., Ni(NH<sub>3</sub>)<sup>2+</sup> is not yet present in significant concentrations (Figure 1(b)) at the same free NH<sub>3</sub> concentration.

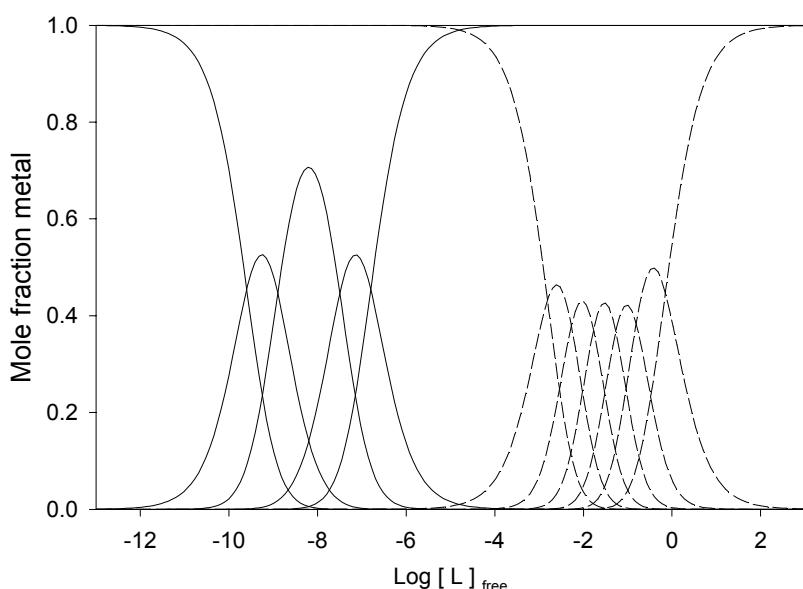

Figure 2. Comparison of the stabilities of Pd(II) and Ni(II) ammine complexes.

When the above information is now applied to select a possible neutral N-donor separating agent which will operate exclusively by the Type II method, pyrazole derivatives were chosen. Its low protonation constant will limit/exclude cation formation, its small formation constants with base metals should seriously limit base metal interferences, but it can be expected to complex strongly with Pd(II).

## EXPERIMENTAL

The preparation of N-decylpyrazole and the procedure followed for the extraction studies were described previously[18]. The same method was followed to functionalise the chlorinated resin.

Batch studies: An amount of dried resin was weighed off and allowed to equilibrate overnight with a HCl solution of the required concentration. The HCl was filtered off and the resin was agitated with a certain volume of 0.1 M Pd(II) (large excess) in the same concentration of HCl at  $\approx$ 180 rev/min for approximately 2 hours. The palladium solution was filtered through a sintered glass quickfit funnel (pyrex G<sub>2</sub>) and the brownish coloured resin was washed with 5

x 25 ml fractions of the required concentration HCl solution. The resin was then "stripped" using 0.75 M NH<sub>4</sub>HSO<sub>3</sub> at pH 6.8.

Column studies were performed using a 300 mm long column with 10 mm internal diameter. Stripping was done by the same reagents as for the batch studies.

## RESULTS AND DISCUSSION

### Pyrazole Derivatives as Separating Agents

These were studied as extractants as well as resins.

#### Extractants

A variety of N-substituted pyrazole compounds was prepared having bulky substituents containing aliphatic, aromatic and mixed groups, in order to study the effect of different parameters like stereochemistry and base strength. The results obtained from N-decylpyrazole (dpyraz) will be discussed in this paper.

The extraction studies were started by equilibrating 0.02 M solutions of each of Pd(II) and Pt(IV) 3.5 M in HCl with 0.18 M chloroform solutions of dpyraz. Analysis of aqueous phases was performed at 30 min intervals. The Pt(IV) extraction occurred almost instantaneously and stayed at ~23% from 30 minutes to 180 minutes. Pd(II) extraction gradually increased from 69% after 30 minutes to 91% after 180 minutes. The fast extraction of Pt(IV) renders the suspicion that cationic species are formed in the organic phase whereas the Pd(II) extraction appeared to be via ligand exchange as anticipated.

HCl phase transfer studies therefore followed, in which equal volumes of 0.18 M solutions of a number of extractants in CHCl<sub>3</sub> were each equilibrated with aqueous HCl solutions varying from 1 M to 5 M. (See Table 1 for the data for dpyraz and 3-methyl-decylpyrazole (mdpyraz)).

*Table 1. Results of HCl loading for pyrazole derivatives in CHCl<sub>3</sub> solutions.*

MHCl	dpyraz	mdpyraz
1	1.51	13.9
2	3.55	-
3	12.72	81.2
4	39.4	89.1
5	70.9	91.8

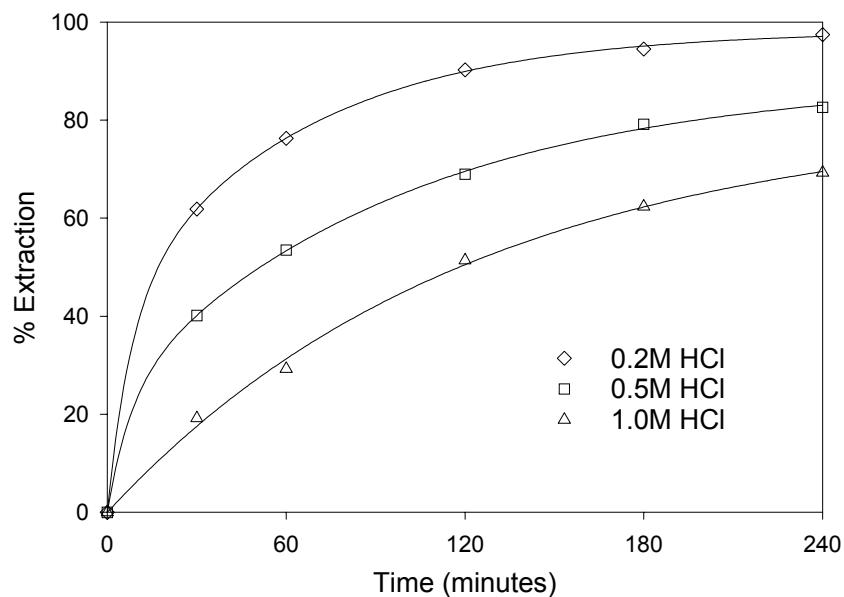

The fractional HCl loading of dpyraz at 3-4 M HCl readily explains why PtCl<sub>6</sub><sup>2-</sup> is extracted from 3.5 M HCl solutions. Studies were subsequently performed at lower HCl concentrations since % HCl loading of only 0.11%, 0.13% and 0.15% were found for 0.1, 0.2 and 0.5 M HCl solutions, respectively. The results of mdpyraz show how HCl loading is affected by only a small increase in basicity of the extractant.

*Table 2. Approximate calculation of separation factors for palladium and platinum as a function of HCl concentration.*

HCl Concentration (M)	% Pd(II) Extraction after 4 hours	% Pt(IV) Extraction after 4 hours	Separation Factor
0.2	97.41	0.01	14000
0.5	82.62	0.97	85
1	69.28	1.36	50

Extraction curves of Pd(II) obtained from a mixture of 0.02 M Pd(II) and 0.02 M Pd(II) in various HCl solutions using 0.18 M dpyraz in  $\text{CHCl}_3$  solution are represented in Figure 3. The corresponding extraction of Pt(IV) from the same solutions are given in Table 2.

These results indicate how Pt(IV) extraction can be correlated with HCl loading and thus cation formation in the organic phase. At the same time Pd(II) extraction is lowered with increase in HCl loading in the region of 0.2 to 1 M aqueous HCl solutions. Electronic spectral analysis of the organic phases indicated the presence of  $\text{PdCl}_2 \cdot 2\text{dpyraz}$  ( $\lambda_{\text{max}} \sim 404$  nm) (those for  $\text{PdCl}_4^{2-}$  (476 nm) and  $\text{Pd}_2\text{Cl}_6^{2-}$  at 440 nm are found at higher wavelengths) [18].

*Figure 3. Extraction curves of Pd(II) from dilute HCl solutions by 0.18 M dpyraz solutions in  $\text{CHCl}_3$ .*

When the above extraction values are used to calculate approximate separation factors, a large value is obtained for 0.2 M HCl solutions though rapidly decreasing with increase in HCl concentration (See Table 2).

Extraction studies performed on base-metals showed that only Fe(III) is extracted from 3 M HCl solutions.

#### **Resin studies**

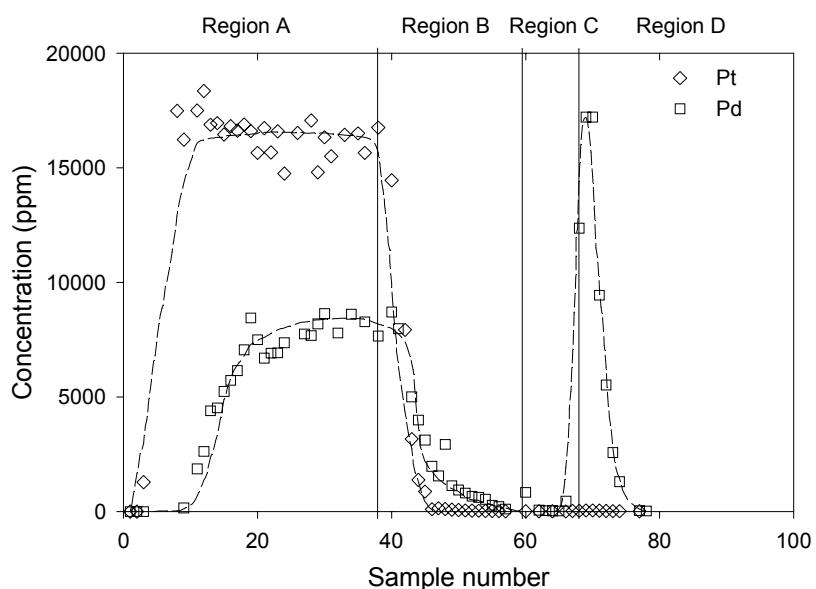

In view of the positive results obtained from the solvent extraction system, especially in the 0.2-1 M HCl region, studies were undertaken with a pyrazole functionalised XAD-16 resin. Batch studies, palladium capacity studies and selectivity studies were performed.

The capacity loading of Pd (g/l) as a function of aqueous HCl concentration is given in Table 3. The decrease of loading of Pd with increase of HCl concentration is again emphasised by these data. The relatively low capacity could possibly be related to the fact that only 50% of the Cl in the chlorinated resin could be replaced by pyrazole in the functionalisation reaction.

*Table 3. The capacity loading of palladium as a function of aqueous HCl concentration.*

Aqueous HCl concentration (M)	Palladium capacity (g/l)
0.1	17.8
0.2	17.7
0.5	7.9
1.0	7.9
3.5	7.2

The curves generated for the loading and stripping of palladium and platinum from a mixture of palladium and platinum in 0.2 M HCl are depicted in Figure 4. The selectivity values (obtained by the ratio of the areas of Pd(II) divided by that of Pt(IV) in the stripping phase as a function of aqueous HCl concentrations from different column studies are given in Table 4.

*Figure 4. Curves generated for the loading (Region A), washing (Region B) and Stripping (Region C) of palladium (0.1 M), and platinum (0.1 M) from their mixture in 0.2 M HCl.*

*Table 4. Selectivity/separation factor as a function of aqueous HCl concentration (M).*

Aqueous HCl Concentration (M)	Selectivity/Separation Factor
0.1	146
0.2	130
0.5	66
1.0	46
3.5	5

Although the selectivity of the resin was much less than that of the solvent extraction system, the kinetics was fast.

In order to determine the durability of the resin, a comparison of capacity loading and selectivity values for the new and 8-month old resin was made (See Table 5).

*Table 5. A comparison of capacity loading and selectivity values for the new and 8-month old resin.*

Aqueous HCl concentration (M)	New Resin		8-month old resin	
	Capacity Loading (g/l)	Selectivity	Capacity Loading (g/l)	Selectivity
0.1	17.7	146	10.0	40.7
0.2	17.7	146	9.6	33.0

In conclusion, the results obtained in this study indicate that reasonably stable and efficient separating agents can be prepared for the isolation of Pd(II) from Pt(IV) using pyrazole derivatives.

An investigation into the nature of the complex species which are formed by the extraction of Pt(IV/II) from hydrochloric acid using *N*-benzoyl-*N'*,*N'*-diethylthiourea and *N*-benzoyl-*N'*,*N'*-di(*n*-butyl)thiourea in chloroform and toluene has been carried out. The study reveals that for Pt<sup>IV</sup> extraction a remarkably complicated distribution of complex species is obtained, arising from *inter alia* possible redox reactions between Pt<sup>IV</sup> and the ligands. In the case of Pt<sup>II</sup> extraction with *N*-acyl(aroyl)-*N'*,*N'*-dialkylthioureas, which is relatively simpler, several protonated species containing coordinated chloride ions ([Pt(L-S,O)(HL-S)Cl], *cis*-[Pt(HL-S)<sub>2</sub>Cl<sub>2</sub>] and *trans*-[Pt(HL-S)<sub>2</sub>Cl<sub>2</sub>]), as well as the well-known *cis*-[Pt(L-S,O)<sub>2</sub>] complex (depending on the extraction conditions), are found in the organic phase.

## INTRODUCTION

Although the discovery of platinum in the sixteenth century did not lead to an immediate realisation of any usefulness for it, it has become one of the most sought-after metals today. With applications for this transition metal as diverse as the manufacture of autocatalysts, to the development of new anti-cancer drugs based on *cis*-platin and its derivatives, to the making of jewellery and ornaments, it is not surprising that research into improved separation of this precious metal, and the other platinum group metals (PGMs), is ongoing. While previous processes for the separation of the platinum group metals (Pt, Pd, Ru, Rh, Os and Ir) were based on the selective precipitation of the metals from a solution mixture, solvent extraction has proven to be more advantageous in many respects, *viz.* efficiency, yield and operating time [1], and investigations into the selective solvent extraction of the platinum group metals are therefore of continued interest.

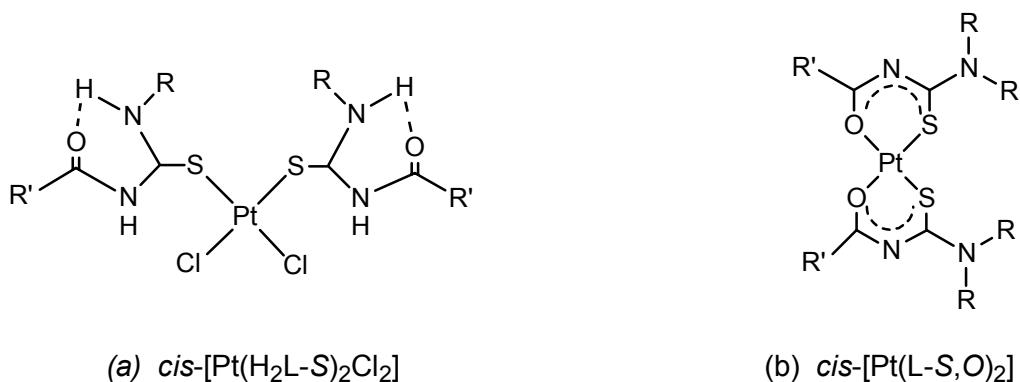

The ligands *N*-acyl(aroyl)-*N'*-alkylthiourea ( $\text{H}_2\text{L}$ ) and *N*-acyl(aroyl)-*N'*,*N'*-dialkylthiourea (HL) have been shown to form very stable neutral complexes with many metal ions, particularly so with the platinum group metals [2,3]. In fact, these ligands have been found to selectively coordinate the PGMs making them ideal candidates for use in the liquid-liquid extraction [4,5], as well as preconcentration and separation [6,7], of the PGMs.

$\text{R}' = \text{phenyl or alkyl group}$

In a study by König *et al.* [4] the efficacy of several *N*-benzoyl-*N'*,*N'*-dialkylthioureas as extraction reagents was illustrated (dialkyl = dimethyl, diethyl, di-*n*-propyl, di-*n*-butyl, di-*n*-hexyl). The authors found that by controlling the pH of the aqueous phase, the PGMs ( $\text{Pt}^{II}$ ,  $\text{Pd}^{II}$ ,  $\text{Ru}^{III}$ ,  $\text{Rh}^{III}$ ,  $\text{Os}^{III}$ ,  $\text{Ir}^{III}$ ) can be separated from several important metals such as iron, cobalt, nickel, copper and zinc. Furthermore, by controlling the pH and the temperature, it is, to some degree, also possible to separate the platinum group metals from each other. Ligands with longer alkyl moieties produce larger distribution coefficients, better phase separation and thus improved extraction. The differences in the extractive abilities of the ligands was ascribed to varying solubilities of the ligands and complexes in the solvents used, as well as to the large variation in complex stabilities; the longer alkyl groups lead, due to larger +I-effects, to increased electron density at the coordinative centers of the ligands (the O- and S-atoms) and thus to more stable complexes. A subsequent investigation by Vest *et al.* [5] showed that the dialkyl-substituted benzoylthioureas,  $\text{HL}$ , are far more efficient in the liquid-liquid extraction of the PGMs than the monoalkyl-substituted analogues,  $\text{H}_2\text{L}$ .

In both the afore-mentioned investigations, however, no description of the coordination chemistry of  $\text{Pt}^{II}$  (or the other PGMs) with the *N*-acyl(aroyl)-*N'*,*N'*-alkylthioureas,  $\text{H}_2\text{L}$ , and *N*-acyl(aroyl)-*N'*,*N'*-dialkylthioureas,  $\text{HL}$ , was given, but in recent years several papers have appeared in this regard. Investigations have shown that the potentially bidentate  $\text{H}_2\text{L}$  ligands co-ordinate to the  $\text{Pt}^{II}$  through the S-atom only, similar to simple unsubstituted thioureas, and not via the O-atom also [8-10]. Crystallographic evidence reveals the monoalkyl-substituted ligands to be locked into a planar six-membered O-C-N-C-N-H ring by means of an intramolecular N-H...O hydrogen bond, thus disallowing coordination via the carbonyl oxygen (Figure 1 (a)). The  $\text{HL}$  ligands, however, coordinate to the  $\text{Pt}^{II}$  via both the S- and the O-atom forming essentially square-planar bis-complexes with loss of the thioamidic proton (Figure 1 (b)). Coordination to  $\text{Pt}^{II}$  by the monoalkyl- and dialkyl-substituted ligands differs in another respect in that the *N*-acyl(aroyl)-*N'*,*N'*-alkylthioureas react with  $\text{PtCl}_4^{2-}$  in neutral aqueous solution to yield mixtures of *cis*- and *trans*- $[\text{Pt}(\text{H}_2\text{L}-\text{S})_2\text{Cl}_2]$  complexes whilst complexation with *N*-acyl(aroyl)-*N'*,*N'*-dialkylthioureas in most cases yields only *cis*- $[\text{Pt}(\text{L}-\text{S},\text{O})_2]$  complexes. *N*-naphthoyl-*N'*,*N'*-dibutylthiourea is the only dialkyl-substituted ligand of this type to have been reported to yield *trans*- as well as *cis*- isomers [11].

*Figure 1. Complexation of  $\text{Pt}^{II}$  with *N*-acyl(aroyl)-*N'*,*N'*-alkylthioureas leads to mixtures of *cis*-, (a), and *trans*- isomers whilst complexation with *N*-acyl(aroyl)-*N'*,*N'*-dialkylthioureas leads predominantly to *cis*-, (b), isomers.*

Whereas the investigations [8-11] into the fundamental coordination chemistry of the  $\text{H}_2\text{L}$  and  $\text{HL}$  type ligands of the PGMs have been performed in essentially neutral solutions, the solvent extraction studies by Vest *et al.* [5] revealed that optimum extraction of the PGMs by the ligands of interest occurred in 2 M hydrochloric acid media, conditions under which  $\text{Pt}^{II}$  species other than those already identified [8-11] might also exist. An investigation of the acid-base chemistry of various *cis*- $[\text{Pt}(\text{L}-\text{S},\text{O})_2]$  complexes [12] elucidated this point ( $\text{HL} = \text{N}$ -benzoyl- $\text{N}'$ , $\text{N}'$ -di(*n*-butyl)thiourea,  $\text{N}$ -(4Br-phenyl)- $\text{N}'$ , $\text{N}'$ -di(*n*-butyl)thiourea,  $\text{N}$ -(4NO<sub>2</sub>-phenyl)-

*N,N'*-di(n-butyl)thiourea). It was shown that treatment of a solution of the uncharged complex *cis*-[Pt(L-S,O)<sub>2</sub>] in chloroform with hydrochloric acid solution results in the formation of three protonated complexes: a partially ring-opened [Pt(L-S,O)(HL-S)Cl] complex which, in the presence of excess conc. HCl, disappeared, presumably becoming further protonated in the acid medium to yield a *cis*-[Pt(HL-S)<sub>2</sub>Cl<sub>2</sub>] complex which in turn isomerizes slowly to the *trans*-[Pt(HL-S)<sub>2</sub>Cl<sub>2</sub>] complex.

The results of investigations by Koch and co-workers give an indication of the types of Pt<sup>II</sup> species that possibly exist in the extraction processes described by Vest *et al.* Since much of the platinum in the extractive industrial process streams occurs in the oxidation state +4 however (as the species PtCl<sub>6</sub><sup>2-</sup>), investigations into the extraction of Pt<sup>IV</sup> and the resultant Pt<sup>IV</sup> species are therefore also of importance. The Pt<sup>IV</sup> chloro-complex (PtCl<sub>6</sub><sup>2-</sup>) is however kinetically less labile than the Pt<sup>II</sup> chloro-complex (PtCl<sub>4</sub><sup>2-</sup>) and this results in slower formation of the extractable Pt<sup>IV</sup> species; the system is thus more difficult to investigate. Moreover, the possibility of a redox reaction between Pt<sup>IV</sup> and the thiourea ligands cannot be excluded. Vest *et al.* improved the rate of extraction of Pt<sup>IV</sup> by addition of tin(II) chloride [13], a reagent which, apart from stabilizing Pt—Cl bonds, also reduces the Pt<sup>IV</sup> to Pt<sup>II</sup> [14].

This paper reports on our preliminary attempts at Pt<sup>IV</sup> speciation in the extraction of this ion with *N*-benzoyl-*N,N'*-diethylthiourea, HL<sup>1</sup>, and *N*-benzoyl-*N,N'*-di(n-butyl)thiourea, HL<sup>2</sup>, as well as Pt<sup>II</sup> speciation in the coordination of this ion with *N*-propanoyl-*N*-morpholinothiourea, HL<sup>3</sup>.

## EXPERIMENTAL

### Preparation of ligands and *cis*-[Pt(L<sup>3</sup>-S,O)<sub>2</sub>] complex

All ligands, HL<sup>1</sup> – HL<sup>3</sup>, were prepared as previously described [9] and were characterised by means of <sup>1</sup>H and <sup>13</sup>C NMR spectroscopy. The neutral complex *cis*-[Pt(L<sup>3</sup>-S,O)<sub>2</sub>] was also prepared and characterized as previously reported [9].

### Solvent extraction procedure

Phase intermixtures in the extractions was achieved either by the use of a shaking apparatus or by means of magnetic stirring. In the first case 1.0 mL of an acidified (2 M HCl) aqueous H<sub>2</sub>PtCl<sub>6</sub>·H<sub>2</sub>O solution (initial concentration of platinum was 23.1 g/L) and 1.0 mL of a CDCl<sub>3</sub> solution of HL<sup>1</sup> (metal/ligand ratio 1:4) were thoroughly mixed at room temperature in a tightly stoppered test-tube on a shaking apparatus for 24 hours. The organic layer was filtered through Extrelut® (to remove traces of water) directly into an NMR tube and spectra acquired. In the second instance extractions were performed by magnetically stirring the two phases in a water-jacketted reaction vessel; the latter allowed temperature control. 10.0 mL of an acidified (2 M HCl) aqueous H<sub>2</sub>PtCl<sub>6</sub>·H<sub>2</sub>O solution (initial concentration of platinum was 22.1 g/L) was vigorously stirred with 10.0 mL of a toluene solution of HL<sup>2</sup> (metal/ligand ratio 1:8) at 80°C. After 3 hours of stirring a sample of the organic phase was filtered through Extrelut® directly into an NMR tube and spectra acquired.

### Protonation experiments

An aliquot of 0.15 mL 6 M aqueous HCl was added directly to an NMR tube containing 0.6 mL of *cis*-[Pt(L<sup>3</sup>-S,O)<sub>2</sub>] complex in CDCl<sub>3</sub>. After vigorously shaking the tube to ensure thorough intermixing of the two phases, the acidified organic layer was allowed to separate and NMR spectra were recorded ca. 7 minutes after acid addition. After spectral acquisition the mineral acid was removed, the organic layer washed with water and then treated with 5 M ammonia solution, and NMR spectra were re-acquired.

## NMR spectroscopy

$^1\text{H}$  and  $^{195}\text{Pt}$  NMR spectra were recorded in 5 mm tubes in chloroform-d ( $^1\text{H}$  and  $^{195}\text{Pt}$ ) or toluene-d<sub>8</sub> ( $^{195}\text{Pt}$ ) solution, using a Varian INOVA 600 MHz spectrometer operating at 600 and 128 MHz respectively ( $^1\text{H}$  at 25°C and  $^{195}\text{Pt}$  at 30°C).  $^1\text{H}$  chemical shifts are quoted relative to the residual  $\text{CDCl}_3$  solvent resonance at 7.26 ppm. The  $^{195}\text{Pt}$  NMR spectra were recorded using spectral widths typically 130 kHz with 15  $\mu\text{s}$  pulses (~90°) and 1.0 s pulse delay. All  $^{195}\text{Pt}$  chemical shifts are quoted relative to external  $\text{H}_2\text{PtCl}_6$  (500mg ml<sup>-1</sup> in 30% v/v  $\text{D}_2\text{O}/1\text{ M HCl}$ ) and are estimated to be accurate to  $\pm 4$  ppm.

## RESULTS AND DISCUSSION

### Pt<sup>IV</sup> speciation

In the first attempt at characterising the Pt<sup>IV</sup> species that occur in the extraction of  $[\text{PtCl}_6]^{2-}$  with an *N*-acyl(aryl)-*N',N'*-dialkylthiourea, an acidified aqueous solution of Pt<sup>IV</sup> was vigorously mixed with a  $\text{CDCl}_3$  solution containing *N*-benzoyl-*N',N'*-diethylthiourea, HL<sup>1</sup>, on a shaking apparatus for 24 hours as described in the experimental section. The organic layer coloured dark yellow indicating the formation of platinum complexes and NMR spectra of this solution were acquired.  $^{195}\text{Pt}$  spectra in the region between 220 and –3700 ppm, relative to the external standard, were recorded; uncertainty as to the species that had formed necessitated this large spectral region but the limits were based on the premise that both Pt<sup>IV</sup> and Pt<sup>II</sup> species would be found in this range. The only indication of platinum in the organic layer however was a very broad (334 Hz) and undefinable peak at –3646 ppm which, despite a long acquisition time (9 h), was of extremely low intensity. The appearance of this peak, as well as a very complex  $^1\text{H}$  spectrum different from that of the ligand, is proof that extraction of the metal had taken place but the very low intensity of the  $^{195}\text{Pt}$  peak suggested that several species were extracted and that the extent of metal separation had been very poor.

To improve the extent of metal separation, a second extraction was performed at higher temperature with a toluene solution containing *N*-benzoyl-*N',N'*-di(n-butyl)thiourea, HL<sup>2</sup>, as described in the experimental section. König *et al.* [4] had concluded that ligands with longer alkyl moieties lead to improved platinum extraction, as does a higher operating temperature; the latter change necessitated the use of an organic solvent with a higher boiling point. After 3 hours of phase contact at 80°C the toluene solution had an extremely dark brown/red appearance indicating significant metal extraction; this was confirmed by the  $^1\text{H}$  spectrum which revealed a plethora of peaks the complexity of which prevented interpretation. To ensure that all possible species would be registered, the platinum spectral region from 3500 to –6000 ppm (relative to the external standard) was scanned, but  $^{195}\text{Pt}$  peaks were only observed between –3100 and –3700 ppm. In this range several peaks appeared (at least 7) with varying line-widths (64 – 208 Hz) but again with surprisingly low intensity despite an acquisition time of 13½ hours. After several days a white/yellow precipitate had formed in the toluene solution. The precipitate was separated, rinsed and re-dissolved in  $\text{CDCl}_3$  and NMR spectra acquired. The  $^1\text{H}$  NMR spectrum is consistent with a species that contains the *N*-benzoyl-*N',N'*-di(n-butyl)thiourea ligand. Moreover, the presence of a  $^1\text{H}$  peak at 11.16 ppm, characteristic of an N-H resonance, confirms that the thioamidic N-atom of the ligand is protonated. The corresponding  $^{195}\text{Pt}$  spectrum of this solution consists of a single, relatively sharp (180 Hz), resonance at -3205 ppm. In the investigation of the acid-base chemistry of various *cis*-[Pt<sup>II</sup>(L-S,O)<sub>2</sub>] complexes by Koch *et al.* [12], the complex *cis*-bis(*N*-benzoyl-*N',N'*-di(n-butyl)thiourea)platinum(II) was prepared and the  $^1\text{H}$  and  $^{195}\text{Pt}$  NMR spectra of this complex and its protonated forms acquired. The authors concluded that one of the doubly protonated forms of *cis*-bis(*N*-benzoyl-*N',N'*-di(n-butyl)thiourea)platinum(II) was a complex denoted as *cis*-[Pt<sup>II</sup>(HL<sup>2</sup>-S)<sub>2</sub>Cl<sub>2</sub>] in which the carbonyl O-donor of the ligand had been displaced from the metal centre by a coordinating chloride ion upon protonation of the thioamidic nitrogen. The resultant N-H resonance was found to appear at 11.14 ppm and the

platinum resonance for this protonated complex was reported at -3218 ppm. Comparison of these  $^1\text{H}$  and  $^{195}\text{Pt}$  chemical shifts (11.14 ppm and -3218 ppm respectively) with those obtained for the re-dissolved precipitate in the present investigation (11.16 ppm and -3205 ppm respectively) suggests that *cis*-[Pt<sup>II</sup>(HL<sup>2</sup>-S)<sub>2</sub>Cl<sub>2</sub>] is one of the species formed in the extraction of Pt<sup>IV</sup> with *N*-benzoyl-*N'*,*N*-di(*n*-butyl)thiourea and thus that some Pt<sup>IV</sup> is reduced to Pt<sup>II</sup> in the process of extraction. The reduction of Pt<sup>IV</sup> by the ligands was not unexpected since several investigations into anti-cancer drugs have revealed that many sulfur-containing biomolecules act as reducing agents, reducing antitumour-active platinum(IV) drugs to their platinum(II) analogues [15].

Although the serendipitous crystallization of one of extracted platinum species has allowed its characterisation, the complexity of the extracted mixture, as revealed by the  $^1\text{H}$  and  $^{195}\text{Pt}$  NMR spectra, indicates that the speciation in the liquid-liquid extraction of Pt<sup>IV</sup> with the ligands of interest must be approached in a piecemeal fashion. This would entail the preparation of possible complex species under experimental conditions relevant to the extraction process, characterisation of these species by means of multinuclear ( $^1\text{H}$ ,  $^{13}\text{C}$  and  $^{195}\text{Pt}$ ) NMR spectroscopy and subsequent correlation of these species-characterisation results with the results obtained from extraction experiments. Since the preparation and characterisation of Pt<sup>II</sup> species will elucidate not only speciation in the solvent extraction of Pt<sup>II</sup> but also that of Pt<sup>IV</sup>, attention was first focused on Pt<sup>II</sup> speciation; a description of the complexes of Pt<sup>II</sup> with *N*-propanoyl-*N'*-morpholinothiourea, HL<sup>3</sup>, follows.

### Pt<sup>II</sup> speciation

Reaction of *N*-propanoyl-*N'*-morpholinothiourea with PtCl<sub>4</sub><sup>2-</sup> (see the Experimental section) yields a product the  $^{195}\text{Pt}$  NMR spectrum of which shows only a single resonance at  $\delta(^{195}\text{Pt}) = -2743$  ppm (Figure 2(a)).

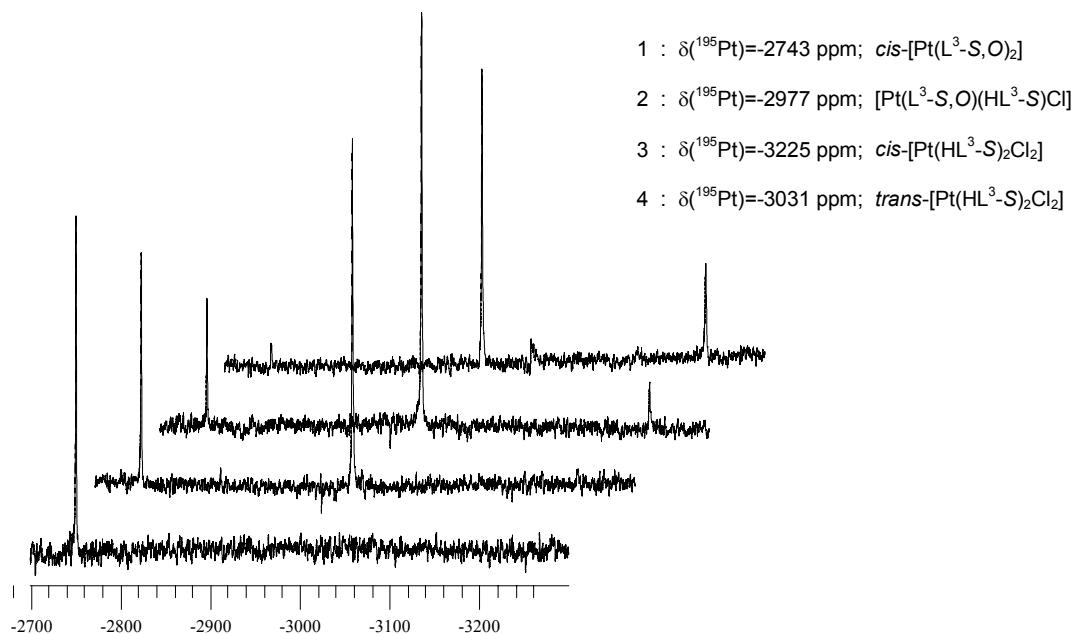

Figure 2. (a)  $^{195}\text{Pt}$  NMR spectrum of *cis*-[Pt(L<sup>3</sup>-S,O)<sub>2</sub>] in  $\text{CDCl}_3$  before acid addition.  
 (b)-(d) Spectra of solution (a) to which 6 M HCl has been added, acquired at the time intervals as indicated.

Although *trans* configurations of Pt<sup>II</sup> complexes with *N*-acyl(aroyl)-*N,N*'-dialkylthioureas are known [11], formation of exclusively the *cis* isomer predominates [12] and since the <sup>195</sup>Pt chemical shift obtained for the product (-2743 ppm) is consistent with <sup>195</sup>Pt shift trends reported by Koch *et al.* for several *cis*-[Pt(L-S,O)<sub>2</sub>] complexes [10, 12, 16], it is concluded that the product obtained is *cis*-bis(*N*-propanoyl-*N*'-morpholinothiourea)platinum(II) (*cis*-[Pt(L<sup>3</sup>-S,O)<sub>2</sub>]; Figure 4). The corresponding <sup>1</sup>H NMR spectrum is consistent with only a single unprotonated complex species, as confirmed by the absence of the characteristic amido N-H resonance in the 10-12 ppm range (detailed <sup>1</sup>H assignments are trivial and will not be given here).

Addition of 0.15 mL 6 M HCl directly to the NMR tube containing *cis*-[Pt(L<sup>3</sup>-S,O)<sub>2</sub>] in CDCl<sub>3</sub> as described in the experimental section, yields a <sup>1</sup>H spectrum (acquired ca. 7 min after addition of the HCl) showing the presence of at least two additional species in solution, characterised by N-H resonances at 10.70 and 10.57 ppm (Figure 3(i)). The appearance of the two N-H resonances reveals that the additional species occur as a result of the protonation of the coordinated ligands by some HCl partitioned into the CDCl<sub>3</sub> phase. After 1 hour 23 min a third protonated species becomes evident, as indicated by an N-H resonance at 10.29 ppm (Figure 3(ii)); the corresponding <sup>195</sup>Pt spectrum at this time (Figure 2(b)) consists of only two resonances at  $\delta = -2743$  and -2977 ppm. With time the concentrations of two of the protonated species increase, as indicated by the increasing intensities of the peaks at 10.57 and 10.29 ppm (Figure 3(iii)-3(viii)) and eventually exist at concentrations which enable them to be detected in the <sup>195</sup>Pt spectra,  $\delta(^{195}\text{Pt}) = -3225$  and -3031 ppm (Figure 2(c) and 2(d)). The protonated species giving rise to the <sup>1</sup>H peak at 10.70 ppm and the <sup>195</sup>Pt peak at -2977 ppm slowly increases and then decreases in concentration whilst the original unprotonated complex,  $\delta(^{195}\text{Pt}) = -2743$  ppm, decreases markedly with time.

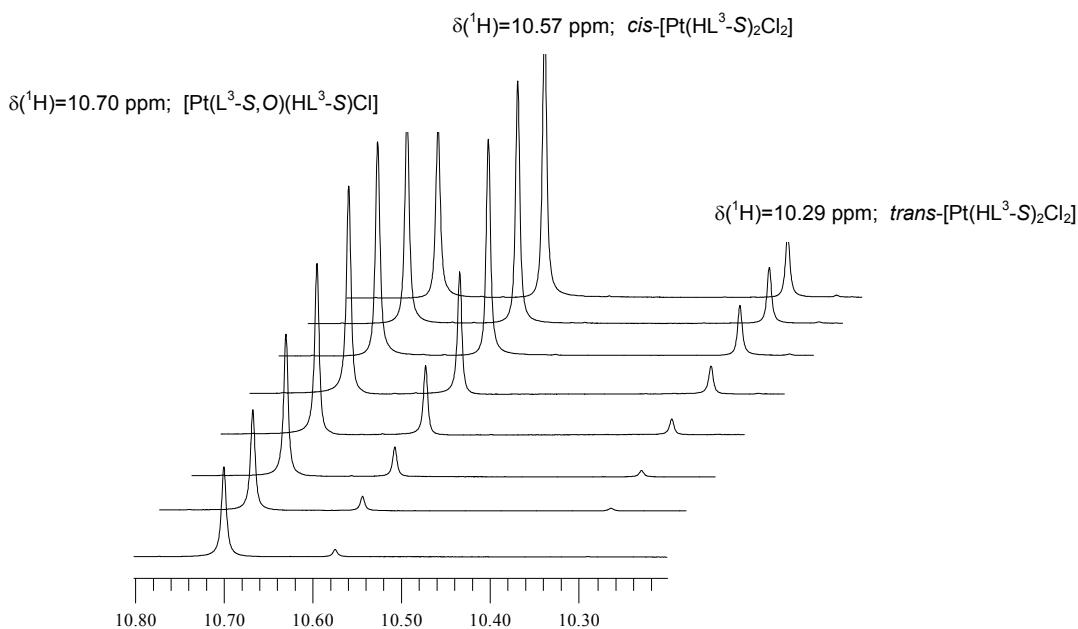

Figure 3. Partial <sup>1</sup>H NMR spectra of *cis*-[Pt(L<sup>3</sup>-S,O)<sub>2</sub>] in CDCl<sub>3</sub> acquired as a function of time after addition of 6 M HCl.

Treatment of the CDCl<sub>3</sub> phase with a small volume of 5 M ammonia as described in the experimental section, results in <sup>1</sup>H and <sup>195</sup>Pt spectra which are identical to those of the initial *cis*-[Pt(L<sup>3</sup>-S,O)<sub>2</sub>] complex with no evidence of any other complex species in solution. Whereas the protonation steps had taken several hours to occur, the solution treated with base had reverted to the original *cis*-[Pt(L<sup>3</sup>-S,O)<sub>2</sub>] complex within minutes (ca. 10 min) indicating that the deprotonation reactions take place much more rapidly across the phase boundary.

In a previous investigation by Koch *et al.* [8], the  $^{195}\text{Pt}$  spectrum of a mixture of *cis*- and *trans*-bis(*N*-benzoyl-*N'*-propylthiourea)dichloroplatinum(II) in  $\text{CDCl}_3$  showed two resonances at -3219 and -3040 ppm. The resonance at -3219 ppm has been assigned to the *cis*-bis(*N*-benzoyl-*N'*-propylthiourea)dichloroplatinum(II) complex (which has also been characterised by means of x-ray crystallography) and the one at -3040 ppm to the *trans*- isomer. Based on these assignments the  $^{195}\text{Pt}$  peak at -3225 ppm in the present investigation is assigned to the doubly protonated species *cis*-[Pt(HL<sup>3</sup>-S)<sub>2</sub>Cl<sub>2</sub>] (Figure 4); a species formed when, upon protonation of the thioamidic N-atoms of *cis*-[Pt(L<sup>3</sup>-S,O)<sub>2</sub>], the carbonyl O-donor atoms are displaced from the metal centre by coordinating chloride ions leaving the ligands monodentately coordinated through the S-atoms only. The smaller  $^{195}\text{Pt}$  peak which develops over time at -3031 ppm is assigned to the *trans*-[Pt(HL<sup>3</sup>-S)<sub>2</sub>Cl<sub>2</sub>] isomer (Figure 4), resulting from the isomerization of the *cis* complex. These assignments are consistent with the generally observed trend that the *cis* isomers for complexes of the type [PtA<sub>2</sub>X<sub>2</sub>] usually appear 200-500 ppm upfield of the *trans* isomers, depending on the nature of the donor atom of ligand A (X = Cl<sup>-</sup>) [17]. The  $^{195}\text{Pt}$  peak at -2977 ppm is assigned to a singly protonated species [Pt(L<sup>3</sup>-S,O)(HL<sup>3</sup>-S)Cl] (Figure 4), a species in which only one of the ligands has been protonated to become monodentately (S-) coordinated to the platinum centre whilst the second ligand remains bidentately (S,O-) bound.  $^{195}\text{Pt}$  chemical shifts are extremely sensitive to changes in the coordination sphere of the metal [17] and an upfield shift change of 234 ppm {-2743 ppm – (-2977 ppm)} as compared to an upfield shift change of 482 ppm {-2743 ppm – (-3225 ppm)}, known to result from a change in coordination sphere from two O-atoms to two chloride ions, would indicate a species in which only one O-atom has been replaced by only a single chloride ion.

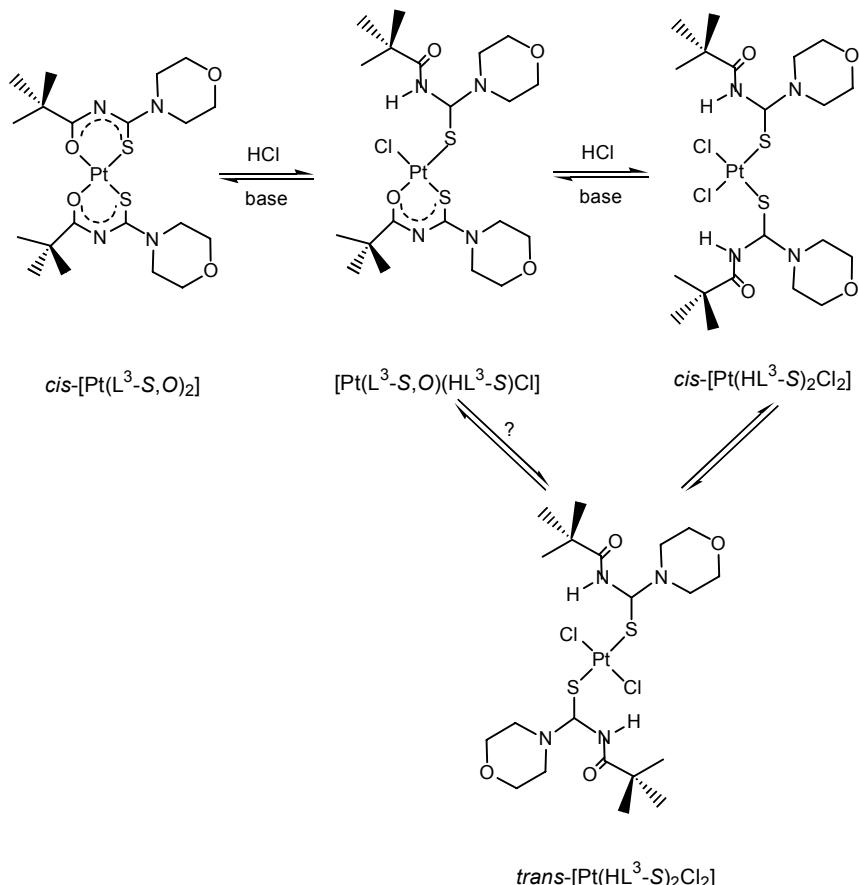

Figure 4. Schematic representation of the formation of various Pt<sup>II</sup> species on addition of HCl to a  $\text{CDCl}_3$  solution of *cis*-[Pt(L<sup>3</sup>-S,O)<sub>2</sub>].

## CONCLUSION

The results of our investigation confirm that Pt<sup>IV</sup> complex species are indeed extracted by *N*-acyl(aryl)-*N,N*'-dialkylthioureas yielding remarkably complex <sup>1</sup>H and <sup>195</sup>Pt NMR spectra of the extracts which are difficult to interpret directly. The possibility of redox reactions between Pt<sup>IV</sup> and the ligands cannot be excluded at present, warranting further study (currently in progress). Nevertheless <sup>1</sup>H and <sup>195</sup>Pt NMR studies of the simpler Pt<sup>II</sup> system shows that under acidic extractive conditions a variety of protonated complexes such as [Pt(L<sup>3</sup>-S,O)(HL<sup>3</sup>-S)Cl], *cis*-[Pt(HL<sup>3</sup>-S)<sub>2</sub>Cl<sub>2</sub>] and *trans*-[Pt(HL<sup>3</sup>-S)<sub>2</sub>Cl<sub>2</sub>], may exist in equilibrium in the organic phase. Treatment of the acidified solution with dilute alkali results in reversion to the *cis*-[Pt(L<sup>3</sup>-S,O)<sub>2</sub>] complex.

# EXTRACTION OF SILVER FROM CONCENTRATED CHLORIDE SOLUTIONS: USE OF TRI-*n*-BUTYL- AND TRI-*n*-OCTYLPHOSPHINE SULPHIDES

Rita S. Capela and Ana P. Paiva

Departamento de Química e Bioquímica, C.E.C.U.L.,  
Faculdade de Ciências da Universidade de Lisboa, Lisboa, Portugal

Tri-*n*-butyl- and tri-*n*-octylphosphine sulphides have been synthesised by reaction of the respective phosphines with sulphur, the results collected for their characterisation and purity being in accordance with expected data. Both alkylphosphine sulphides were then evaluated for silver extraction from concentrated chloride media, a stabilised sodium thiosulphate aqueous solution being utilised for the stripping of the metal ion. The selectivity of both extractants towards the precious metal, when 10- to 60-fold molar contents of Cu(II), Fe(III) and Pb(II) are present in the feed aqueous medium, was also investigated. The information obtained from the study of the dependency of silver ion distribution data on acid and chloride contents, as well as on extractant concentration, allows the proposal of the most probable silver extraction pathways. The overall results achieved are systematically compared with those previously obtained for triisobutylphosphine sulphide, commercially available from Cytec under the trade name of Cyanex 471X.

## INTRODUCTION

Chloride hydrometallurgy has been frequently considered for the treatment of complex sulphide ores and concentrates [1], and it is known that the resulting leaching solutions usually may contain traces of silver in their composition.

Precipitation in silver chloride form and cementation [2] are widely used methods to separate the precious metal from complex chloride aqueous phases. However, in addition to those, solvent extraction can be an interesting approach to efficiently and selectively recover silver remaining dissolved in highly concentrated chloride leaches [1], as the anionic chlorocomplexes of the type  $\text{AgCl}_2^-$ ,  $\text{AgCl}_3^{2-}$  and  $\text{AgCl}_4^{3-}$  are known to be responsible for the increasing solubility of silver chloride when high chloride concentrations coexist in the aqueous solution [3].

Several organic extractants have been investigated for silver recovery from concentrated chloride media [4]; amongst the most efficient, a monomeric amide derivative of a calix[4]arene [5], diphenyl- and di-*n*-butylthioureas [6] and triisobutylphosphine sulphide (TIBPS, active ingredient of Cyanex 471X, commercially available from Cytec) [7] deserve a special mention.

In fact, all extractants proved to be very efficient for silver extraction, the thiourea derivatives and TIBPS acting through a sort of “solvation” reaction pathway [4, 6], whereas silver cation suffered extraction by the calix[4]arene compound through an anionic exchange equilibrium [5].

When selectivity of extraction is considered, base metals such as Fe(III), Cu(II) and Pb(II) seriously affect the performance of thiourea derivatives towards Ag(I), as they also are extensively co-extracted [6]. TIBPS is much more selective for silver under similar experimental conditions, with separation factor values of 9, 23 and 111 achieved for Ag(I) / Cu(II), Ag(I) / Fe(III) and Ag(I) / Pb(II), respectively, when the three metal ions co-existed with Ag(I) in 10- to 60-fold molar excesses in the initial aqueous solution [7].

With the exception of triphenylphosphine sulphide (TPPS) [8], no other phosphine sulphide than TIBPS has been tested for silver recovery from chloride solutions. The presence of the aromatic rings in the TPPS structure markedly decreased the extraction affinity of the organic compound for Ag(I) contained in concentrated chloride solutions, which is a quite surprising result [8] if the similarities of TIBPS and TPPS are taken into account. However, this poor extraction behaviour would not be expected if new phosphine sulphides with different aliphatic alkyl groups other than isobutyl were used instead.

In order to check the influence of the nature of the alkyl groups of phosphine sulphides for Ag(I) extraction from concentrated chloride solutions, tri-*n*-butyl- and tri-*n*-octylphosphine sulphides (TBPS and TOPS, respectively) were synthesised and tested for silver recovery. In fact, it seems interesting to evaluate if an isomeric branched or linear alkyl group in the extractants (isobutyl in TIBPS and *n*-butyl in TBPS) differentiates their affinity towards Ag(I), both in terms of efficiency and selectivity. In addition, the size of the alkyl group in the organic molecule may also play an important role in the metal ion extraction, therefore the performance of TOPS was simultaneously investigated.

## EXPERIMENTAL

Tri-*n*-butyl- and tri-*n*-octylphosphine sulphides were synthesised by reaction of the respective phosphines with excess sulphur ( $S_8$ ) under a nitrogen atmosphere, using toluene as solvent [9]. The extent of both reactions was controlled by T.L.C. After completeness, the solvent was evaporated on the rotary evaporator. The yields obtained were quantitative. The purity of both liquids was checked by GC, revealing values of about 95% for TBPS and 90% for TOPS. Characterisation was accomplished by IR, MS and  $^1H$ ,  $^{13}C$  and  $^{31}P$  NMR, the results obtained being in accordance with expected data.

Aqueous solutions for the extraction experiments were prepared using hydrochloric acid and sodium chloride, generally containing 2 M HCl + 3 M NaCl; however, for the study of the chemical reactions involved or the influence of acidity, different proportions of both reagents, or HCl alone, were also used. Ag(I) feed solutions, with concentrations of about  $1.4 \times 10^{-3}$  M, were made by dissolution of the required amount of  $AgNO_3$  (Merck, 99.5% purity) in the base-electrolytes. In addition to Ag(I), solutions containing  $3 \times 10^{-2}$  M Cu(II),  $9 \times 10^{-2}$  M Fe(III) and  $1 \times 10^{-2}$  M Pb(II) were prepared from the respective chloride salts in the 2 M HCl + 3 M NaCl aqueous phase. All chemicals were pro-analysis. For the stripping experiments, a stabilised sodium thiosulphate solution whose composition is referred to by Rickelton and Robertson [10] was employed. Organic phases were obtained by dissolution of TBPS or TOPS in 1,2-dichloroethane (1,2-DCE, Riedel-de-Haen, 99.8%).

Extraction and stripping experiments were carried out by mixing equal volumes of aqueous and organic phases (A/O=1) for 30 minutes, at room temperature and at a constant stirring speed of 1000 rpm, which was enough to guarantee a good emulsion. A similar procedure was also adopted for the evaluation of the selectivity of both extractants towards Ag(I). For the investigation of the extraction reactions and influence of acidity, a double-wall cell with circulation of water from a thermostat, in order to control the temperature (25°C), was used instead.

Analysis of the metal contents in the aqueous phases, before and after extraction, was carried out by Flame Atomic Absorption Spectrophotometry using a Unicam 929 model. For each sample, three aliquots were analysed and the values obtained were critically treated and only accepted if a reasonable relative standard deviation was obtained. Metal ion concentrations in organic phases were calculated by mass balance. For the majority of the cases, at least two sets of experiments were accomplished in order to confirm all data obtained.

## RESULTS AND DISCUSSION

### Extraction and Stripping

In order to check whether TBPS and TOPS are suitable extractants for silver ion from concentrated chloride base-electrolytes, 0.1 M solutions of both organic compounds in 1,2-DCE were used to extract  $1.4 \times 10^{-3}$  M of Ag(I) contained in a 2 M HCl + 3 M NaCl aqueous phase. The results obtained are presented in Table 1, the values displayed being the average of at least four experiments for each ligand.

*Table 1. Percentages of Ag(I) extraction by TBPS and TOPS.*

Extractant	% of Ag(I) extraction
TBPS	85 ± 3
TOPS	76 ± 4

Both TBPS and TOPS are good extractants for Ag(I) recovery from typical concentrated chloride aqueous phases, TBPS being the most efficient of the two. For an identical set of experimental conditions, TIBPS exhibits Ag(I) extraction values of about 77% [7], therefore TBPS seems to be slightly more efficient than TIBPS. This latter ligand is comparable to TOPS as far as its extraction performance towards the precious metal is concerned.

Stripping of the Ag(I) loaded organic solutions was accomplished by use of a stabilised 1 M sodium thiosulphate solution [10]. The performance of this aqueous phase for recovery of the Ag(I) contained in the loaded TBPS or TOPS solvents is presented in Table 2.

*Table 2. Percentages of Ag(I) stripping from TBPS and TOPS.*

Extractant	% of Ag(I) stripping
TBPS	76
TOPS	96

Table 2 shows that the stabilised sodium thiosulphate aqueous solution is an efficient Ag(I) stripping agent. Ag(I) from TOPS is easier to strip than from TBPS, this order being the inverse of the one found for extraction. For similar experimental conditions, stripping of Ag(I) from TIBPS is more difficult to achieve, as values of only 57% were reported [7].

Concerning total Ag(I) recovery, the use of TBPS allowed a 65% silver recovery, whereas TOPS achieved an overall performance of about 73%. Both extractants compare well with the solvent extraction behaviour of TIBPS for Ag(I) recovery from concentrated chloride phases [7]. In addition, it can be concluded that changing the *n*-butyl groups in TBPS to their branched isomers in TIBPS decreases the extraction efficiency towards Ag(I), as well as the stripping of the precious metal from the organic solvent. TOPS can also be considered a promising extractant.

### Selectivity of Ag(I) Extraction

The behaviour of TBPS and TOPS towards Ag(I) when the precious metal co-exists with larger concentrations of base metals such as Cu(II), Fe(III) and Pb(II) is quite interesting to evaluate, as it is a situation which can occur if a chloride leaching of a complex sulphide ore or concentrate is considered. Therefore, a synthetic feed solution containing  $1.4 \times 10^{-3}$  M Ag(I), in addition to  $3 \times 10^{-2}$  M Cu(II),  $9 \times 10^{-2}$  M Fe(III) and  $1 \times 10^{-2}$  M Pb(II) in a 2 M HCl + 3 M NaCl base-electrolyte, was put in contact with either a 0.1 M 1,2-DCE solution of TBPS or TOPS, following the general experimental conditions reported earlier. Data related to TIBPS are also included [7]. The results obtained are listed in Table 3.

Table 3. Selectivity of TBPS, TOPS and TIBPS for Ag(I) extraction.

Extractant	Separation Factor Ag(I) / Cu(II)	Separation Factor Ag(I) / Fe(III)	Separation Factor Ag(I) / Pb(II)
TBPS	4	5	20
TOPS	5	8	99
TIBPS [7]	9	23	111

A general insight through the contents of Table 3 reveals that TBPS and TOPS exhibit a quite good selectivity for Ag(I). In fact, it must not be forgotten that all the basic metals are much more abundant in the feed aqueous solution than the precious metal itself. TOPS shows a better selectivity for Ag(I) than TBPS.

This feature can be considered an interesting result if data related to TBPS are compared with those of TIBPS. It can be concluded that changing the isobutyl groups in TIBPS to their linear isomers in TBPS affects negatively the selectivity of TBPS for Ag(I), which is precisely the inverse situation found for the extraction / stripping of Ag(I) in the absence of other metal ions.

The stabilised sodium thiosulphate solution was also applied on the metal ion stripping of the loaded organic phases resulting from the selectivity experiments. It has been found that the stripping agent is not selective for Ag(I), as Cu(II) and Fe(III) were also extensively stripped. In addition to the poor extraction performance exhibited by both ligands towards Pb(II), the stripping of this metal ion by the thiosulphate aqueous solution has not been successful.

### Extraction Pathways involving TBPS and TOPS

In order to establish the probable Ag(I) extraction pathways by TBPS and TOPS, several series of extraction experiments were carried out in order to evaluate the dependence of Ag(I) distribution coefficient on extractant and chloride concentrations. The extraction of  $1.4 \times 10^{-3}$  M of Ag(I) contained in a 2 M HCl + 3 M NaCl medium was accomplished using different concentrations of TBPS and TOPS, whereas a 0.06 M solution of TBPS or TOPS was used to extract  $1.4 \times 10^{-3}$  M of Ag(I) from solutions with different chloride concentrations, although containing a fixed 2 M HCl portion. The temperature of extraction was controlled at 25°C. The overall results obtained are plotted in Figures 1 and 2.

The experimental extractant / Ag(I) ratio, given by the slope of the straight lines which best fit the distribution data, have the values of 1.8 for TBPS ( $R^2 = 0.990$ ) and 2.3 for TOPS ( $R^2 = 0.991$ ). Regarding the chloride / Ag(I) ratio, using a similar approach, the analysis of the slopes give -4.0 for TBPS ( $R^2 = 0.995$ ) and -4.1 for TOPS ( $R^2 = 0.998$ ). Therefore, a preliminary conclusion is that both extractants follow identical Ag(I) extraction pathways, as the data collected are similar.

The influence of the aqueous medium acidity on the overall extraction process was also investigated for both extractants. Sets of extraction experiments involving 0.1 M concentrations of TBPS or TOPS in 1,2-DCE were carried out, using aqueous solutions with  $1.4 \times 10^{-3}$  M of Ag(I) contained in a 5 M total chloride concentration, for which the HCl content varied between 1 and

5 M. Therefore, whenever necessary, addition of NaCl was made. The results obtained put in evidence that increasing concentrations of HCl slightly enhance Ag(I) extraction, e.g., from 1 M to 5 M HCl, extraction of Ag(I) by TBPS passed from 75% to 82%, whereas for TOPS it increased from 66% to 82%.

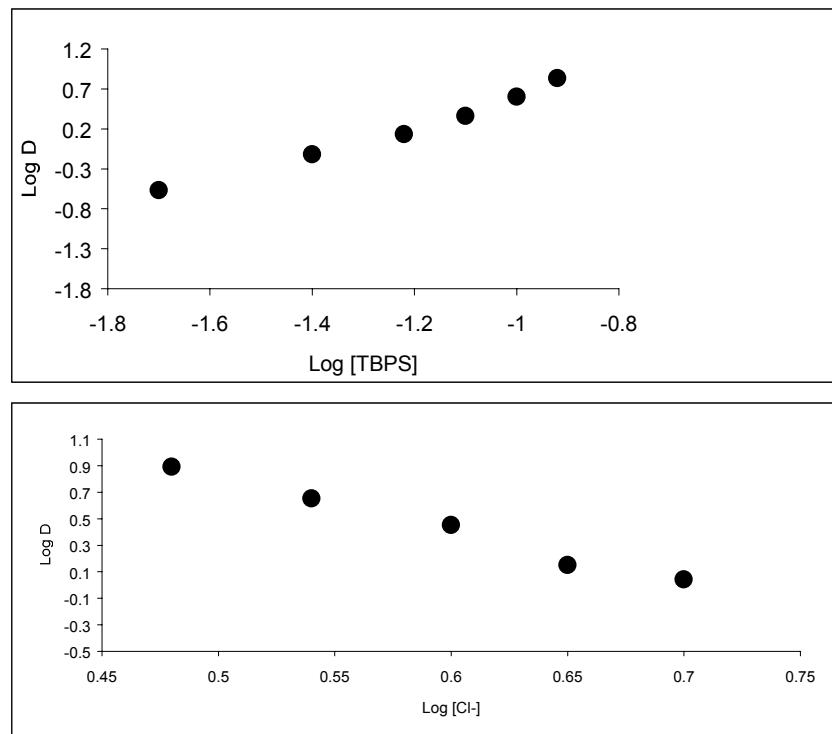

Figure 1. Dependence of Ag(I) distribution coefficient on TBPS and chloride concentration.

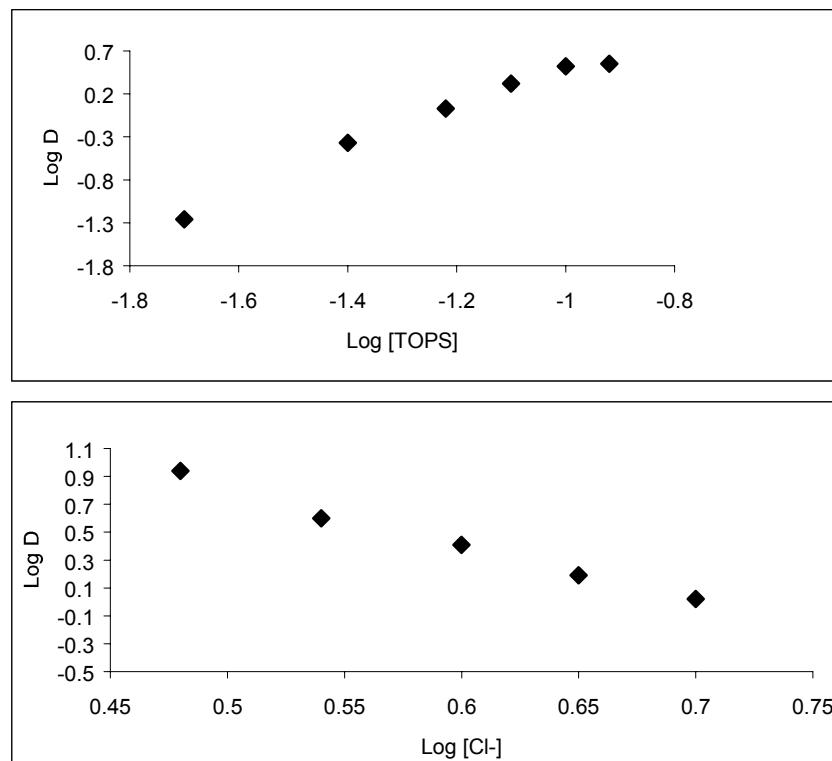

Figure 2. Dependence of Ag(I) distribution coefficient on TOPS and chloride concentration.

A possible interpretation of these acidity data is that a direct chemical exchange of H<sup>+</sup> on the extraction reaction is not likely to occur, however H<sup>+</sup> or Na<sup>+</sup> must appear as counter cations of the Ag(I) anionic chlorocomplexes. It is reasonable to suppose that, in the absence of Na<sup>+</sup>, the viscosity and density of the aqueous solutions should decrease, and the mentioned effect of those parameters certainly facilitates the physical phenomena associated with the extraction process, therefore enhancing the Ag(I) extraction efficiency.

Based on the experimental extractant / Ag(I) ratio, two molecules of TBPS or TOPS must be involved with each Ag(I) species. However, the values of -4 collected for the slopes of the chloride / Ag(I) ratios are more difficult to explain. According to literature, for chloride solutions between 1 and 5 M NaCl, the predominant Ag(I) chlorocomplex is always AgCl<sub>3</sub><sup>2-</sup> [3]. A possible explanation is that TBPS or TOPS may have the particularity to act over a sort of AgCl<sub>3</sub><sup>2-</sup> dimer, namely AgCl<sub>3</sub><sup>2-</sup>.AgCl<sub>3</sub><sup>2-</sup>, giving rise to something such as AgCl.2L.AgCl (L = TBPS or TOPS) in the organic phase and releasing 4 Cl<sup>-</sup> for each Ag(I) species, Equation (1).

This interpretation is based on the assumption that D, for these systems, may be defined as presented in Equation (2).

$$D = [\text{AgCl} \cdot 2\text{L} \cdot \text{AgCl}] / [\text{AgCl}_3^{2-} \cdot \text{AgCl}_3^{2-}]_{\text{eq}} \quad (2)$$

The influence of chloride ion on Ag(I) extraction by TBPS and TOPS seems to be different from that suffered by TIBPS under similar experimental conditions, as the slope of log D vs. log [Cl<sup>-</sup>] for Ag(I) extraction by this latter extractant was found to be -2.4 [7].

However, Abe and Flett also studied Ag(I) extraction from chloride media by TIBPS [11], stating the formation of L<sub>2</sub>AgCl species, although mentioning a slope of -3.6 for the log D vs. log [Cl<sup>-</sup>]. This latter result was attributed to the presence of inextractable anionic Ag(I) complexes in the aqueous phase [11]. Hence, the interpretation of this particular feature deserves further research.

Study on the extraction of Fe, Cu, Ni and Co from chloride and sulphate solutions with different binary extractants varying aqueous acidity has been carried out. In binary extractant systems iron(III) is extracted from chloride solutions with high distribution coefficients for a wide range of aqueous acidities. Compositions of extracted species are different depending on acidity. Usually both iron and copper are poorly extracted from sulphate solutions with anion-exchange and neutral extractants. Nevertheless, Fe(III) as well Cu(II) are effectively extracted from cobalt and nickel sulphate electrolytes with binary extractants due to the high concentration of the sulphate in the aqueous phase. Using the mixtures of binary extractants and aldoximes the separation of Ni and Co can be achieved. The highest separation coefficients are however realized in the extraction from nitrate solutions.

### INTRODUCTION

Establishment of basic principles of binary extraction of acids and metal salts and advantages of binary extraction in comparison with extraction using initial ion-exchange and neutral extractants has lead to further developments of the extraction method. To date a series of fundamental and applied research initiatives into mineral acid and metal salt extraction with binary extractants have been performed [1-5]. However, there are a great number of extraction systems, which are in need of a study to solve some problems in extraction and separation of the substances. In this work the the solvent extraction behaviour of Fe(III) and non-ferrous metals with binary extractants in chloride and sulphate solutions is examined in order to indicate conditions for the recovery and separation of these metals.

### EXPERIMENTAL

#### Extraction of Fe(III) from Chloride and Sulphate Solutions

For the extraction of iron with binary extractants of different compositions, chloride and sulphate solutions with a wide range of aqueous acidities were used. Salts of trioctylmethylammonium, such as 4-tert-butylphenolate, caprylate and di(2-ethylhexyl)-phosphate, were employed as extractants. The binary extractants ( $R_4NA$ ) were prepared by mixing equimolar amounts of  $R_4NCl$  and organic acid (HA) in toluene and with subsequent washing of organic solutions with 1 M NaOH or water.

### Extraction of Fe(III) and Cu(II) from Sulphate Electrolytes

For refining sulphate nickel and cobalt electrolytes binary extractants of different composition based on quaternary ammonium bases (QAB) were examined. Ni and Co electrolytes were prepared as saturated solutions of sulphates of these metals with concentrations of Ni ~120 g/l and Co ~118 g/l. Sulphates of copper or iron were added into the electrolytes prepared adjusting  $C_{Fe(Cu)} = 1$  g/l. Solutions of salts of trioctylmethylammonium with different organic acids (di(2-ethylhexyl)phosphoric, caprylic, 2-ethylheptylcarboxylic acids) were used as extractants.

### Extraction of Ni and Co from Sulphate and Nitrate Solutions

Aldoximes of simple structure have been shown to extract nickel selectivity from cobalt in aqueous solutions [10-12]. However, owing to the thermodynamic stability of the extracted species in aldoxime systems, stripping of Ni is difficult. To study improved stripping extraction of Ni and Co from sulphate and nitrate solutions by mixtures of binary extractants and heptanealdehyde (Ox) of linear structure were examined. Salts of trialkylbenzylammonium, trialkylmethylammonium and tetraoctylammonium with anions of organic acids (caprylic,  $\alpha,\alpha$ -monocarboxylic) were used as binary extractants.

## RESULTS AND DISCUSSION

### Extraction of Fe(III) from Chloride and Sulphate Solutions

In previous studies of the extraction of Fe(III) from chloride solutions with binary extractants we found that the complex acid, HFeCl<sub>4</sub>, is extracted from acidic solutions [2]. The extraction power of binary extractants based on tetraalkylammonium and trialkylammonium decreases in the series: 2,6-tert-butylphenolate > 2-kumylphenolate > 4-tert-butylphenolate >  $\alpha$ -monocarboxylate > *n*-caprylate. The use of binary extractants instead of alkylammonium chloride leads to decreasing distribution coefficients of iron,  $D_{Fe}$ . As a result, the concentration of iron in raffinates increases in the stripping by water in comparison with the R<sub>4</sub>NCl system according to principles of binary extraction.

Using 4-tert-butylphenol and caprylic acid, the C<sub>R4NCl</sub>: C<sub>HA</sub> ratios were 1:3 and 1:2 respectively. The experimental data (Figure 1, curves 1-3) show that iron(III) is extracted by the binary extractants from chloride solutions for a wide range of aqueous acidities. Dependencies of distribution coefficients exhibit a minimum, obviously, due to different extraction mechanisms.

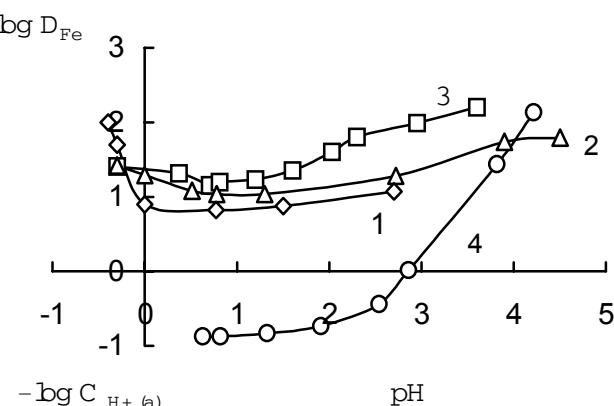

Figure 1. Extraction of Fe(III) from chloride (1-3) and sulphate (4) solutions by 0.01 M solutions of alkylphenolate (1), caprylate (2, 4) and dialkylphosphate (3) of trioctylmethylammonium in toluene depending on aqueous acidity.

$$C_{Cl(a)} = 2.5 \text{ M} \quad (1-3); \quad C_{SO_4(a)} = 2.5 \text{ M} \quad (4).$$

The extraction of iron from sulphate solutions occurs to an appreciable extent only from weak acidic media (Figure 1, curve 4). The enhancement of distribution coefficients of iron with increasing pH of the aqueous phase more than 2 is observed for all dependencies.

As indicated previously [7], iron from chloride acidic solutions is mainly extracted by anion-exchange extractants as ion associates involving the  $\text{FeCl}_4^-$  anion. The absorption spectra of the organic phases after iron extraction by binary extractants from acidic chloride solutions exhibit absorption bands at  $\lambda_{\text{max}}$  equal to 318 and 365 nm in the visible range, characterized for the spectrum of  $\text{FeCl}_4^-$  complex anion [7]. This indicates that iron is recovered from chloride solutions in the region of 2 M HCl to pH values  $\sim 2$  in the form of  $\text{FeCl}_4^-$  complex anion. Studying the distribution of chloride between toluene solutions of alkylphenolate, caprylate, dialkylphosphate of QAB and acidic chloride solutions the binary extractants were found to transfer to the chloride form in a range of 1-3 M HCl [4]. The distribution of iron under these conditions proceeds through anion-exchange mechanism:

Subscripts (a) and (o) denote species in the aqueous and organic phases respectively.

With a decrease in aqueous acidity, an equilibrium:

is shifted to the formation of the binary extractant for the systems involving dialkylphosphate and caprylate of QAB, and distribution of iron can occur through binary mechanism:

It seems reasonable that the decrease in distribution coefficients of iron in the range 2 M HCl to pH  $\sim 1$  is accounted for by decreasing portion of the extracted species  $\text{FeCl}_4^-$ . In QAB caprylate system a formation of iron caprylate in the organic phase is also possible. It is known that in the Fe(III) extraction by caprylic acid a three-nuclear complex,  $\text{Fe}_3\text{A}_9$ , is recovered into the organic phase [8]. Thus, when both anionic and cationic forms are distributed into the organic phase, extraction of iron by caprylate of trioctylmethylammonium can be described as a summary equation:

The observed increase of  $D_{\text{Fe}}$  values at pH  $> 3$  (Figure 1) is obviously related to this phenomenon.

Trioctylmethylammonium dialkylphosphate involves a strong organic acid ( $\text{pK}_a \sim 2$ ), and extraction of iron as a dialkylphosphate should occur at lower pH values. The spectra of extracts were observed to indeed change at pH  $\sim 0.8$ . The absorption maxima at 318 and 365 nm gradually disappeared, and a new band with  $\lambda_{\text{max}} = 285$  nm appeared. The extraction of iron also improves with increasing pH  $> 1$  (Figure 1, curve 3). According to published data on Fe extraction by di(2-ethylhexyl)phosphoric acid as the complex  $\text{FeA}_3$  [9] and data on the state of binary extractant [4], iron distribution by trioctylmethylammonium dialkylphosphate in an intermediate range can be represented as a summary equation:

and in a range of pH  $> 3$  as follows:

The extraction of iron from sulphate solutions is more pronounced at lower acidity in QAB caprylate system (Figure 1, curve 4) due to the high energy of hydration of sulphate. With increasing pH, the Fe extraction improves due to forming caprylate of iron,  $\text{Fe}_3\text{A}_9$ , in the organic phase.

### Extraction of Fe(III) and Cu(II) from Sulphate Electrolytes

A choice of binary extractants for extraction and (or) separation of Fe(III) and Cu(II) is defined by objects and solvable problems. For selective recovery of copper from Fe-containing solutions, for example, solutions after leaching of oxidized ores dialkyldithiophosphate of tetraalkylammonium can be employed as an extractant [2]. This system is characterized by high separation coefficients,  $\beta_{\text{Cu}/\text{Fe}}$ , up to  $1 \cdot 10^4$ , a high extractant capacity and fast extraction and stripping kinetics. Copper can be stripped using ammonia solutions.

*Table 1. Extraction and stripping of Cu and Fe in systems Ni electrolyte – QAB salts.  
Stripping solution – 0.05 M  $\text{H}_2\text{SO}_4$*

Extractant	$C_{\text{ex}}, M$	$D_M$		Stripping efficiency, %	
		Cu	Fe	Cu	Fe
Caprylate	0.53	3.94	-	71.1	-
	0.45	1.63	74	90.7	1.0
	0.25	-	33	-	36.4
	0.15	0.002	1.64	-	75.5
Alkylcarboxylate	0.53	5.23	-	82.8	-
	0.45	1.38	60	95.0	12.3
	0.38	0.212	48	97.3	27.5
	0.25	-	16	-	41.2
Alkylphosphate	0.45	0.009	74	94.4	5.4
	0.25	-	5.90	-	28.2
	0.15	0.001	1.22	-	53.9

$C_{\text{ex}}$  - concentration of extractant

The data shows that the most effective extraction of copper occurs from Ni sulphate solutions by carboxylate and caprylate of QAB (Table 1). Iron can be recovered by different QAB salts from Ni sulphate solutions. In contrast to the copper extraction, the highest distribution coefficients for iron are observed in QAB alkylphosphate system. Extraction of sulphates of Cu and Fe by salts of QAB with organic acids can be described in general form as follows (using copper example):

Extraction of Cu and Fe proceeds due to the high concentration of the sulphate in the aqueous phase. Copper and iron can be stripped by water or weak acidic solutions owing to a decrease in sulphate concentration in the aqueous phase. Indeed, Cu and Fe are effectively stripped from the organic phase by a 0.05 M solution of  $\text{H}_2\text{SO}_4$  in systems involving alkylcarboxylate and caprylate of QAB using one step of stripping. At the same time, the values of  $D_{\text{Cu}}$  and  $D_{\text{Fe}}$  remain high in the extraction by these extractants (Table 1). Extraction of Cu and Fe from Co sulphate solutions was found to be effective also in systems involving QAB salts. Then these metals can be stripped from the organic phase with a 0.05M solution of  $\text{H}_2\text{SO}_4$  (Table 2).

*Table 2. Extraction and stripping of Cu and Fe in Co electrolyte – QAB salts systems.  
Stripping solution – 0.05 M H<sub>2</sub>SO<sub>4</sub>*

Extractant	C <sub>ex</sub> , M	D <sub>M</sub>		Stripping efficiency, %

	0.50	-	4.73	-	32.0
	0.45	0.134	1.55	97.6	52.0

### Extraction of Ni and Co from Sulphate and Nitrate Solutions

Systems involving mixtures of binary and neutral extractants are of a special interest. When a neutral extractant forms more stable complexes with coordination to the atom of one of the metals, an increase of separation coefficients would be expected. In the extraction of Ni and Co with mixtures of binary extractants and heptanealdoxime it was shown that extraction characteristics obtained for simpler binary extractant systems remained the same for these systems. In particular, the extraction of metals doesn't depend on pH values, and the extraction of salts decreases in the series: Ni(NO<sub>3</sub>)<sub>2</sub> > NiCl<sub>2</sub> > NiSO<sub>4</sub>. With increasing concentration of an anion of mineral salt in the aqueous phase, distribution coefficients of metals enhance. An increase in a concentration of organic acid in the organic phase results in decreasing distribution coefficients due to interactions of monocarboxylic acid with aldoxime and R<sub>4</sub>NA forming compounds such as HA<sup>n</sup>Ox and R<sub>4</sub>NA<sup>m</sup>HA. In some extraction systems Co(II) in the organic phase oxidizes partially by oxygen of air. Conditions preventing cobalt oxidation in the organic phase were found.

Data obtained are given in Table 3 from which it follows that the highest separation coefficients of Ni and Co ( $\beta_{Ni/Co}$ ) are realized in the extraction from nitrate solutions using the mixtures of QAB alkylcarboxylates with aldoxime. Besides, the distribution coefficients of nickel from sulphate solutions are less than 0.2 complicating the use of these extractants in the technological processes. In a range of high pH values metals are extracted by mixtures of binary extractants and Ox through cation-exchange mechanism:

Intermediate complexes such as M(Ox)<sub>4</sub>AB (B<sup>-</sup> - nitrate, for example) can be also formed in the organic phase. Nickel and cobalt can be stripped from the organic phase by water through binary mechanism in consequence of forming a stable salt, R<sub>4</sub>NA:

Thus, the use of mixtures of binary extractants with aldoxime results in increasing distribution coefficients,  $\beta_{Ni/Co}$ , in comparison with binary extractants owing to the primary coordination of molecules of aldoxime to the atom of nickel [12]. On the other hand, metals can be stripped from the organic phase more easily compared to the system involving only aldoxime. To obtain more concentrated raffinate of nickel mixtures of ammonium bicarbonate and ammonia should be used for stripping.

4-Diazopyrazol-5-one ligands carrying a range of substituents can be readily prepared by coupling aryl diazonium salts on to the appropriate pyrazolones. Hydrocarbon-soluble versions have been shown to be selective and robust extractants for copper from ammoniacal sulfidic ore leach solutions. Cobalt(III), copper(II), nickel(II) and zinc(II) complexes with 4-(4-*tert*-butylphenyldiazo)-3-methyl-1-phenyl-5-pyrazolone (LH) have been characterised by X-ray crystallography. Solvent extraction studies with analogous compounds have shown that pH<sub>1/2</sub> values for copper(II) vary depending on the substitution on the pyrazolone ring. Using two stages of extraction and two stages of stripping, the N-*tert*-butyl analogue gave stage efficiencies of 90% in extract and 95% in strip. Using an advance electrolyte of 45g/l copper(II), recovery of greater than 93% was achieved. Whilst diazopyrazolone extractants are strong enough for use with ammoniacal feeds and show good loading and stripping characteristics, the compounds are highly coloured and this may limit their use as commercial extractants.

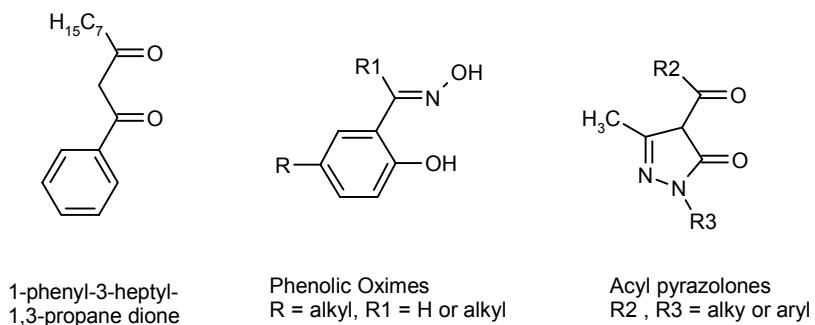

## INTRODUCTION

Over 2.3 million tonnes of copper, equivalent to one fifth of total world production, are currently recovered each year by hydrometallurgical processes involving solvent extraction from acidic sulfate leach solutions. The economic and environmental benefits of such processes make them attractive alternatives to smelting. A considerable amount of research and development [1,2] has been directed at recovery of copper from chloride and ammoniacal leach solutions as these will extend the range of ores which can be efficiently processed hydrometallurgically. More recently, a process has been developed based on ammoniacal leaching of chalcocite-based ores under mild conditions [3]. This generates two copper streams - an enriched ore, covellite, which can be treated in a conventional smelter, and a concentrated aqueous solution (ca. 5 M, pH 8.5 - 10) containing ammine complexes (Equation 1).

Solvent extraction with a weakly acidic reagent, as in Equation 2, regenerates the leachant, which is recycled. Stripping the copper from the loaded organic solution with acid (Equation 3), followed by electrowinning the copper (Equation 4), regenerates the extractant without overall consumption of acid. The recycling of reagents between the unit operations leads to a remarkable materials balance with the overall process being represented by Equation 5. Overall, more than 97 % of the total copper present in the ore can be recovered by the combination of hydrometallurgical and smelting processes with less than 3 % being lost to tailings [1].

The pH of the lixiviant and the leach conditions employed are such that very little of the iron present in the ores and, only small quantities of other transition metals, are transferred to the pregnant leach solution (PLS). Typically the PLS has a composition of ca. 280 g l<sup>-1</sup> Cu, 440 ppm Zn, <1 ppm Fe, 1 ppm Mn and <<1 ppm Ni [4]. As a consequence, and in marked contrast to the acid leach process, the solvent extractant used to recover the copper is not required to show very high selectivity for copper over iron or high "strength" because the extraction equilibrium (Equation 2) is effectively buffered by [NH<sub>4</sub>]<sup>+</sup>/NH<sub>3</sub>. A "weak" extractant also has the advantage that stripping the copper with spent electrolyte is facile and a good copper transfer efficiency is obtained in the circuit. A reagent such as, 1-phenyl-3-heptyl-1,3-propane dione (mixed isomer heptyl substituent, Figure 1) provides "strength" and selectivity well suited to ammoniacal recovery processes. However, a potential problem with organic reagents which contain reactive carbonyl groups is their ability to form the corresponding imines in the presence of high levels of NH<sub>3</sub> and at the temperature typically used in the leaching process, 45°C. Apart from the potential loss of the active reagent from the system, these imines may also build up in the organic phase leading to poor stripping and may contribute to poor phase disengagement which will consequently lead to high entrainment of the aqueous phase in the loaded organic. For these reasons other systems are now being considered [5].

*Figure 1. Structures of commercial metal extractants and acylpyrazolones.*

Acylpyrazolones (Figure 1) also form neutral  $\beta$ -diketonate-type complexes suitable for extraction of a range of metals into organic solvents[ 6-9] and have been considered [10] as alternatives for use in ammoniacal leach circuits. However, the low solubility of their metal complexes limits [10] their usefulness. The structurally related diazopyrazolones (Figure 2) have not been previously investigated as copper extractants, but possess very well defined synthetic chemistry [11] due to their extensive use in the dyestuffs industry [12]. They have been shown [13] to form neutral 2:1 complexes with copper with an N<sub>2</sub>O<sub>2</sub><sup>2-</sup> donor set analogous to that in the very successful phenolic oxime extractants (Figure 1) used to recover copper from acidic leach solutions. In this paper we report the extraction properties of a series of diazopyrazolones with a range of first row transition metals. The crystallography of the complexes has been reported previously [14].

## RESULTS AND DISCUSSION

### Preparation of the Ligands

The free ligands (Figure 2) **1-7** were readily prepared by coupling the appropriate pyrazolone and diazonium salt derived from the required *para*-substituted aniline. All are highly coloured (yellow/orange), and diazopyrazolones have been used extensively for over a century in the dyestuffs industry [12]. Ligands **1-4** with N-phenyl, N-methyl and unsubstituted pyrazolone units are solids which are easily recrystallised and characterised, their solubilities and those of their copper(II) complexes in hydrocarbon solvents were poor. Incorporation of a *t*-butyl group on the pyrazolone and a branched alkyl group in the *para*-position of the phenylazo group gave ligands **5-7**, with much higher solubility in hydrocarbons and could only be isolated as viscous oils.

### Metal Complexes

All the complexes are very highly coloured. The colour changes associated with complex formation can be used to monitor the displacement of metals from the ligand in solvent extraction experiments. Whilst the solubilities of the metal complexes in hydrocarbons were generally low, ligands **5-7** and their copper complexes were judged to be sufficiently soluble to allow solvent extraction experiments to be performed.

<b>2</b>	H	Ph	
<b>3</b>	t-Bu	H	
<b>4</b>	t-Bu	Me	
<b>5</b>	t-Bu	t-Bu	
<b>6</b>	s-Bu	t-Bu	
<b>7</b>	branched-nonyl	t-Bu	

Figure 2. Structures of diazopyrazolones.

### Solvent Extraction

It is convenient to assess the strength of extractants that operate on a “pH-swing” controlled process of the type shown in Equation 2, by determining their pH<sub>½</sub> values (the pH values associated with 50 % theoretical loading of a particular metal). The pH<sub>½</sub> values for 0.1 M toluene solutions of **5-7** obtained with acidic solutions of copper(II) sulfate were ca. 3.7, much higher than those for the “strong” phenolic oxime extractants (Figure 1), which are used commercially for the recovery of copper from acid sulfate leach solutions and have pH<sub>½</sub> values of < 2.0. The diazopyrazolone pH<sub>½</sub> value of ca. 4 is almost ideal for an ammoniacal leach circuit. Good loading is likely with the [NH<sub>4</sub><sup>+</sup>]/NH<sub>3</sub> buffered feed solution, whilst almost quantitative stripping is expected when using spent tankhouse electrolyte (pH 0 - 0.5).

S-curves can also be used to assess the selectivity of metal extraction. A toluene solution of **1** was contacted with aqueous solutions of cobalt(II), nickel(II), copper(II) and zinc(II) sulfates at various pH values (Figure 3). The pH<sub>½</sub> values obtained (Cu; 4.7, Zn; 5.8 and Ni; >7.0) are consistent with selectivities which follow the Irving-Williams order of complex stabilities, but with the nickel(II) complex formation being more disfavoured than normal relative to zinc. Reproducibility of extraction of cobalt was poor and the results were consistent with extraction of cobalt(II) and subsequent oxidation to cobalt(III). Such oxidation is likely to make stripping difficult on both thermodynamic and kinetic grounds. If cobalt is present this will be converted by the leachant to kinetically inert and thermodynamically stable cobalt(III) ammine complexes in the ammoniacal pregnant leach solution.

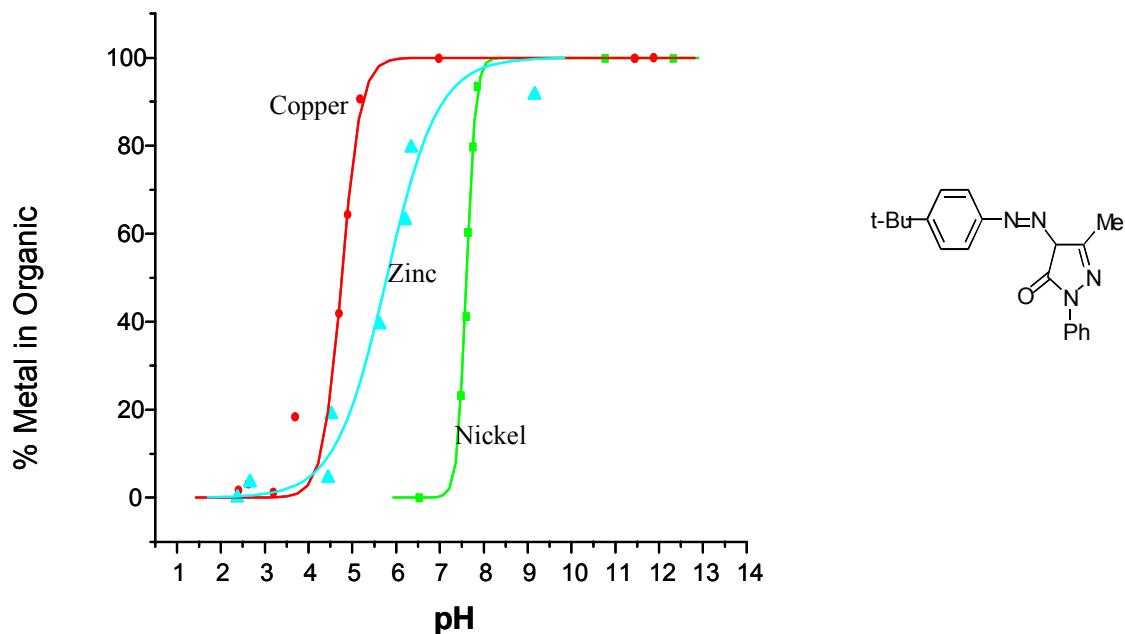

Figure 3. Extraction of copper, zinc and nickel by ligand 1 as a function of pH.

The position of the isotherm confirms that the azopyrazolones are weak extractants for copper when compared with conventional low pH phenolic oxime extractants because of their much higher pH<sub>½</sub> for extraction (ca. 3.7 vs. 0.3).

The extraction isotherms for analogues with R1 as tert-butyl and R2 as tert-butyl, s-butyl or nonyl are all very similar and weak. Figure 4 shows that extraction isotherms where R2 is tert-butyl but R1 varies from tert-butyl through methyl to phenyl become weaker though sharper.

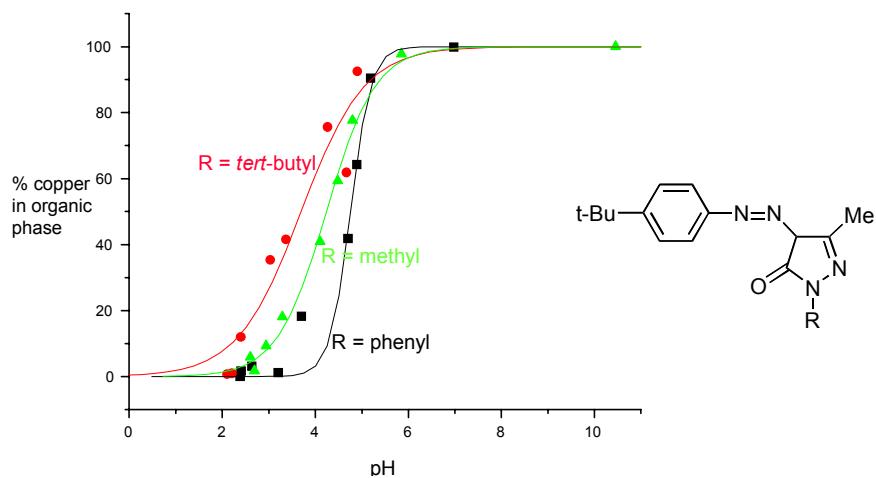

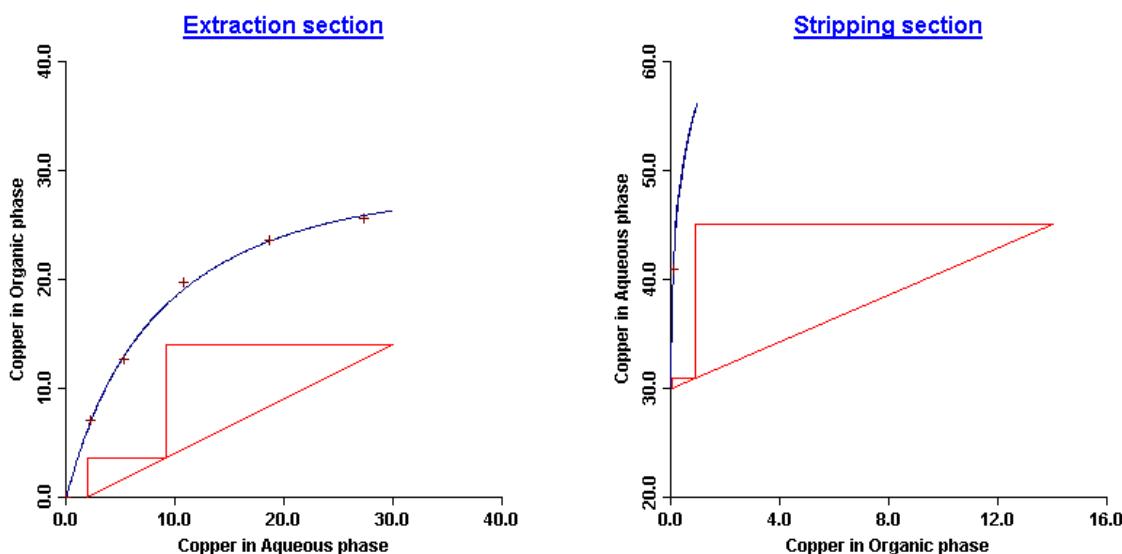

Figure 4. Extraction of copper by ligands 1,4 and 5 as a function of pH.

Figure 5 shows equilibrium isotherms for **7** with McCabe-Thiele constructions for the recovery of copper from a Cu 30 g l<sup>-1</sup>, SO<sub>4</sub><sup>2-</sup> 75 g l<sup>-1</sup>, NH<sub>3</sub> 45 g l<sup>-1</sup> feed and stripping with 30 g l<sup>-1</sup> copper and 180 g l<sup>-1</sup> sulfuric acid. The McCabe-Thiele data were modelled using the programme MINCHEM [15] for a process based on 2 stages of extraction and 2 stages of stripping and assuming 90 and 95 % stage efficiencies in extract and stripping respectively. The computed model indicates that copper recoveries in excess of 93 % may be expected, while producing a regenerated electrolyte containing 45 g l<sup>-1</sup> copper from which the copper metal value may then be recovered in a conventional electrowinning process.

*Figure 5. McCabe-Thiele constructions for the recovery of copper with Ligand 7 1.0 M in kerosene (20 % aromatic/80 % aliphatic content). All scales g l<sup>-1</sup>.*

The stability of the solvent extractant to the basic conditions of an ammoniacal leach process is of paramount importance. A preliminary assessment of the robustness of the diazopyrazolone **5** was performed by contacting separate samples of a 0.056 M solution of **5** in toluene with equal volumes of 34 g l<sup>-1</sup> (19 × excess of copper) and 3.4 g l<sup>-1</sup> (1 × excess of copper) ammoniacal copper feeds at room temperature over a period of 552 h (23 days). Analysis of both the aqueous and organic phases using ICP-AES showed that, within experimental error, the amount of copper extracted did not decrease over this time period demonstrating that the ligand does not undergo chemical degradation and is stable to prolonged contact with ammoniacal feeds. An important feature of the diazopyrazolone ligands which underpins their potential for use in a copper/ammoniacal circuit is that they are significantly weaker complexing agents for copper than the structurally related phenolic oximes. A series of X-ray structure determinations has been reported previously [15] in an attempt to define the origin of this difference.

## CONCLUSIONS

Diazopyrazolone ligands of the types described above are good candidates for extractants to recover copper from ammoniacal pregnant leach solutions. Good copper transfer efficiency can be obtained; they are relatively weak extractants and are very efficiently stripped by acidic spent tankhouse electrolyte. Whilst the buffering effect of the ammoniacal feed solution ensures good loading of copper into the organic phase in the extract stages and they appear to show good resistance to chemical degradation, their intense colour may restrict their use as commercial metal extractants.

\*\*\*Department of Chemistry, University of Edinburgh, Edinburgh, UK

The aim of the studies now reported was to investigate synergistic extraction of Co(II), Ni(II), Cu(II) and Zn(II) with a mixed ligand system consisting of a macrocyclic amine and an organic acid. A key design feature of such mixed extractant systems is their ability to form supramolecular assemblies which are preorganized for metal complexation and which are able to reversibly transfer metal cations from an aqueous feed solution. Experiments were performed to elucidate the inter-dependence of the extraction behaviour on the metal ion type, the nature of the diluent as well as the concentration ratio of both extractants, and the pH of the aqueous solution. Furthermore, an NMR titration study of assembly formation in solution and an X-ray structure of a relevant crystallized ligand adduct have been obtained in order to aid understanding of the observed solvent extraction results.

### INTRODUCTION

There is a current need in solvent extraction processes for a rational approach towards the development of selective reagents for toxic and/or valuable metal-ion mixtures even if they are only present at low concentrations. Synergistic effects can contribute to both enhanced selectivity as well as to more efficient metal extraction behaviour [1-3]. The use of supramolecular ligand systems as extractants may help control separation processes [4-6] and also aid the discovery of novel synergistic principles [7]. A key system type showing high synergistic behaviour towards metal extraction involves the combination of a crown ether and a cation-exchanging extractant of, for example, a chelating or organic acid type. In such cases the generally accepted explanation for observed synergism is related to complex formation of the metal ion with both components giving rise to a saturated coordination sphere of the metal ion that in turn yields increased lipophilicity of the extracted complex [7].

The supramolecular self-assembly process offers a new approach to the design of synergistic systems. Based on weak hydrogen bonding, two or more potential ligand molecules can form an organized assembly that, taken together, may be considered to approximate an assembled coordination sphere of the metal ion. Such ligand assemblies have been investigated between cyclam and 4-*tert*-butylbenzoic acid [8], 2-benzylphenol and 2-benzylphenolate [9] as well as between guanosine and isoguanosine nucleosides [10, 11]. Recently we have discussed some general aspects of tailoring molecular assemblies for metal ion binding using host-guest systems formed between carboxylic acids and macrocyclic amine-containing ligands [12]. Overall, the aims of the presented study were two-fold: (i) to investigate the formation of selected molecular assemblies incorporating *tert*-butylbenzoic acid **HR** and the azamacrocyclic **L** (Figure 1) and (ii) to use these molecular assemblies in selected solvent extraction experiments.

*Figure 1.* Compounds investigated.

## EXPERIMENTAL

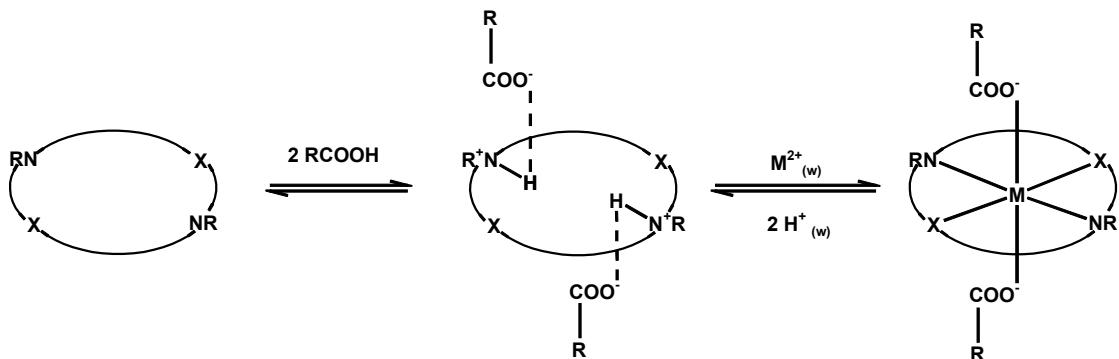

Where available, all chemicals were A.R. grade. Macrocycle **L** ( $R = H$ ) was prepared as described elsewhere [13]; an analogous procedure starting from 4-nonylsalicylaldehyde [14] was employed for **L** ( $R = C_9H_{19}$ ). Slow crystallization of an acetonitrile solution containing **L** ( $R = H$ ) and **HR** in a ratio of 1:2 yielded crystals of the corresponding 2:1 adduct which were suitable for X-ray structure determination [15]. The nmr titration experiments were performed on a AM 300 Bruker spectrometer at 25 °C. Weighted amounts (3-5 mg) of **HR** were added incrementally to a solution (0.075 M) of **L** ( $R = C_9H_{19}$ ) in  $CDCl_3$  contained in the nmr tube while the corresponding induced  $^{13}C$  and  $^1H$  chemical shifts were monitored.

Extraction studies were performed at  $25 \pm 1^\circ C$  in 2 cm<sup>3</sup> microcentrifuge tubes by mechanical shaking. The phase ratio  $V_{(org)}:V_{(w)}$  was 1:1 (0.5 cm<sup>3</sup> each); the shaking period was 30 min for Co(II), Cu(II), Zn(II) and 24 h for Ni(II). All samples were centrifuged after extraction. The metal concentration in both phases was determined radiometrically using  $\beta$ -emission ( $^{63}Ni$ ; liquid scintillation counter Tricarb 2500/Canberra Packard), and  $\gamma$ -radiation ( $^{60}Co$ ,  $^{64}Cu$ ,  $^{65}Zn$ ; NaI(Tl) scintillation counter Cobra II/Canberra Packard). The pH of aqueous solution was adjusted using 0.05 M 2-[N-morpholino]ethanesulfonic acid (MES)/ NaOH (pH = 5.5).

## RESULTS AND DISCUSSION

The general reaction scheme for the solvent extraction of a metal ion by a mixed extraction system consisting of a macrocyclic amine and an organic acid is given in Figure 2.

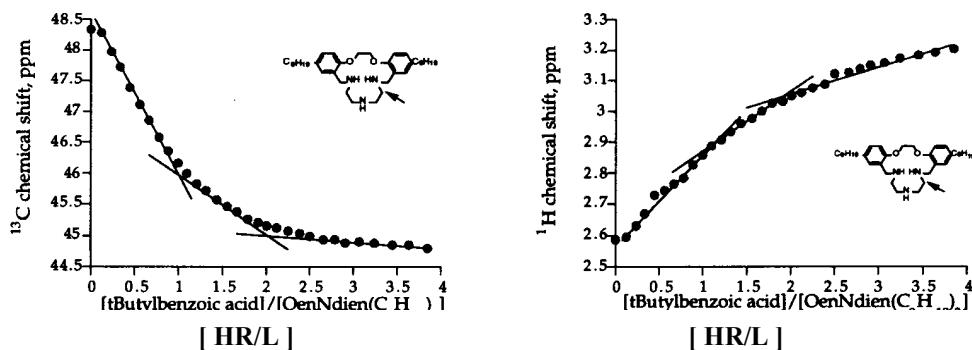

For a synergistic effect by the present mechanism to operate, the formation of an assembled extractant package with defined stoichiometry should be favourable and this species will be responsible for the metal ion transfer from the aqueous into the organic phase. The benefits of such assembly formation could be manifested as improvements in both technical (extractability, selectivity) and economic (solvent losses, easier synthesis of a preorganized extractant) parameters.

*Figure 2. General scheme for metal extraction on the bases of a 2:1 assembly between an organic acid and a macrocyclic amine.*

### Formation of Supramolecular Assemblies

$^{13}\text{C}$  and  $^1\text{H}$  NMR titration studies in  $\text{CDCl}_3$  were performed in order to probe the formation of defined assemblies between 4-*tert*-butylbenzoic acid (**HR**) and the macrocyclic amine (**L**) ( $R = \text{C}_9\text{H}_{19}$ ). The results of the investigation are illustrated in Figure 3 and provide clear evidence for the existence of 1:1 and 2:1 adduct species (**HR** : **L**) in solution. A similar result was obtained from parallel titrations involving **HR** and **L** ( $R = \text{H}$ ).

*Figure 3. Plots of the chemical shifts of the  $^{13}\text{C}$  and  $^1\text{H}$  resonance vs. the ratio  $\text{HR}/\text{L}$ .*

Such a stoichiometry is also confirmed in the solid state by an X-ray structure analysis of a crystalline 2:1 assembly between **HR** and **L** ( $R = \text{H}$ ); details are shown in Figure 4. The carboxylic groups interact directly via hydrogen bonds with two amine nitrogens of the macrocycle and one included water molecule [15].

### Solvent Extraction Studies

Preliminary extraction experiments have been performed for  $\text{Co}(\text{II})$ ,  $\text{Ni}(\text{II})$ ,  $\text{Cu}(\text{II})$  and  $\text{Zn}(\text{II})$  in the system  $\text{M}(\text{NO}_3)_2\text{-NaNO}_3\text{-MES/NaOH buffer/L-}\text{HR-CHCl}_3$  in order to investigate the prospect of enhanced affinity of the extractant assembly for suitable metal ions. The results shown in Figure 5 provide clear evidence for the existence of a strong synergistic effect in all cases. The order of increasing extractability by the extractant assembly is  $\text{Ni}(\text{II}) > \text{Cu}(\text{II}) > \text{Co}(\text{II}) \sim \text{Zn}(\text{II})$ .

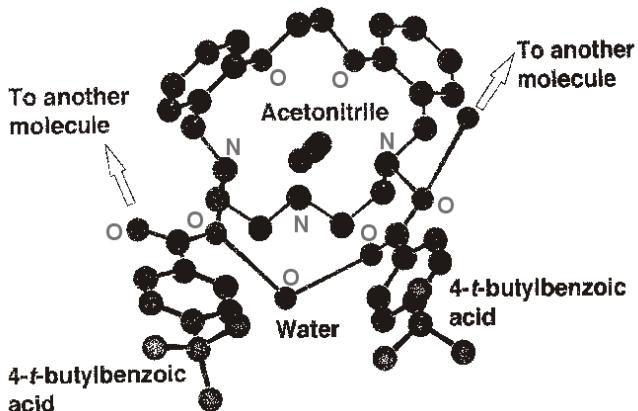

Figure 4. X-ray crystal structure of the supramolecular 2:1 assembly between **HR** and **L** ( $R = H$ ).

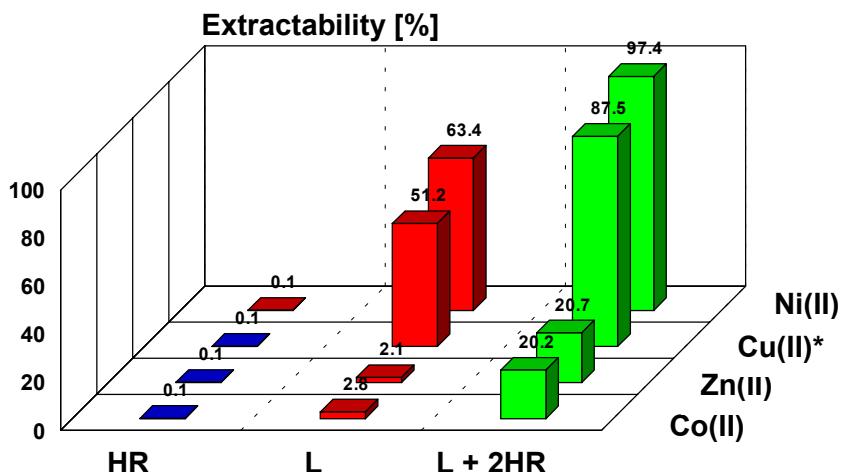

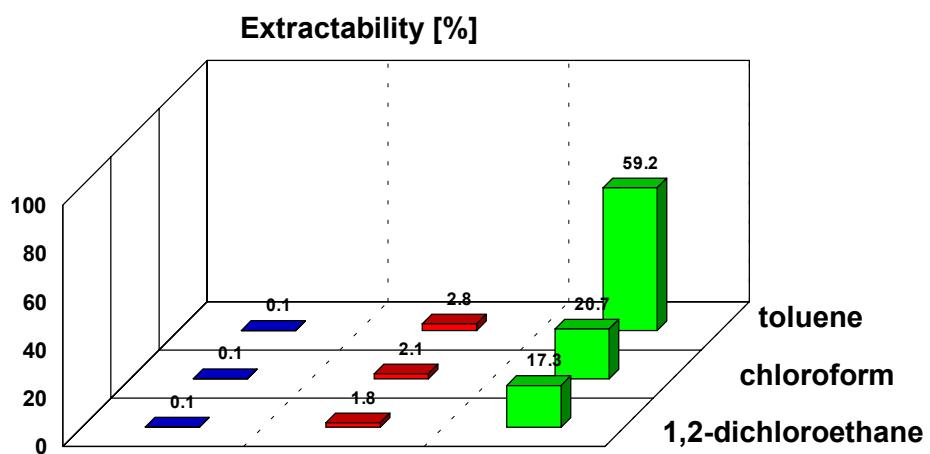

Figure 5. Influence of assembly effect on metal ion extraction by **HR/L** ( $R = C_9H_{19}$ ).  
 $[M(NO_3)_2] = 1 \cdot 10^{-4} M$ ; pH = 5.5 (MES/NaOH buffer);  $[NaNO_3] = 1 M$ ;  $[HR] = 2 \cdot 10^{-3} M$  and  
 $[L] = 1 \cdot 10^{-3} M$  in chloroform (\* without  $NaNO_3$ ).

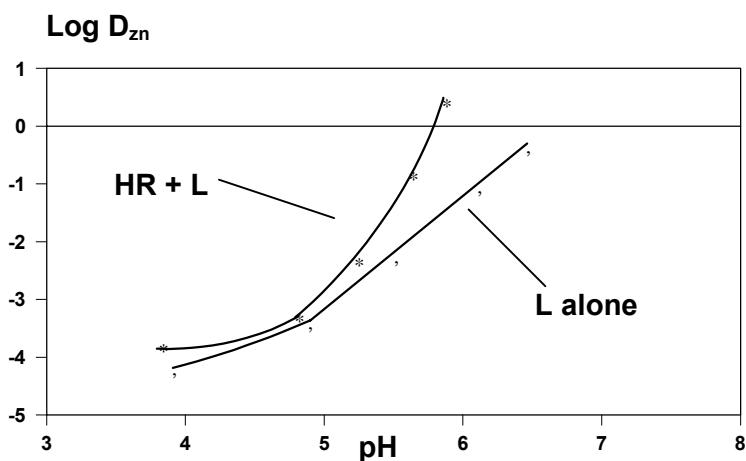

The graduation observed for Ni(II), Co(II) and Zn(II) is in a good agreement with the order of the stability constants obtained in methanol [16]. It is interesting to note that in competition extraction experiments a pronounced preference for Zn(II) over Co(II) has been observed although the single metal extraction data are comparable. Of the metal ions studied, the Ni(II) system was observed to be very slow to reach equilibrium; hence a shaking time for the Ni(II) case of 24 h was employed while for the other metal ion cases it was 30 min.

The influence of the diluent on the extractability of Zn(II) serves to illustrate the importance of weak interactions between the components in the extraction system. Employment of toluene yielded a significant improvement in extraction efficiency in contrast to the use of more polar chlorinated hydrocarbons (cf. Figure 6). Most likely the competitive formation of hydrogen bonding between the extractants and diluents is responsible for the decreased extraction efficiency in the latter cases.

As expected, the extraction equilibrium strongly depends on the pH of the aqueous phase. As shown in Figure 7, the synergistic effect of the extractant assembly is significantly enhanced at pH values higher than 5. The increasing slope of the curve in the Log  $D_{Zn}$  – pH diagram is obviously connected with the complicated pH-dependent behaviour of the species present in solution.

*Figure 6. Influence of diluents on the assembly effect for Zn(II) extraction.*  
 $[Zn(NO_3)_2] = 1 \cdot 10^{-4} M$ ;  $pH = 5.5$  (MES/NaOH buffer);  $[NaNO_3] = 1 M$ ;  $[HR] = 2 \cdot 10^{-3} M$  and  
 $[L] (R = C_9H_{19}) = 1 \cdot 10^{-3} M$  in different diluents.

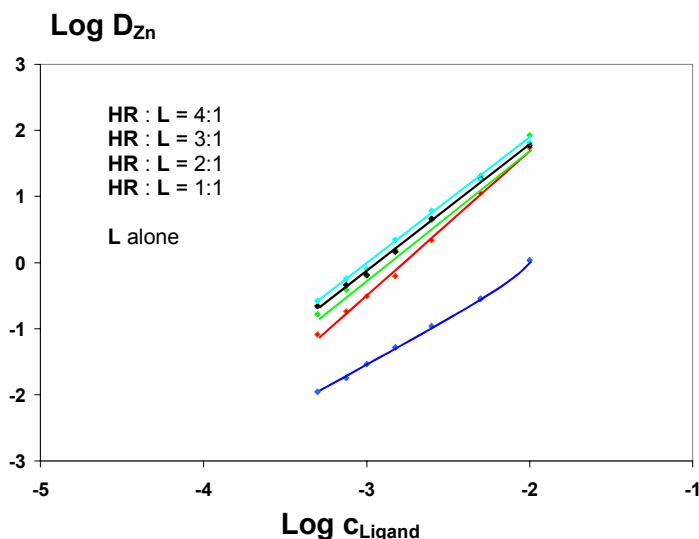

*Figure 7. Influence of pH on assembly effect for Zn(II) extraction.*  
 $[Zn(NO_3)_2] = 1 \cdot 10^{-4} M$ ;  $[NaNO_3] = 1 M$ ; pH variation with  $HNO_3$ ;  $[L] = 1 \cdot 10^{-3} M$  and  
 $[L](R = C_9H_{19}) = [HR] = 1 \cdot 10^{-3} M$  in chloroform.

In order to gain information about speciation, a series of experiments was performed involving Zn(II) extraction with the individual extractants alone and with them present in varying ratios. The extraction dependence on extractant concentrations is shown in Figure 8.

The results indicate apparent stoichiometries for the Zn(II) complexes extracted by **L** ( $R = C_9H_{19}$ ) alone of 1:1 and 2:1 ( $L:M$ ) [similar behaviour was also observed for Ni(II)]. The addition of **HR** to the organic phase results in an improvement in extraction efficiency and a change of speciation of the complexes formed. It is clear from Figure 8 that, for an extractant ratio **HR : L** of 1:1, extraction is very significantly increased. Further addition of **HR** to yield a **HR : L** ratio of 2:1 gives an additional slight rise, whereas for the 3:1 or 4:1 mixtures the extraction remains almost the same. The observance of an optimum synergistic effect for the 2:1 assembly is in clear agreement with the general ligand assembly effect postulate illustrated in Figure 2. Perhaps surprisingly, the slopes of the curves in the  $\log D_{zn}$ - $\log c_L$  diagram at constant **HR : L** ratios are in all cases about 2 and are significantly higher than for the macrocycle alone (slope about 1.5). A series of structural studies in both solution and the solid state on different metal complexes of azamacrocycles of the present type have shown a

considerable variation of coordination patterns occurs, the latter depending on a range of experimental factors [13, 16, 17]. As a consequence, in the absence of further data it appears inappropriate to speculate here about the architectures adopted by the metal complex species in the present systems. This aspect will be the subject of a future study.

**Figure 8.** Variation of  $\log D_{Zn}$  with ligand concentration at different  $HR : L$  ( $R = C_9H_{19}$ ) ratios for Zn(II) extraction.  $[Zn(NO_3)_2] = 1 \cdot 10^{-4} M$ ;  $[NaNO_3] = 1 M$ ;  $pH=5.5$  (MES/NaOH buffer);  $[L] = 5 \cdot 10^{-4} \dots 1 \cdot 10^{-2} M$  in chloroform.

## BETA-DIKETONE COPPER EXTRACTANTS: STRUCTURE AND STABILITY

Gary A. Kordosky, Michael J. Virnig and Phillip Mattison\*

Cognis Corporation, Tucson, United States of America

\*Cognis Corporation, Cincinnati, United States of America

The beta-diketone based reagent, LIX 54, has many outstanding properties for the extraction of copper from ammonia leach solutions. However, it has recently been found that the beta-diketone in LIX 54 reacts slowly with free ammonia in the presence of copper to form a ketimine product. The ketimine product results in a reduced rate of copper stripping, higher entrainment of aqueous in the loaded and stripped organic, and higher entrainment of organic in the pregnant strip electrolyte. Several new beta-diketone molecules were synthesized and their copper extraction properties as well as their resistance to ketimine formation were determined. These new beta-diketone molecules retain many of the outstanding properties of LIX 54 while the formation of ketimine is significantly reduced as the structure of the beta-diketone is altered in a systematic way.

### INTRODUCTION

The beta-diketone reagent, LIX 54, was introduced in 1975 as a reagent designed specifically for the extraction of metals from ammonia solutions [1]. The outstanding properties of this reagent when compared to the oxime copper extraction reagents include:

- High fluidity which allows the use of high reagent concentrations such that the organic phase in a continuous solvent extraction circuit can transfer up to ~ 32 g/l Cu.
- Low chemical loading of ammonia.
- Ease of stripping copper from the loaded copper organic phase, allowing the plant operator to tailor the acid and copper concentrations in the pregnant strip solution.

Over the years LIX 54 has been used in a number of small copper solvent extraction (SX) plants to extract copper from ammonia leach solutions, including spent etchant solutions from the circuit board industry [2] and ammonia leach solutions resulting from the leaching of lead dross [3]. For the most part, these plants are conservatively designed and the free ammonia in the leach solution is relatively low. Some plants have been in operation for over 15 years and feedback from the plant operators suggested that these plants were running relatively well.

During the development of the ammonia leaching process for Escondida copper concentrates, LIX 54 was run in the pilot-plant campaign and, from available reports, the small continuous solvent-extraction plant appeared to run well [4]. The Escondida commercial copper leach / SX / electrowinning plant at Coloso, Chile, was designed to produce a leach solution having about 32 to 35 g/l Cu, 40 g/l total ammonia at a pH of 9.5.

The commercial solvent extraction plant had a 2 extraction, 1 wash, 1 strip stage configuration with a three minute mixer retention in extraction and in strip. The organic phase was made up to a concentration that loaded about 32 g/l Cu.

## THE PROBLEM

When the Escondida plant at Coloso started up, the solvent extraction circuit operated very well for some period of time; entrainment was low and the stripping of the organic was efficient. Because the Coloso plant was on and off line as startup problems were encountered and solved, the behavior of the organic in the solvent extraction plant was not well documented during this time. After about 4 to 6 months of operation, it was noted that the stripping efficiency of the organic had decreased and entrainment had increased considerably, particularly entrainment of aqueous in the loaded and stripped organic, along with entrainment of organic in the pregnant strip solution. This, in turn, resulted in poor copper transfer efficiency, high ammonia consumption across the solvent extraction circuit and organic carryover to the tankhouse.

Both Cognis and Escondida made an effort to solve the problem by finding a simple method to regenerate clean circuit organic. Clay treatment, which is used successfully to treat many contaminated circuit organic solutions in typical acid leach copper solvent extraction circuits [5], was only partially effective in treating the Coloso circuit organic. Escondida developed an effective organic regeneration process consisting of contacting the circuit organic with a 600 to 900 g/l sulfuric acid solution followed by clay treatment of the acid-treated organic. Acid treatment caused formation of a viscous tarry third phase that entrained circuit organic and acid, creating a disposal problem. Cleaned organic performed well for only a short period of time before becoming contaminated again, meaning that any cleaning process had to be run continuously.

## IDENTIFICATION OF THE OFFENDING SPECIES

Infrared analysis showed that the circuit organic from the Coloso plant contained a small amount of ketimine functionality (Figure 1). Further work showed that ketimine was formed by the reaction of the beta-diketone extractant in LIX 54 with ammonia and, to add an ironic twist, the formation of ketimine takes place faster in the presence of copper than in the absence of copper.

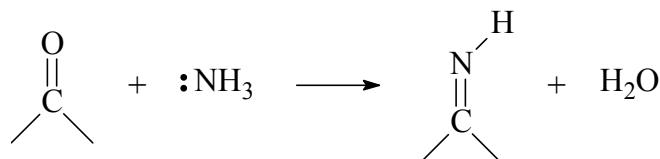

Figure 1. Ketimine formation.

High purity ketimine was produced by the reaction of the beta-diketone in LIX 54 with a concentrated solution of ammonia. This high purity ketimine was used to spike fresh LIX 54 solutions in diluent so that the properties of the LIX 54 solutions spiked with ketimine could be compared to the properties of fresh LIX 54 solutions having no ketimine and with the properties of the organic phase from the Coloso plant. A ketimine-spiked solution of LIX 54 showed the same problems as the organic phase from the solvent extraction plant at Coloso, but not to the same extent as seen in the plant. Thus it appeared that the ketimine was indeed part of the problem, but perhaps not the only problem.

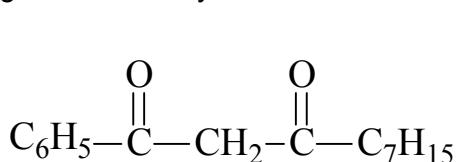

A series of simple spiking tests showed that many of the reagents used in the upstream processing of the ore or in other parts of the plant interacted with ketimine-spiked LIX 54 to give much slower copper stripping kinetics and much higher entrainment than ketimine by itself. Additionally it was shown conclusively that the presence of ketimine in the circuit organic caused the clay treatment process to be less effective than it normally is.

At this time the decision was made to develop an alternative to the beta-diketone extractant in LIX 54 with the goal being the development of an extractant that would retain all the good properties of LIX 54, but, would not form ketimine under the existing circuit conditions.

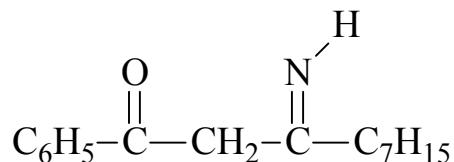

### ALTERNATIVE MOLECULES

Because the active extractant in LIX 54 (Figure 2) has two carbon-oxygen double bonds that could react with ammonia to form ketimine, it was reasoned that the first step of the process to develop an alternative to the beta-diketone in LIX 54 was to determine the structure of any and all ketamines in the circuit organic. Somewhat to Cognis' surprise, the ketamine shown in Figure 3 was the only ketamine found in the circuit organic.

Organic chemistry tells us that the most likely direction from which ammonia attacks a

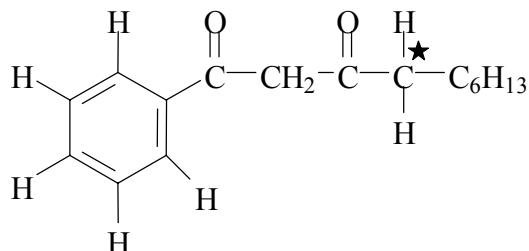

*Figure 2. Active extractant in LIX 54.*

*Figure 3. Only ketimine formed by LIX 54.*

carbon-oxygen double bond is at the carbonyl carbon. A careful look at the structure of the beta-diketone in LIX 54 (Figure 4) shows that the carbonyl carbon which forms the ketimine is not particularly sterically hindered since there are two small hydrogen atoms bonded to  $\text{C}^*$  in addition to one larger C atom.

*Figure 4. Active extractant in LIX 54.*

It was then reasoned that one way to decrease or even prevent formation of the offending ketimine was to synthesize beta-diketones that had greater steric hindrance around the reactive carbonyl carbon. It is known from organic chemistry that one way to increase steric hindrance around a carbonyl carbon is to increase the bulk around the carbon (shown as  $\text{C}^*$ ) next to the reactive carbonyl carbon. One way to increase the bulk around  $\text{C}^*$  is to increase the number of carbons and decrease the number of hydrogens bonded to  $\text{C}^*$ .

To test the reasoning, three alternative beta-diketone molecules were synthesized: XI-55, XI-N54 and XI-57 shown in Figures 5, 6 and 7, respectively.

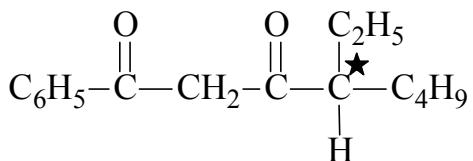

Figure 5. Active extractant in XI-55.

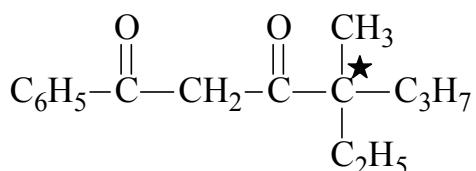

Figure 6. Active extractant in XI-N54.

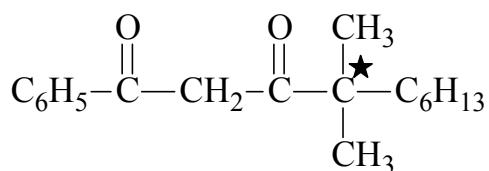

Figure 7. Active extractant in XI-57.

Note that while the basic molecular structure of the beta-diketone in LIX 54 has been retained in each of the new betadiketones, there is a systematic change in the structure of the new beta-diketones at C<sup>\*</sup> when compared to the beta-diketone in LIX 54. The betadiketone in LIX 54 has two hydrogens and one carbon bonded to C<sup>\*</sup>, in XI-55 there is one hydrogen and two carbons bonded to C<sup>\*</sup> and in both XI-N54 and XI-57 there are three carbons bonded to C<sup>\*</sup>.

## TESTING OF NEW MOLECULES

### Extraction

The three new molecules were synthesized and purified to give low viscosity light yellow liquids. The three new molecules were formulated in Conoco 170E at a level sufficient to load about 30 g/l Cu and then run through performance tests along with LIX 54-100. In the first test, 25 ml of the respective organic phase was vigorously contacted for two minutes with 25 ml of a standard synthetic leach solution containing 30 g/l Cu, 30 g/l NH<sub>3</sub> and 30 g/l ammonium sulfate. After the phases separated, the organic phase was filtered and analyzed for copper by atomic absorption spectrophotometry (AA) and for ammonia content using a Cognis method [6]. A portion of the organic phase was contacted vigorously two more times with fresh synthetic leach solution twice for two minutes each contact, then filtered and analyzed to give a copper maximum load.

A second sample of XI-57 was vigorously contacted with a synthetic stability leach solution containing 30 g/l Cu, 44 g/l NH<sub>3</sub> and 20 g/l ammonium sulfate in a round bottom flask fitted with a stirring rod and paddle for one week at 45 °C. This sample of "aged XI-57" was stripped with sulfuric acid until no copper was present on the organic phase and then taken through the same set of experiments as described directly above. The results of this series of copper and ammonia loading tests are shown in Table 1.

Table 1. Copper and ammonia loading for various beta-diketones.

	LIX 54	XI-55	Neo-54	XI-57	XI-57 Aged
Max load (g/l Cu)	30.0	27.8	27.3	30.2	26.8
One contact (g/l Cu)	23.5	22.4	20.8	21.3	19.7
Max load (%)	78	81	76	71	74
NH <sub>3</sub> loading (g/l)	0.32	0.28	0.13	0.094	0.10

The new beta-diketones retain the very good fluidity of LIX 54. Both XI-55 and neo-54 have about the same extractive strength as LIX 54 as shown by the % copper max loading after one contact with a synthetic standard leach solution, while XI-57 appears to be a slightly weaker extractant than LIX 54. Ammonia loading on the new beta-diketones is less than the ammonia loading on LIX 54, in the case of Neo-54 and XI-57 less than 1/2. These new beta-diketones appear to retain the very good properties of LIX 54.

### Ketimine Formation

The various beta-diketones were then tested for ketimine formation using an accelerated ketimine formation test. A 0.95 molar solution of the respective beta-diketone in the diluent Conoco 170E was vigorously contacted for six days at 45 °C with the synthetic stability leach solution containing 30 g/l Cu, 44 g/l NH<sub>3</sub> and 20 g/l ammonium sulfate. After the test was completed, the organic phase was stripped of the loaded copper by vigorous contact with an aqueous solution of 150 g/l sulfuric acid until the respective organic phase was light yellow in color indicating that all the copper had been stripped. The organic phase was then washed twice with water and filtered. The ketimine content of the organic phase was determined by gas chromatography with a detection limit of 0.01%. The results are given in Table 2.

*Table 2. Ketimine formation of various beta-diketones.*

Beta-diketone	Ketimine content by weight
LIX 54	0.98%
XI-55	None detected
XI-N54	None detected

Neither XI-55 nor XI-N54 form ketimine under conditions where LIX 54 shows significant ketimine formation.

### Stripping Kinetics

Stripping kinetics were determined for fresh and aged samples of the respective beta-diketones. A sample of the respective organic phase was vigorously contacted one time at an O/A = 1 with the standard synthetic leach solution for two minutes. Within a few minutes after the phases had separated, 100 ml of the copper loaded organic phase was added to a 2.25 inch square box and stirred at 1750 rpm with a slotted impeller 1.25 inches in diameter. Then 100 ml of an aqueous solution containing 35 g/l Cu and 150 g/l sulfuric acid was added over 5 seconds. Samples of the dispersion were removed at specified times, the organic phase for each sample analyzed for copper and stripping kinetics calculated. Under these conditions, all fresh beta-diketones strip almost completely in 30 seconds. Stripping kinetics for aged and aged then clay treated beta-diketones are given in Table 3.

*Table 3. Percent copper stripping for various aged beta-diketones.*

Time (s)	LIX 54-100		XI-55		XI-N54	XI-57
	Aged	Clay treated*	Aged	Clay treated**	Aged	Aged
30	41%	95%	70%	98%	100%	92%
60		100%		100%		100%
120			96%			
180	98%					

\* Clay treatment is with 3 g clay / 100 ml of aged organic phase.

\*\* Clay treatment is with 1 g clay / 100 ml of aged organic phase.

LIX 54 stripping kinetics are unique. A LIX 54 solution loaded with copper from an ammonia solution will show slower strip kinetics the longer the solution stands before being stripped. If LIX 54 after being stripped is reloaded with copper from ammonia and then stripped immediately, the strip kinetics are very rapid. Interestingly, if the loaded LIX 54 is washed with phthalate buffer solution to remove ammonia, the strip kinetics do not slow with time.

When the new more hindered beta-diketones are loaded with copper and allowed to stand for a long period of time, the stripping kinetics are rapid even when ammonia is not scrubbed from the loaded organic. The authors have no explanation why the strip kinetics of LIX 54 slow with time when a small amount of co-loaded ammonia remains on the organic phase.

It is known that stripping kinetics are slowed by the presence of ketimine. Aged LIX 54 shows a dramatic slowing of copper strip kinetics that can be reversed with a heavy clay treatment. Aged XI-55 shows some slowing of stripping kinetics that can be reversed with a light clay treatment, while aged XI-N54 and XI-57 both show rapid strip kinetics. This suggests that XI-55 may form a very small amount of ketimine or some other species that retards copper stripping, but that XI-N54 and XI-57 do not.

### **Long-Term Continuous Circuit Testing**

A sample of XI-57 was compared to LIX 54-100 in a small continuous SX mini-plant treating a leach solution from the Coloso ammonia leach plant under conditions similar to those in the Coloso SX plant. Within several weeks after start up, the LIX 54 in the mini-plant began to show slower stripping kinetics and increased transfer of ammonia to the wash stage. After three months in the mini-plant, the XI-57 retained fast copper stripping kinetics and ammonia transfer to the wash stage was less than 25% of the ammonia transfer shown by LIX 54. Infrared analysis of the XI-57 that had been in the mini-plant for three months did not detect the presence of ketimine. The results of the long-term continuous circuit testing were consistent with the previous tests. XI-57 did not appear to form ketimine under conditions where LIX 54 forms ketimine, ammonia transfer was much less than with LIX 54, copper stripping kinetics remain rapid and XI-57 was shown to be a slightly weaker copper extractant than LIX 54.

## **CONCLUSION**

The goal of synthesizing beta-diketones that resist ketimine formation while still retaining the very good properties of LIX 54 was achieved by applying well-known organic chemistry principals relating chemical structure to reactivity. The new more hindered beta-diketones do not form ketimine under conditions where the less hindered beta-diketone in LIX 54 readily forms ketimine. A reagent based on the structure of either XI-N54 or XI-57 should be an excellent extractant for copper from ammonia.

## SOLVENT EXTRACTION OF IRON(III) FROM HYDROCHLORIC ACID SOLUTIONS BY DIHEXYL SULPHOXIDE

Taichi Sato\*, Izumi Ishikawa, Keiichi Sato and Yoshitomo Noguchi

Faculty of Engineering, Shizuoka University, Hamamatsu, Japan

\* Also at Queen's University, Metallurgical Engineering Department, Kingston, Ontario, Canada

The extraction of iron(III) from aqueous solutions containing hydrochloric acid and/or lithium chloride has been carried out using dihexyl sulphoxide (DHSO, R<sub>2</sub>SO) in benzene. The organic extracts were examined by infrared and ultraviolet spectroscopies. As a result, it was found that the distribution coefficient rises with increasing chloride ion concentration in the aqueous solution, and that the extraction equilibrium of iron(III) from hydrochloric acid solutions by DHSO can be expressed as:

### INTRODUCTION

As the presence of a sulphur atom facilitates the combination of extractants with class b metal ions, sulphur-containing compounds have been used as solvent extractants for various valuable metals. In particular, it has been found that dialkyl-sulphides and -sulphoxides are effective extractants for silver and mercury [1-4]. The present authors have therefore examined the extraction of silver(I) and mercury(II) by dihexyl sulphide (DHS, R<sub>2</sub>S) [5,6], and the extraction of mercury(II) by dihexyl sulphoxide (DHSO, R<sub>2</sub>SO) [6]. However, since DHSO contains an oxygen atom in addition to a sulphur one, it is expected that the extractability of metals by DHSO should be generally more effective than that by DHS. Accordingly, when DHSO is used as an extractant for a metal such as mercury, it is an important problem to separate the valuable metal from iron(III). Thus this study extends the work to obtain further information on the extraction of iron(III) from hydrochloric acid solutions by DHSO in order to compare with the results for the extraction of mercury [6].

### EXPERIMENTAL

The DHSO was synthesized by means of oxidation from DHS (Daihachi Chem. Ind. Co., Ltd.) [7]: 35 cm<sup>3</sup> each of acetic acid and acetic anhydride and 20 cm<sup>3</sup> of a 30% aqueous solution of hydrogen peroxide were added to 50 cm<sup>3</sup> of DHS drop-wise during 1 h; the mixture was cooled with ice and then stirred for 3 h at 273 K. After the completion of the reaction was confirmed by TLC, the DHSO was extracted into chloroform and washed first with water, then with 10 % sodium carbonate, and finally with water again. The white crystals obtained after the removal of chloroform by evaporation were purified by recrystallization.

Aqueous solutions of iron were prepared by dissolving ferric chloride (FeCl<sub>3</sub>.6H<sub>2</sub>O) in hydrochloric acid of selected concentration. In general, the concentration of the metal salt was 1 g dm<sup>-3</sup> except for the loading tests. All chemicals were of analytical reagent grade.

Equal volumes (15 cm<sup>3</sup> each) of organic and aqueous phases were placed in a 50 cm<sup>3</sup> stoppered conical flask and shaken for a selected time in the thermostatic water bath at 293 K, except for the experiment on temperature effect. Preliminary experiments showed that equilibrium was complete in 10 min. The mixture was quickly separated by centrifugation, and then both phases were assayed to determine the distribution coefficient ( $E_a^{\circ}$ , the ratio of the equilibrium concentration of metal in the organic phase to that in the aqueous phase). Iron in the organic phase was stripped with 1 mol dm<sup>-3</sup> hydrochloric acid. The concentration of iron in aqueous solution was determined by EDTA titration using xylenol orange (XO) as the indicator. The chloride concentration and the water content in the organic phase were determined by the use of Volhardt's method and Karl Fischer titration, respectively.

The infrared (IR) spectra of the organic extracts were determined on JASCO models IRA-1 (4000-650 cm<sup>-1</sup>) and IR-F (700-200 cm<sup>-1</sup>) using a capillary film between thallium halides or polyethylene films. The ultraviolet (UV) absorption spectra were recorded on a Hitachi model 340 spectrophotometer using 1.0 x 1.0 cm fused silica cells.

## RESULTS AND DISCUSSION

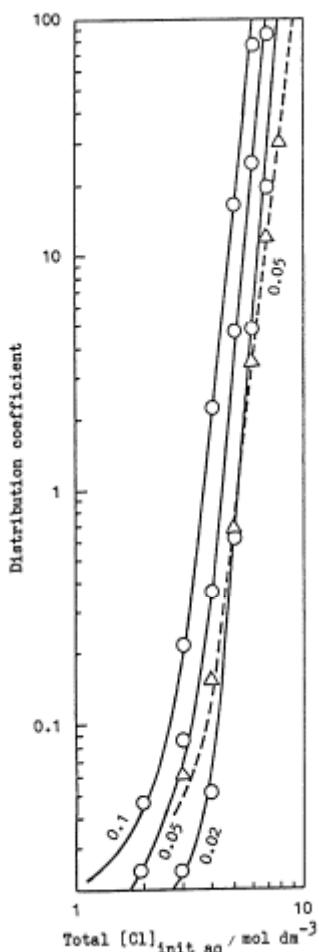

### Extraction Isotherms

The extraction of iron(III) from hydrochloric acid solutions by DHSO was carried out by varying the aqueous acidity. The distribution coefficient rose sharply with increasing initial concentration of hydrochloric acid as shown in Figure 1. When hydrochloric acid in the aqueous phase was replaced by lithium chloride, the extraction behaviour of iron(III) resembled that from hydrochloric acid solutions alone.

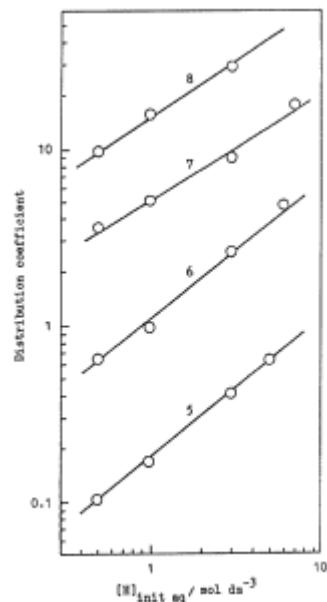

The log-log plots of  $E_a^{\circ}$  vs.  $[R_2SO]_{eq} = [R_2SO]_{init} - 2[Fe]_{org}$  at a constant hydrochloric acid concentration gave straight lines with the following slopes: 2.08, 1.80 and 1.75 at 4, 5 and 6 mol dm<sup>-3</sup> HCl, respectively, and 1.94, 1.82, 1.75 and 1.76 at 0.1 mol dm<sup>-3</sup> HCl + LiCl (of 5, 6, 7 and 8 mol dm<sup>-3</sup>), respectively. These results show that the dependence of distribution coefficient on the DHSO concentration is second-power at constant aqueous acidity.

In the extraction of iron(III) from hydrochloric acid solutions by DHSO, the continuous variation of  $[Fe]_{org}$  plotted as a function of mole fraction  $[Fe]_{init\ aq}/([Fe]_{init\ aq} + [R_2SO]_{init})$  at a fixed total concentration of  $[Fe]_{init\ aq} + [R_2SO]_{init} = 0.04$  mol dm<sup>-3</sup>, at 6 mol dm<sup>-3</sup> HCl and at 0.2 mol dm<sup>-3</sup> HCl + 5.8 mol dm<sup>-3</sup> LiCl gave a maximum of 0.33. This shows that the combination of DHSO with iron is in the molar ratio of 2:1 depending on aqueous acidity. However, since the distribution coefficient from acid alone is higher than that from a mixture of hydrochloric acid and lithium chloride, the effect of proton concentration on the distribution coefficient has been examined [6]. When the initial hydrochloric acid concentration was varied at a constant chloride concentration in the aqueous phase ( $[Cl]_{init\ aq} = [HCl]_{init\ aq} + [LiCl]_{init\ aq}$ ), the distribution coefficient increased linearly with increasing the proton concentration in aqueous phase as indicated in Figure 2. The slopes ( $\partial \log E_a^{\circ} / \partial \log [H]_{init\ aq}$ ) were 0.80, 0.78, 0.64 and 0.66 at the total  $[Cl]_{init\ aq}$  of 5, 6, 7 and 8 mol dm<sup>-3</sup>, respectively, with 0.02 mol dm<sup>-3</sup> DHSO. It is thus presumed that the dependence of distribution coefficient on the proton concentration in aqueous phase is the first-power. Besides, the loading test of iron in the organic phase indicated the stoichiometry of the extracted species. With increasing the initial aqueous iron concentration at 6 mol dm<sup>-3</sup> HCl, the molar ratio  $[Fe] / [Cl] / [R_2SO] / [H_2O]$  in the organic phase approaches 1:4:2:0, exhibiting the composition  $FeCl_3 \cdot HCl \cdot 2R_2SO$  (as  $HFeCl_4 \cdot 2R_2SO$ ).

Hence the following equilibrium equation is inferred for the extraction of iron(III) from hydrochloric acid solutions by DHSO:

*Figure 1. Extraction of iron(III) from HCl solutions by DHSO in benzene. The numerals on the curves are DHSO concentrations in  $\text{mol dm}^{-3}$ . Solid and broken lines represent the extraction from HCl solutions and mixed  $0.1 \text{ mol dm}^{-3}$  HCl / LiCl solutions, respectively.*

*Figure 2. Dependence of distribution coefficient on aqueous proton concentration for the extraction of iron(III) from mixed solutions of HCl and LiCl with  $0.02 \text{ mol dm}^{-3}$  DHSO in benzene (numerals on the lines are total  $[\text{Cl}]_{\text{init aq}}$  ( $= [\text{HCl}]_{\text{init aq}} + \text{LiCl}_{\text{init aq}}$ ) /  $\text{mol dm}^{-3}$ ).*

### IR and UV Spectra

The organic extracts with  $0.2 \text{ mol dm}^{-3}$  DHSO in benzene, from aqueous solutions containing ferric chloride of  $2$ ,  $5$  and  $20 \text{ g dm}^{-3}$  at  $0.2 \text{ mol dm}^{-3}$   $\text{HCl} + 5.8 \text{ mol dm}^{-3}$   $\text{LiCl}$ , were examined by IR spectroscopy. The IR spectra of the organic extracts exhibit the absorption due to the  $\text{S=O}$  stretching vibration at  $990 \text{ cm}^{-1}$ , shifted from the band which appears at  $1050 \text{ cm}^{-1}$  in a free DHSO [6]. With increasing metal concentration, its absorption band increases in intensity, and in addition the  $\text{Fe-Cl}$  stretching frequency appears at  $378 \text{ cm}^{-1}$ .

The UV spectra of the organic extracts were examined in the extraction with  $0.1 \text{ mol dm}^{-3}$  DHSO in cyclohexane from aqueous solutions containing ferric chloride of  $0.02 \text{ g dm}^{-3}$  in hydrochloric acid. In the spectra of aqueous ferric chloride solutions in hydrochloric acid, the

absorption at 335 nm appears in 2-4 mol dm<sup>-3</sup> HCl, and then the absorption bands at 245, 316 and 364 nm appear gradually with increasing the acid concentration in 5-9 mol dm<sup>-3</sup> HCl. According to Metzler *et al.* [8], the absorptions at 245, 316 and 365 nm are due to FeCl<sub>4</sub><sup>-</sup>. This is supported by the reports that the dominant species of ferric chloride is FeCl<sub>4</sub><sup>-</sup> [9,10]. In contrast, as shown in Figure 3, the spectra of the organic extracts show the absorption bands at 316 and 364 nm similar to the pattern of the aqueous ferric chloride solutions in 5-9 mol dm<sup>-3</sup> HCl. We have also observed that the absorptions at 245, 314 and, 364 nm due to the species FeCl<sub>4</sub><sup>-</sup> for the organic extracts from hydrochloric acid solutions at higher acidities by an  $\alpha$ -hydroxyoxime [11]. Accordingly, it is inferred that the organic extracts from aqueous solutions containing ferric chloride in hydrochloric acid exist as the stoichiometric composition of HFeCl<sub>4</sub>.2R<sub>2</sub>SO.

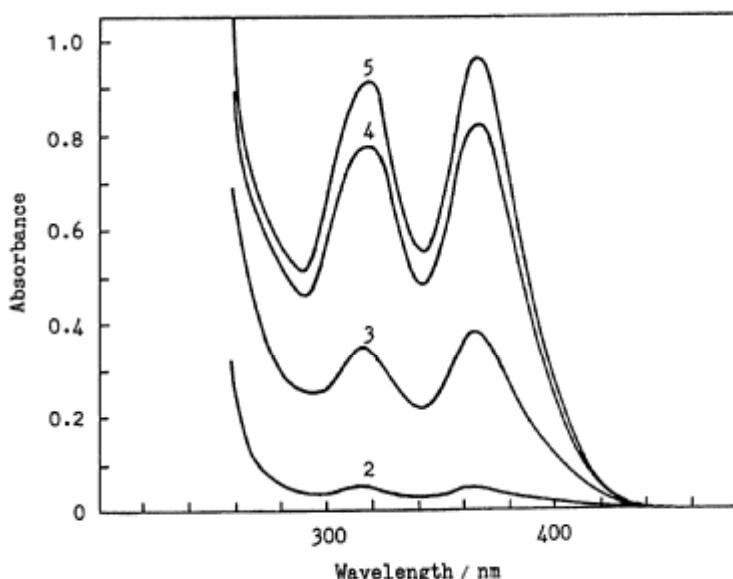

Figure 3. Absorption spectra of the organic extracts with 0.1 mol dm<sup>-3</sup> DHSO in cyclohexane from aqueous solutions containing ferric chloride 0.02 g dm<sup>-3</sup> in hydrochloric acid (numerals on curves are initial HCl concentrations / mol dm<sup>-3</sup>).

Table 1. Temperature-dependence of distribution coefficient for the extraction of iron(III) from 4 and 6 mol dm<sup>-3</sup> hydrochloric acid solutions with DHSO in benzene.

[HCl] init ag /mol dm <sup>-3</sup>	[DHSO] /mol dm <sup>-3</sup>	E <sub>a</sub> <sup>o</sup>				
		283K	293K	303 K	313 K	323K
4	0.05	0.422	0.360	0.345	0.321	0.287
6	0.02	5.02	4.55	4.36	4.16	3.40

### Temperature Effect

The extraction of iron(III) from 4 and 6 mol dm<sup>-3</sup> hydrochloric acid solutions with 0.05 and 0.02 mol dm<sup>-3</sup> DHSO in benzene, respectively, was carried out at temperatures between 283 and 323 K. The results showed that the distribution coefficient decreases with rising temperature. From this, the values of heat of reaction (change of enthalpy,  $-\Delta H$ ) in Eq. (1) were estimated as 9.19 and 14.7 kJ mol<sup>-1</sup>, respectively. When the heat of reaction for DHSO (hard base) with iron (hard acid) is compared to that for DHSO (hard base) with mercury (soft acid), estimated as 35.2 kJ mol<sup>-1</sup> [6], the former value is expected to be smaller than the latter one.

## CONCLUSION

The extraction of iron(III) from hydrochloric acid solutions by DHSO has been examined under different conditions. As a result, it is seen that the extraction of iron(III) involves the solvating reaction according to:

In comparison with the results for the extraction of mercury(II) [6], since the extraction from hydrochloric acid solutions by DHSO for mercury (II) is effective at low aqueous acidity more than that for iron(III), the separation of mercury(II) from iron(III) is preferably carried out at below  $2 \text{ mol dm}^{-3}$  HCl .

## SOLVENT EXTRACTION OF IRON(III) FROM HYDROCHLORIC ACID SOLUTIONS USING N,N'-DIMETHYL-N,N'-DIPHENYLMALONAMIDE

M. C. Costa and A. P. Paiva\*

This work is focused on the ability of N,N'-dimethyl-N,N'-diphenylmalonamide to extract iron(III). The results have shown that iron(III) can be efficiently and selectively extracted from hydrochloric acid solutions. The effect of variables including acidity and chloride concentration of the aqueous phases, as well as the influence of the diluent, is researched and discussed. The analysis of the aqueous solutions after contact with the organic phase showed that iron(III) was quantitatively extracted from HCl solutions between 0 to 12 M, maintaining the total chloride concentration with LiCl at 12 M. Regarding selectivity studies, the extraction of other metals such as Cu(II), Zn(II) and In(III), usually present in typical pregnant leaching solutions, was also investigated. Significant selectivity over these metals can be achieved, since no extraction other than iron(III) was detected. Preliminary assays of the stripping of iron(III) from the organic phase to a purified aqueous medium showed that iron(III) can be partially recovered. The overall results obtained for this malonamide derivative are generally compared, in terms of extraction and stripping properties, with the behaviour of N,N'-dimethyl-N,N'-diphenyltetradecylmalonamide, the subject of previous studies.

### INTRODUCTION

The extractive properties of diamides were clearly demonstrated by Musikas and co-workers [1,2], who developed studies concerning their utilisation in the nuclear processing industry as solvent extraction agents. Therefore, N,N'-tetraalkylmalonamides were considered important alternatives to the organophosphorus compounds - e.g., tributylphosphate (TBP) - because they efficiently extract trivalent, tetravalent and hexavalent actinides and lanthanides from nitric acid medium [3,4] and because of their environmental advantages [5]. The ability of malonamides to extract polyvalent metals can be explained by the weak basic nature of the amide carbonyl group [4,6]. In the last decade considerable effort on the development of different molecular structures has been made with the aim of optimising the extractive performances of malonamides for the nuclear industry metals. Thus, the synthesis of different structures is being stimulated since the nature of the N-substituents in diamides greatly affects the distribution ratios of several actinides and lanthanides [7,8]. In fact, the selection of the substituents on the nitrogen atoms (R and R') is very important to facilitate metal-ion co-ordination and to allow the solubility of the diamide and its adducts in the organic phase. In order to attain both objectives, R and R' should have different sizes. If R is a small group (typically methyl) and R' a bigger one, both criteria are satisfied: the stereochemical hindrance around the carbonyl oxygen atoms is kept to a minimum and both oxygen atoms can co-ordinate to a metal ion [8] and the lipophilic character of the ligands is attained by the presence of a higher chain - alkyl or aryl groups - at R'. In order to increase the solubility of the diamide in the organic solvent (and thus of the metallic complexes) one of the methylenic hydrogen atoms can be substituted by an alkyl group [9].

N,N'-dimethyl-N,N'-diphenylmalonamide (DMDPHMA), whose structure is presented in Figure 1, was chosen for this research. In this molecule the aforementioned criteria for the selection of R and R' are satisfied.

*Figure 1. General structure of DMDPHMA.*

The phenyl groups, bonded to the nitrogen atoms, act as electron acceptors, thus giving the molecular structure a less basic character. These phenyl rings affect the extractive properties of DMDPHMA for the extraction of metallic nitrates from highly concentrated nitric media [10], as the competition between metallic complexes and the acid for the diamide is reduced.

Previous studies using substituted diamides have shown that these compounds can also be successfully used for the extraction of Fe(III) from hydrochloric acid medium [11,12]. The selectivity exhibited over some basic metals is a very promising result that led to this research.

## EXPERIMENTAL

### Synthesis of DMDPHMA

N,N'-dimethyl-N,N'-diphenylmalonamide was synthesised by reaction of methylaniline and dimethylmalonate: methylaniline (222 g, 2.051 mol) was mixed with dimethyl malonate (137 g, 0.99 mol) and then heated at 180 °C for 3 h. After distillation the mixture still reacted for 1 h. A white solid formed on cooling. The product was washed with diethyl ether and recrystallised from ethyl acetate to give pure DMDPHMA. The synthesised compound (26% overall yield) was characterised by melting point and elemental analysis (CE Instruments EA 1110 CHNS-O) (Table 1), and by spectroscopic techniques such as mass spectroscopy and <sup>1</sup>H NMR. For mass spectroscopy Trio 1000 equipment was used. The <sup>1</sup>H (300 MHz) NMR spectrum was obtained with a Bruker AMX-300 spectrometer using CDCl<sub>3</sub> as solvent and TMS as the standard. Mass spectroscopy and <sup>1</sup>H NMR data are presented in Tables 2 and 3, respectively.

*Table 1. Melting point and elemental analysis for DMDPHMA.*

Melting point Literature [8] This work	(°C)		
	105-106	107-108	
Elemental analysis Theoretical Experimental	C (%)	H (%)	N (%)
	72.3	6.4	9.9
	72.3	6.6	9.4

*Table 2. Proton NMR assignments for DMDPHMA.*

Molecular structure	$^1\text{H}$ NMR
	$^1\text{H}$ NMR assignments: 3.0 (2 H, s, a) 3.2 (6 H, s,b) 7.0-7.1 (4 H, d, c) 7.3-7.4 (6 H, t, d)

s – singlet, d – doublet, t – triplet

$^1\text{H}$  NMR data are in agreement with previous reported results [8].

*Table 3. Mass spectroscopy data for DMDPHMA.*

Molecular peak: $\text{C}_{17}\text{H}_{18}\text{N}_2\text{O}_2 \cdot \ddagger = 282$ (48%)
$\text{C}_{10}\text{H}_{10}\text{NO}_2 \cdot \ddagger = 176$ (23%)
$\text{C}_9\text{H}_{10}\text{NO} \cdot \ddagger = 148$ (37%)
$\text{C}_8\text{H}_8\text{NO} \cdot \ddagger = 134$ (83%)
$\text{C}_7\text{H}_8\text{N} \cdot \ddagger = 106$ (100%)
$\text{C}_6\text{H}_5 \cdot \ddagger = 77$ (91%)

The obtained spectrum is in accordance with the expected fragmentation of the molecule.

### Solvent Extraction Experiments

Extraction experiments were performed by shaking the aqueous and the organic phases for 15 minutes at a constant speed (1000 rpm), at a temperature of 25 °C, with a ratio of 1 between the two phases. DMDPHMA solutions (~0.1 M and ~0.01 M) in toluene,  $\text{CCl}_4$  or 1,2-dichloroethane were used as the organic phases. Hydrochloric acid solutions (1, 3, 4, 5, 6, 7, 8, 10 and 12 M) and metal feed solutions with ~0.01 M iron(III) in HCl (prepared by dissolving iron(III) chloride hexahydrate) were used as aqueous phases. Solutions containing ~0.01 M of other metals (copper(II) and indium(III)) as chloride salts were also used. In some metal solutions the total chloride concentration was maintained at 12 M by adding LiCl. The metal content in the aqueous phases was analysed before and after extraction by flame atomic absorption spectroscopy (Shimatzu AA 680), using three aliquots of each sample. The values obtained were treated and only accepted if a reasonable standard deviation were obtained. In all cases three sets of experiments were performed in order to confirm the data obtained. The aqueous and the loaded organic phases were analysed by UV-visible spectroscopy (Shimatzu UV 160).

Stripping experiments were conducted by contact with the loaded organic phase with distilled water or diluted HCl solution (~0.4 M) using the same conditions as for extraction.

All chemicals and reagents used were of analytical reagent grade.

## RESULTS AND DISCUSSION

### Extraction of Iron(III)

The ability of DMDPHMA to extract iron(III) from hydrochloric acid solutions was studied. The results obtained are presented in Figure 2. Iron(III) extraction increases as the hydrochloric acid concentration increases. For  $C_{\text{HCl}} \geq 7 \text{ M}$  metal extraction is higher than 90%, while only 25% was achieved from  $C_{\text{HCl}} = 5 \text{ M}$ . For  $C_{\text{HCl}} \leq 3 \text{ M}$  metal extraction is lower than 2%. Thus, it is possible to conclude that the extraction of iron(III) depends on the hydrochloric acid concentration.

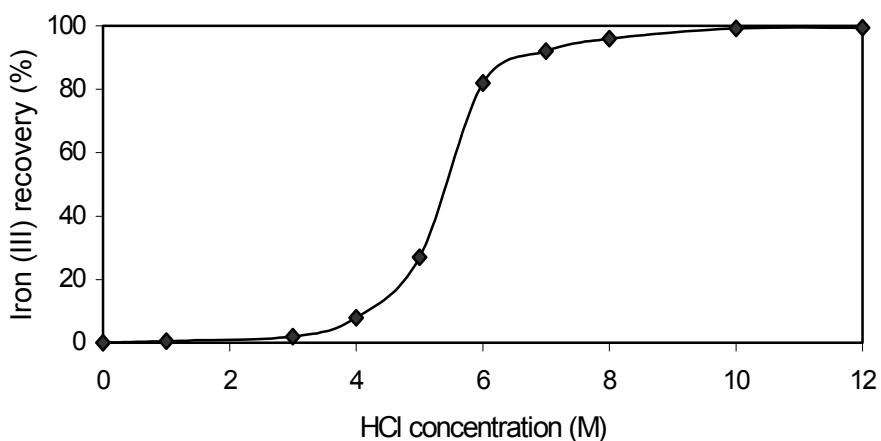

Figure 2. Iron(III) extraction with DMDPHMA from HCl solutions.

The use of different diluents such as  $\text{CCl}_4$  and 1,2-dichloroethane does not significantly affect the extraction of iron(III): 5-6% was achieved for  $C_{\text{HCl}} \leq 3 \text{ M}$ , when each of the alternative diluents were used.

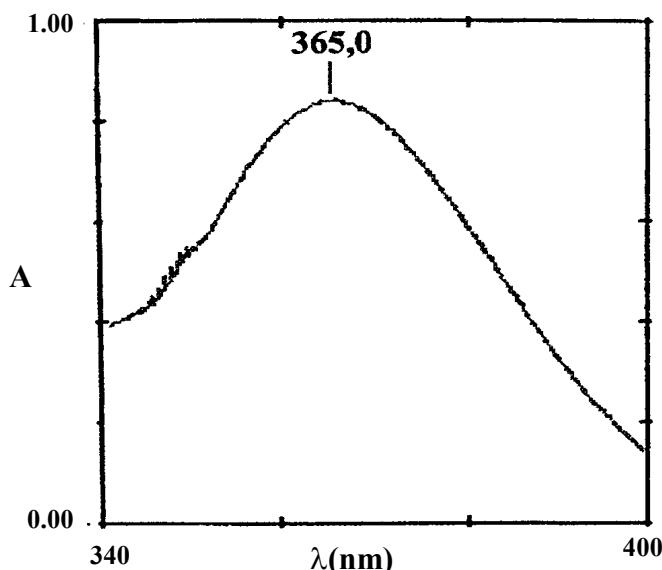

Similar extraction behaviour was obtained for analogous experimental conditions with the corresponding alkylated malonamide ( $\text{N,N}'\text{-dimethyl-N,N}'\text{-diphenyltetradecylmalonamide}$ , DMDPHTDMA) [13].

The results of iron(III) extraction with DMDPHMA (~0.1 M) from HCl solutions from 0 to 12 M, with 12 M of total chloride concentration achieved by adding LiCl, show a quite different extraction profile: in these cases iron(III) is totally removed, regardless of the acid concentration. Even in solutions containing only LiCl (12 M), the metal is also completely extracted. When the concentration of the extractant is decreased (~0.01 M), the extraction of iron is almost unaffected, and therefore, the metal is still removed with an efficiency higher than 90%.

Studies with the alkylated malonamide (DMDPHTDMA) showed different extraction behaviour: no extraction was detected for  $C_{\text{HCl}} < 4 \text{ M}$ , while for higher acid concentrations the metal was completely removed [11,12]. This suggests that alkylated and the non-alkylated malonamides extract iron(III) by different extraction mechanisms.

Solvent extraction essays from hydrochloric acid solutions containing metals other than iron(III) – Cu(II), Zn(II) and In(III) - were carried out. No extraction was detected in the presence or in the absence of iron(III). The selectivity of Fe(III) over the metals under study is a very important result, mainly considering that in particular conditions zinc is frequently co-extracted together with iron by extractants commonly used (e.g., TBP, Alamine 336, D2EHPA) [14,15]. The co-extraction of iron(III) and copper from chloride media is also reported [15] (e.g., Alamine 336). The selectivity towards a large number of other base metal cations, usually present in pregnant mineral leaching solutions, such as Fe(II), Pb and Ni, is being researched.

In this project a preliminary attempt to find out which iron(III) species is preferably extracted by DMDPHMA from chloride media is made based on the extraction data obtained and on evidence given by spectroscopic techniques. The results presented above and the ultra-violet spectra of the charged organic phases (Figure 3) suggest that iron is extracted in the form of anionic chlorocomplex tetrachloroferrate  $\text{FeCl}_4^-$ .

*Figure 3. Region of the UV-spectrum of loaded DMDPHMA.*

In fact the peak observed at 365 nm can probably be assigned to the anionic chlorocomplex, since the literature refers to the existence of an intense charge-transfer band at 364 nm for this complex [16]. This peak was clearly identified in the aqueous phases containing a hydrochloric acid concentration higher than 4 M, proving that the increase in chloride concentration favours the formation of  $\text{FeCl}_4^-$  and therefore iron(III) extraction.  $\text{FeCl}_4^-$  is referred to in the literature as predominant at high  $\text{Cl}^-$  concentrations [17]. For lower chloride concentrations chloro, aqua, and hydroxy species are mentioned [17] and, therefore, different spectra for the aqueous solutions were obtained (a peak near 340 nm appeared in that region of the UV spectrum), indicating that the anionic chlorocomplex species is not predominant. The new band is probably due to the presence of iron complexes containing chloride ions and water in their co-ordination sphere [18], which are not extracted by DMDPHMA.

Further studies to clarify the mechanism of extraction are being carried out.

The extraction data of malonamides for iron(III) from a hydrochloric acid medium show a different behaviour from those presented by the same compounds in the extraction of actinides and lanthanides from nitric acid solutions. A reason for this difference is obviously related with the utilisation of different media, where logically different equilibria are involved, leading possibly to different mechanisms of extraction.

### Stripping Experiments

Stripping experiments of iron(III) from the loaded organic phase to a purified aqueous phase were carried out using water and diluted HCl solutions (~0.4 M). In both cases iron(III) was only partially re-extracted after 15 minutes of contact between the two phases. Results from 23% to 38% were obtained with diluted acid solutions, while 28% was achieved using water.

Assays performed with the loaded alkylated malonamide, DMDPHTDMA, showed that iron(III) was quantitatively re-extracted by water or diluted HCl solutions [11], which proves the importance of the malonamide structure for efficient metal stripping.

## STUDY OF Sc AND Zr EXTRACTION REACTIONS BY REACTIVE MATERIALS CONTAINING ACIDIC ORGANOPHOSPHOROUS EXTRACTANTS

Jose-Luis Cortina, Vadim Korovin\* and Yuriy Shestak\*

Department of Chemical Engineering, Polytechnical University of Catalonia,  
Barcelona, Spain

\*Pridneprovski Scientific Centre, Ukrainian Academy of Sciences,  
Dnieprodzerzhinsk, Ukraine

Extraction properties of polymer reactive materials prepared by impregnation of macroporous polymers with DEHPA have been evaluated. NMR spectroscopy was used to determine the extraction mechanism of Sc and Zr with DEHPA (HA) in both carbon tetrachloride and when impregnated onto solid adsorbents. Extraction of Sc and Zr from acidic solutions showed changes in the composition of the extracted complexes when compared with liquid /liquid extraction. While in liquid/liquid extraction systems mixed complexes of Zr and Sc with anions of the aqueous phase ( $\text{NO}_3^-$  and  $\text{Cl}^-$ ) and the anionic form of DEHPA ( $\text{A}^-$ ) are extracted, in solid supports simples complexes of Zr and Sc with the anionic form of DEHPA ( $\text{A}^-$ ) were found. The ability to interact with extracted cations by both ion-exchange mechanism and formation of co-ordination bond with P=O group of DEHPA=HA molecules was corroborated. The availability of two active centers on HA ligands allows the formation of polynuclear complexes with metal ions.

### INTRODUCTION

Selective adsorption systems based on extractant supported in carriers are seen as an important emerging alternative approach to well established technologies such as solvent extraction (SX) and ion exchange (IX). These materials, in which the active phase is impregnated or physically immobilised into a porous carrier may be used widely for metal extraction, separation and preconcentration schemes in, for example, reversed-phase extraction chromatography, membrane extraction, and hydrometallurgy of rare-earth, non-ferrous and noble metals. These supported extractant materials are produced either by direct impregnation of a porous carrier by the liquid extractant (SIR), or by introduction of the extractant during synthesis of the porous matrix (solid extractants (TVEX)).

They have a number of processing advantages over techniques like resin ion exchange and liquid-liquid extraction. Thus when compared to conventional ion exchange resins they provide increased selectivity for a metal without the reduction in kinetics and capacity experienced by chelating ion exchange resins. Also when compared with liquid-liquid extraction, these systems provide a more efficient extractant use with minimal use of organic solvents, leading to a reduction in waste and hence a more environmentally desirable process. Authors of early papers did not notice any differences between the capacity of the extractant when present in the porous matrix and when used in liquid-liquid extraction.

However, recently it has been shown in a number of cases that the polymer matrix influences not only the extraction kinetics, but also the formation of metal complexes with the extractant in the organic phase [1-3].

These peculiarities on the metal extracted complexes and the influence of the solid carrier have been studied and described by partners of the present paper. Earlier work [3-6] comparing the extraction of a number of metals by extractants in the liquid phase and present in a polymer matrix by means of IR, NMR spectroscopy and mercury porosimetry has shown that: the porous matrix did not only change the composition and structure of extracted complexes, but also, in a number of cases, led to an increase in extractant capacity. This is the case for neutral extractants where the influence of the matrix on metal extraction was largely dependent on the extraction mechanism; for solvation extraction mechanism of a single metal the polymer matrix showed very little influence either on extractant capacity or the composition of extracted compounds; for systems forming metal complexes with labile co-ordination spheres the presence of the polymer matrix changes the composition and correlation of extracted compounds, simultaneously increasing the extractant capacity near extractant saturation.

The present paper describes the extraction of rare-earth (Zr(IV), Sc(III)) metals with impregnated reactive polymers containing DEHPA. These reactive materials were prepared by polymerisation of the polymer monomers in the presence of DEHPA. The extraction patterns in terms of metal extraction reactions and identification of extracted complexes in both organic solvents and solid supports were studied by using NMR spectroscopy.

## EXPERIMENTAL

### Preparation of DEHPA Solid Adsorbents

Synthesis of solid extractant (TVEX) containing DEHPA was carried out in a glass reactor fitted with a mixer, thermometer and back-flow condenser. Starch solution (0.4%), used as emulsion stabiliser, was first added to the reactor [7]. Then reaction mixture containing styrene, divinylbenzene, DEHPA and benzoyl peroxide as initiator of radical copolymerisation were fed into the reactor at 323 K with agitation. Polymerisation was carried out for 8 h. The TVEX granules were washed with water and dried with nitrogen. DEHPA loading was evaluated by washing a known amount of resin with ethanol, which elutes DEHPA for subsequent determination by potentiometric titrations.

### Rare Earth Extraction Evaluation

#### *Liquid-liquid and solid-liquid experiments*

Liquid-liquid extraction experiments were performed using 0.05 mol/L solutions of Sc(III) and 0.5 mol/L solutions of Zr(IV) and variable concentrations of HCl (from 0.2 to 7.9 mol/L) and HNO<sub>3</sub> (from 2.2 to 8.1 mol/L), respectively. DEHPA solutions in CCl<sub>4</sub> were 0.3 mol/L for Sc(III) experiments and 0.5 and 1.8 mol/L for Zr(IV) experiments. Equal volumes of aqueous and organic phases were used. Agitation times of 30 minutes were enough to reach equilibrium. For solid extraction systems a volumetric phase ratio of 4 (resin/aqueous) was used while equilibration times of 1440 minutes were used. Detailed description of the different runs is collected in tables 1 and 2. Sc and Zr concentration in aqueous phase was measured using photometric titration by EDTA.

#### *NMR spectroscopy measurements*

<sup>31</sup>P (81.04 MHz) and <sup>45</sup>Sc (48.62 MHz) NMR high resolution spectra were recorded using impulse spectrometer Bruker CXP-200. Positive chemical shifts correspond to decrease of magnetic field. Chemical shifts were referenced to a 85 % phosphoric acid solution for <sup>31</sup>P and a 0.1 mol/L acidified Sc(ClO<sub>4</sub>)<sub>3</sub> solution <sup>45</sup>Sc. Relative intensities of badly resolved

spectra were defined by searching system parameters (position, width, height) minimising root-mean-square deviation of calculated and experimental spectra [7].

## SCANDIUM EXTRACTION

$^{45}\text{Sc}$  NMR spectra of liquid and solid Sc-containing extracts comprise broad singlet signals with chemical shifts -9.6 ppm (535-560 Hz) for  $\text{CCl}_4$  extracts and -10.4 ppm (2420-2480 Hz) for solid ones. Measured values of chemical shift indicated the absence of  $\text{Cl}^-$  ions in scandium co-ordination sphere. Former studies revealed [8] that inclusion of every  $\text{Cl}^-$  ion to Sc co-ordination sphere resulted in signal shift approximately 45 ppm to low field up to +249 ppm for  $[\text{ScCl}_6]^{3+}$  complex.

$^{31}\text{P}$  NMR spectra of extracts and TVEX in Figure 1 showed up to a maximum of three peaks (A, B and C). Signal A (1.2-1.7 ppm) in spectra of initial DEHPA in  $\text{CCl}_4$  and TVEX-DHEPA corresponds to non-coordinated DEHPA molecules while signal B (-4.5-4.7 ppm) in all Sc-containing samples corresponds to DEHPA molecules bound with scandium. Besides, a third signal C in the spectra of some specimen with chemical shift twice as much as the chemical shift for signal B (Figure 1, spectra 2, 4, 5) was associated to DEHPA molecules bound with 2 Sc ions (*i.e.*, “bridge” extractant molecules).

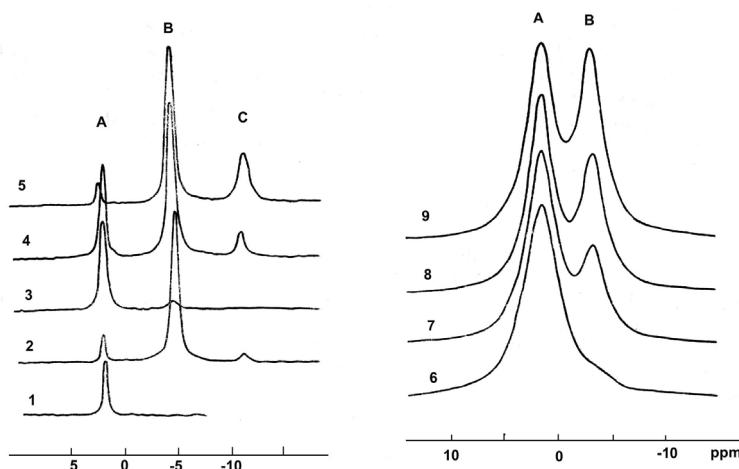

Figure 1.  $^{31}\text{P}$  NMR spectra of initial 0.3 mol/L DEHPA in  $\text{CCl}_4$  (1); Sc-containing extracts (2-5) and TVEX-DEHPA samples (6-9).

Average solvate number (ASN) (Table 1), which defines the number of extractant molecules bonded with metal ion, was calculated on the basis of DEHPA/Sc mol ratio (R) and relative intensity (I) of B and C signals (signals from bonded extractant molecules) using the following equation  $\text{ASN} = R^* (I_B + I_C) / 100$ .

ASN values of 6 for  $\text{CCl}_4$  suggested that the extraction of scandium proceeds with the formation of the complex  $\text{Sc}(\text{A}_2\text{H})_3$ . ASN values less than 6 together with absence of  $\text{Cl}^-$  ions in Sc first co-ordination sphere may be explained by either inclusion of water molecules or formation of scandium polymer bonds with HA. Since the amount of extractant “bridge” molecules is negligible (according to NMR data), decrease of ASN value may be explained by inclusion of water molecules to Sc first co-ordination sphere.

Table 1. Scandium average solvate number in extracts and TVEX-DEHPA.

Run #	Sample	[HCl], mol/L	R $C_{HA}/C_{Sc}$	Relative Signal Intensity, % (I)			ASN
				I <sub>A</sub>	I <sub>B</sub>	I <sub>C</sub>

11	Extract # 6	Water	6.1	8.3	88.0	3.7	5.6
<b>TVEX-DEHPA</b>							
12	TVEX-DEHPA	0.2	5.6	97.2	2.8	0	0.2
13		1.1	5.6	92.4	7.6	0	0.4
14		2.4	5.6	72.7	27.3	0	1.5
15		4.2	5.6	70.4	29.6	0	1.7
16		6.3	5.6	61.5	38.5	0	2.2
17		7.60	5.62	59.8	40.2	0	2.3

For conditions with minimum ASN values of 4 (run # 7) extraction will take place with scandium ions bound to 4 DEHPA molecules and 2 water molecules as could be seen in the following two possible structures:

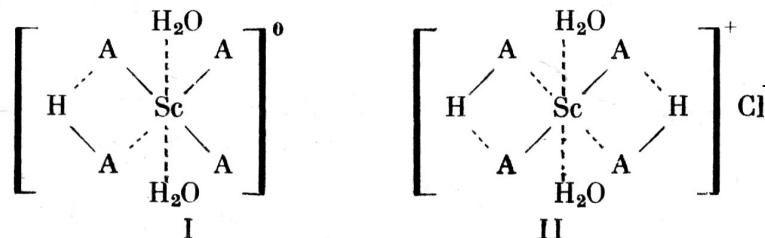

Figure 2. Proposed Sc-DEHPA structures.

Rinsing of CCl<sub>4</sub> phases with water (runs 9-11) resulted in an increase of content of HA molecules co-ordinated to scandium, a decrease of concentration of non-coordinated extractant, decrease of "bridge" molecule amount and an ASN increase. Besides, analysis of rinsing water revealed the presence of HCl and absence of scandium ions. These facts confirm the entry of Cl<sup>-</sup> ions to scandium extracted complexes.

Thus, present results allow concluding that Cl<sup>-</sup> ions are not found in the first co-ordination sphere and, the extraction mechanism could be described as:

where n = 0 – 3 depending upon acidity of aqueous phase.

For TVEX-DEHPA scandium is extracted as complexes with common formula  $[\text{Sc}(\text{H}_2\text{O})_6\text{A}_n]_{3-n}$ , where n equals 0 - 3 according to ASN values. Thus, Sc extraction by TVEX-DEHPA is accompanied by substitution of  $\text{Cl}^-$  ions in Sc first coordination sphere by  $\text{A}^-$  ions; and extraction mechanism may be presented by the following equations:

## ZIRCONIUM EXTRACTION

$^{31}\text{P}$  NMR spectra of DHEPA solution in  $\text{CCl}_4$  and TVEX-DHEPA consist of three singlet signals A, B and C (Figure 3). Signal A (+1.6 to -1.8 ppm) corresponds to non-bonded extractant molecules while signal B (-5.9 to -5.3 ppm) was associated to monodentate extractant ligands ( $\text{A}^-$ ) in Zr co-ordination sphere. Signal C (-15.1 to -15.2 ppm) was associated to bridge ligands that simultaneously interact with two zirconium ions forming polynuclear complexes Zr-A-Zr. It should be pointed out that the amount of "bridge" DHEPA molecules is small in all the organic phases with a maximum of 7 %.

Based on DHEPA/Zr mole ratio (R) and relative intensity (I) of B and C signals in the NMR spectra, the average solvate number of DEHPA molecules for Zr cations was calculated for the studied system. The data obtained are given in Table 2.

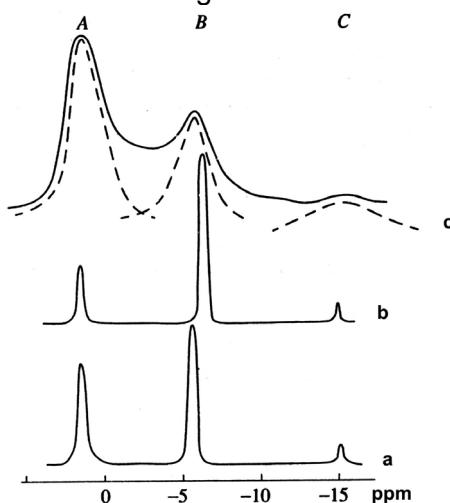

Figure 3.  $^{31}\text{P}$  NMR spectra of zirconium extracts: (a) 0.3 mol/L DEHPA; (b) 0.3 mol/L DEHPA after water rinsing, (c) TVEX-DEHPA.

ASN value for zirconium extraction by 0.3 mol/L (runs 1-5) and 1.9 mol/L (runs 8-12) DEHPA in  $\text{CCl}_4$  is less than 4, i.e., amount of  $\text{A}^-$  ions in co-ordination sphere of  $\text{Zr}^{4+}$  ion is not sufficient to compensate its charge. Consequently, for the studied conditions extraction takes place with formation of compound mixed complexes with  $\text{A}^-$  and  $\text{NO}_3^-$  anions; and extraction mechanism may be described by the following equation:

Table 2. Zirconium extraction by DEHPA and TVEX-DHEPA runs.

Run	Organic Phase	[HNO <sub>3</sub> ], mol/L	Loading, mol Zr/L	HA/ Zr Ratio	Intensity, %			ASN
					I <sub>A</sub>	I <sub>B</sub>	I <sub>C</sub>

		5.7	0.36	6.2	78.9	18.7	2.4	1.3
		7.9	0.38	5.9	80.8	16.7	2.5	1.1

On the basis of ASN value, the following complexes are extracted within the studied aqueous phase acidity (2.2 - 8.1 mole/L): Zr(NO<sub>3</sub>)<sub>4</sub>(HA)<sub>2</sub> (I), ZrA(NO<sub>3</sub>)<sub>3</sub>(HA)<sub>2</sub> (II), ZrA<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>(HA)<sub>2</sub> (III). Their structure may be presented by the following formulas:

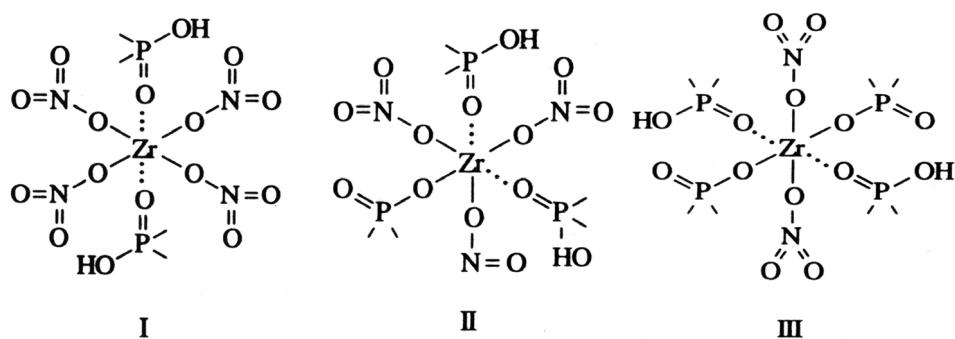

Figure 4. Proposed Zr-DEHPA structures.

ASN value decreases with acidity increase that may be caused by decrease of compound III content and increase of content of forms I and II at increase of NO<sub>3</sub><sup>-</sup> content in organic phase. CCl<sub>4</sub> extracts from experiments 1 and 5 were rinsed with water. Zirconium was not found in rinsing water however acidity of aqueous phase increased. The amount of non-bonded DEHPA molecules essentially decreased (see Figure 3 curve b); the amount of bonded extractant molecules increased with an ASN increase from 3.2 to 5.8 (runs # 1 and 6) and from 2.8 to 4.2 (runs # 5 and 7). The water rinsing resulted in removal of NO<sub>3</sub><sup>-</sup> ions from organic phase and substitution of these positions by A<sup>-</sup> anions which gives the following Zr extraction reaction:

For Zr extraction by TVEX-DEHPA the ASN value is half as much for solvent extraction and decreases from 1.6 to 1.1 with an increase of the aqueous phase acidity. This indicates that one zirconium cation interacts with one or two HA molecules in solid extractant forming mainly complexes I and II in organic phase.

## CONCLUSIONS

Differences in metal extraction by DEHPA and TVEX-DEHPA is caused by the extractant state in the porous carrier. Small signal broadening in TVEX spectra as compared with DHEPA solution in  $\text{CCl}_4$  indicates the liquid state of the extractant in matrix. Part of the extractant is held due to physical adsorption and "meshing" of big and branched alkyl radicals in the polymer structure. This limits the mobility of extractant molecules and decreases their competitiveness with nitric ions during filling of Zr co-ordination sphere. This mechanism is similar to sorption of metal cations by ion-exchange resins where functional groups are fixed in a polymer frame.

The extraction of tetravalent titanium, zirconium and tin from hydrochloric acid solutions by LIX 63 (5,8-diethyl-7-hydroxy-6-dodecanone oxime, HR) in kerosene was investigated. The organic extracts were examined by infrared and nuclear magnetic resonance spectroscopy. In the range of 0.1-10 mol dm<sup>-3</sup> HCl, the extraction efficiency of LIX 63 is in the order Sn > Ti > Zr at [HCl] < 1 mol dm<sup>-3</sup>, Ti > Zr > Sn at [HCl] = 1-3 mol dm<sup>-3</sup> and Ti > Sn > Zr at [HCl] > 3 mol dm<sup>-3</sup>. As a result, the equilibrium equations are proposed as follows: for Ti(IV),  $\text{Ti}(\text{OH})_2^{2+}(\text{aq}) + 2\text{HR}(\text{org}) \leftrightarrow \text{Ti}(\text{OH})_2\text{R}_2(\text{org}) + 2\text{H}^+(\text{aq})$  and  $\text{Ti}(\text{OH})_2\text{Cl}_2(\text{aq}) + 2\text{HR}(\text{org}) \leftrightarrow \text{Ti}(\text{OH})_2\text{Cl}_2 \cdot 2\text{HR}(\text{org})$ ; for Zr(IV),  $\text{ZrCl}_4(\text{aq}) + \text{HR}(\text{org}) \leftrightarrow \text{ZrCl}_4 \cdot \text{HR}(\text{org})$ ; for Sn(IV),  $\text{SnCl}_2^{2+}(\text{aq}) + 2\text{HR}(\text{org}) \leftrightarrow \text{SnCl}_2\text{R}_2(\text{org}) + 2\text{H}^+(\text{aq})$  and  $\text{SnCl}_4(\text{aq}) + \text{HR}(\text{org}) \leftrightarrow \text{SnCl}_4 \cdot \text{HR}(\text{org})$ .

## INTRODUCTION

The extraction of divalent metals such as copper, nickel and cobalt by  $\alpha$ -hydroxyoximes has been reported extensively [1], but little attention has been paid to the extraction of tri- and tetravalent metals. From the viewpoint of hydrometallurgical processing, however, solvent extraction of tri- and tetravalent elements is of significance because of an increase in industrial demand. Accordingly, our studies have been conducted on the complexes formed in the extraction of copper from hydrochloric acid solutions by an  $\alpha$ -hydroxyoxime (such as 5,8-diethyl-7-hydroxy-6-dodecanone oxime, HR, the active component of LIX 63), and in addition the extraction of divalent cobalt, nickel and copper and trivalent gallium, indium, thallium and iron [2-5]. The present paper extends the work to the extraction of tetravalent titanium, zirconium and tin from hydrochloric acid solutions by an  $\alpha$ -hydroxyoxime.

## EXPERIMENTAL

LIX 63 (Henkel Corp., now Cognis) used as the  $\alpha$ -hydroxyoxime was purified by the method according to an earlier paper [6], and diluted with purified kerosene. Stock solutions of metal chlorides were prepared as follows: titanium chloride solution is obtained by dissolving titanium hydroxide, precipitated by addition of ammonium hydroxide to titanium tetrachloride, in hydrochloric acid. Aqueous solutions of zirconium and tin were obtained by dissolving their chlorides ( $\text{ZrCl}_4$  and  $\text{SnCl}_4 \cdot x\text{H}_2\text{O}$ ) in hydrochloric acid of the selected concentration. The concentrations of titanium, zirconium and tin were generally 1 g dm<sup>-3</sup> as the respective chlorides, except for loading tests. All chemicals used were of an analytical reagent grade.

Equal volumes (15 cm<sup>3</sup> each) of the aqueous and organic phases placed in 50 cm<sup>3</sup> stoppered conical flask were shaken for a certain period by a mechanical shaker at 298 K, except the experiments on temperature effect. Preliminary experiments showed that the equilibria for titanium, zirconium and tin were attained in 8, 2 and 3 h, respectively. After separation of both phases by centrifugation, the aliquots of the both phases were pipetted for analysis. Metals in the organic phase were stripped with 1 mol dm<sup>-3</sup> sodium hydroxide solution and concentrated hydrochloric acid for titanium, 6 mol dm<sup>-3</sup> nitric acid and 2-ethylhexyl alcohol for zirconium and 2 mol dm<sup>-3</sup> hydrochloric acid and 2-ethylhexyl alcohol for tin, respectively. The addition of the alcohol plays the role of promoting the dehydration of the extracted species. The extraction coefficient, E<sub>a</sub><sup>°</sup>, was determined as the ratio of the equilibrium concentration of metal in the organic phase to that in the aqueous phase.

The concentration of titanium in aqueous solution was obtained by adding excess of EDTA and back-titration with zinc sulphate solution at pH 7 using Eriochrome Black T. The concentrations of zirconium and tin were assayed by EDTA titration using xylene orange as the indicator. The infrared (IR) spectra were recorded on JASCO models IRA-1 (4000-650 cm<sup>-1</sup>) and IR-F (700-200 cm<sup>-1</sup>) using a capillary film between thallium halide plates or polyethylene films. The nuclear magnetic resonance (NMR) spectra were obtained for the organic extracts dissolved in carbon tetrachloride using a Hitachi model R-24 with the use of tetramethylsilane as the internal reference.

## RESULTS AND DISCUSSION

### Extraction Isotherms

The extraction of tetravalent titanium, zirconium and tin from hydrochloric acid solutions by different concentrations of LIX 63 in kerosene gives the results shown in Figures 1 to 3. Figure 1 shows that with increasing in the aqueous acidity, the distribution coefficient for titanium(IV) decreases gently up to 1 mol dm<sup>-3</sup> and rises to a maximum at 2 mol dm<sup>-3</sup> and then falls. In Figure 2, with increasing in the aqueous acidity, the distribution coefficient for zirconium rises to a maximum at 2 mol dm<sup>-3</sup> and then falls up to 7 mol dm<sup>-3</sup> and rises again. The distribution behaviour of tin(IV) resembles that of titanium(IV) as seen in Figure 3: with increasing in the aqueous acidity, the distribution coefficient decreases to a minimum at 2 mol dm<sup>-3</sup> and rises to a maximum at 3 mol dm<sup>-3</sup> and then falls. When the extraction efficiency of LIX 63 for titanium(IV), zirconium(IV) and tin(IV) is compared at the aqueous acidity in the range of 0.1-10 mol dm<sup>-3</sup> HCl, it is in the order Sn > Ti > Zr at [HCl] < 1 mol dm<sup>-3</sup>, Ti > Zr > Sn at [HCl] = 1-3 mol dm<sup>-3</sup> and Ti > Sn > Zr at [HCl] > 3 mol dm<sup>-3</sup>, respectively. In the extraction of titanium(IV) at 1 mol dm<sup>-3</sup> =< [HCl], when hydrochloric acid in aqueous solution is partly replaced by lithium chloride, the distribution coefficient rises with the total chloride ion concentration.

This suggests that the total chloride concentration is the controlling factor (Figure 1). From this, it is deduced that there are two different regions in which the extraction occurs involving different mechanism. The variation of the distribution coefficient is attributed to the chelation mechanism similar to a cation exchange reaction in the weak acid region, and arises from a solvating reaction at higher acidities. But there is no simple aquated Ti<sup>4+</sup> ion because of the extremely high charge-to-radius ratio, and in aqueous solutions hydrolyzed species occur and basic oxo salts or hydrated oxides may precipitate. Besides, as the titanyl ion, TiO<sup>2+</sup>, seems to exist neither in solutions nor in crystalline salts, the species [Ti(OH)<sub>2</sub>(H<sub>2</sub>O)<sub>4</sub>]<sup>2+</sup> is in general considered to be the prevailing species in dilute aqueous solutions of titanium salts. However, since the extraction of zirconium(IV) at [HCl] =< 1 mol dm<sup>-3</sup> reveals the rising in the distribution coefficient with increasing in the total chloride ion concentration for the aqueous solutions of 0.7 mol dm<sup>-3</sup> HCl + LiCl, the results shown in Figure 2 arise from a solvating reaction. In addition, the extraction of zirconium(IV) from aqueous solutions at pH 2 by LIX

63 forms a third phase. In contrast, the extraction of tin(IV) is analogous to that of titanium(IV): the distribution coefficient is not much affected with increasing in the total chloride ion concentration for the aqueous solutions of  $0.4 \text{ mol dm}^{-3}$  HCl + LiCl.

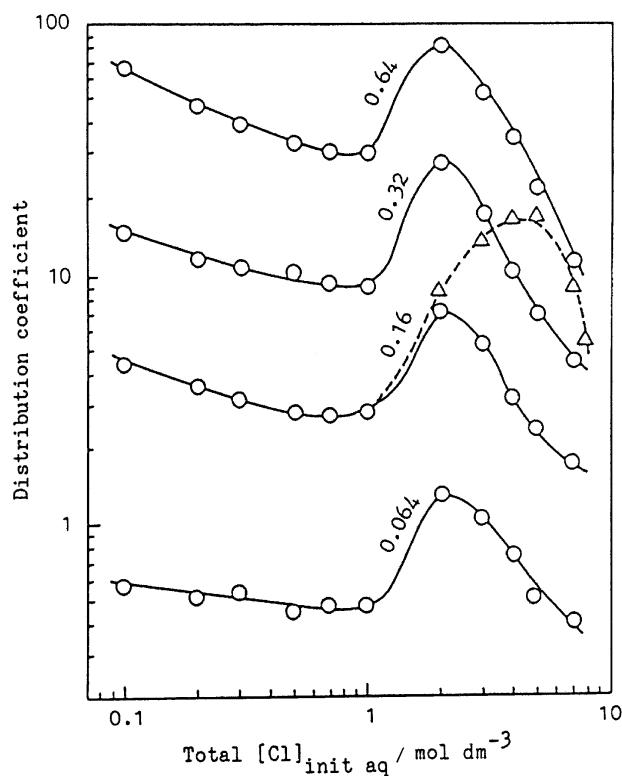

Figure 1. Extraction of titanium(IV) from HCl solutions by LIX 63 in kerosene. Numerals upon the curves are LIX 63 concentrations /  $\text{mol dm}^{-3}$ ; continuous and broken lines represent the extraction from HCl solutions and mixed  $1 \text{ mol dm}^{-3}$  HCl / LiCl solutions, respectively.

Table 1. Slope of log-log plots of  $E_a^\circ$  vs.  $[\text{HR}]_{\text{eq}}$  for the extraction of titanium(IV), zirconium(IV) and tin(IV) from hydrochloric acid solutions with LIX 63 in kerosene.

$[\text{HCl}]_{\text{init aq}}$ $\text{mol dm}^{-3}$	Slope		
	Ti	Zr	Sn
0.1	1.8	-	2.0
0.3	1.7	1.1	1.9
0.5	1.8	0.8	1.8
1	1.8	1.1	1.4
2	1.9	1.2	1.2
3	1.9	1.1	1.2
5	1.8	1.1	1.0
10	1.8	1.0	1.0

Log-log plots of  $E_a^\circ$  vs.  $[\text{HR}]_{\text{eq}} = [[\text{HR}]_{\text{init}} - n[\text{M}]_{\text{org}}]$  where  $\text{M} = \text{Ti}, \text{Zr}$  or  $\text{Sn}$  and  $n$  denotes the solvation number, at constant hydrochloric acid concentration give the straight lines with slopes of 1-2 as illustrated in Table 1. It is thus seen that their distribution coefficients have first- and second-power dependences on LIX 63 concentration, indicating the formation of mono- and di-solvates.

This is also supported by the loading test of the metals in the organic phase. When the metals are extracted with  $0.064 \text{ mol dm}^{-3}$  LIX 63, the molar ratio of the extract  $[\text{Ti}] / [\text{Cl}] / [\text{HR}] / [\text{H}_2\text{O}]$ , seems to approach to 1:2:2:1 at 2 mol  $\text{dm}^{-3}$  HCl,  $[\text{Zr}] / [\text{Cl}] / [\text{HR}] / [\text{H}_2\text{O}]$  to 1:4:1:4 at 2 mol  $\text{dm}^{-3}$  HCl and  $[\text{Sn}] / [\text{Cl}] / [\text{HR}] / [\text{H}_2\text{O}]$  to 1:2:2:1 and 1:4:1:1 at 0.4 and 5 mol  $\text{dm}^{-3}$  HCl. These results suggest the formation of  $\text{TiCl}_2 \cdot 2\text{HR} \cdot \text{H}_2\text{O}$ ,  $\text{ZrCl}_4 \cdot \text{HR} \cdot 4\text{H}_2\text{O}$ ,  $\text{SnCl}_2 \cdot \text{R}_2 \cdot \text{H}_2\text{O}$  and  $\text{SnCl}_4 \cdot \text{HR} \cdot \text{H}_2\text{O}$ , respectively. Hence the following equilibrium equations are proposed:

Here, (a) and (o) represents the species in the aqueous and organic phase, respectively.

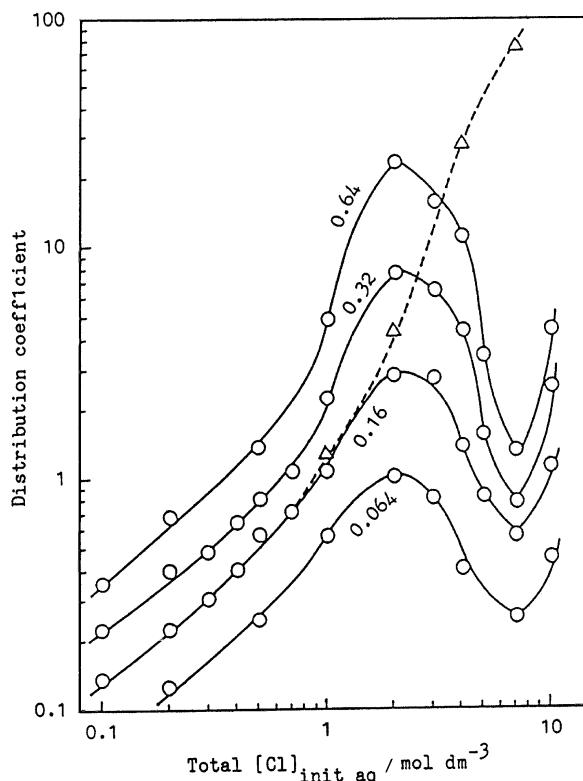

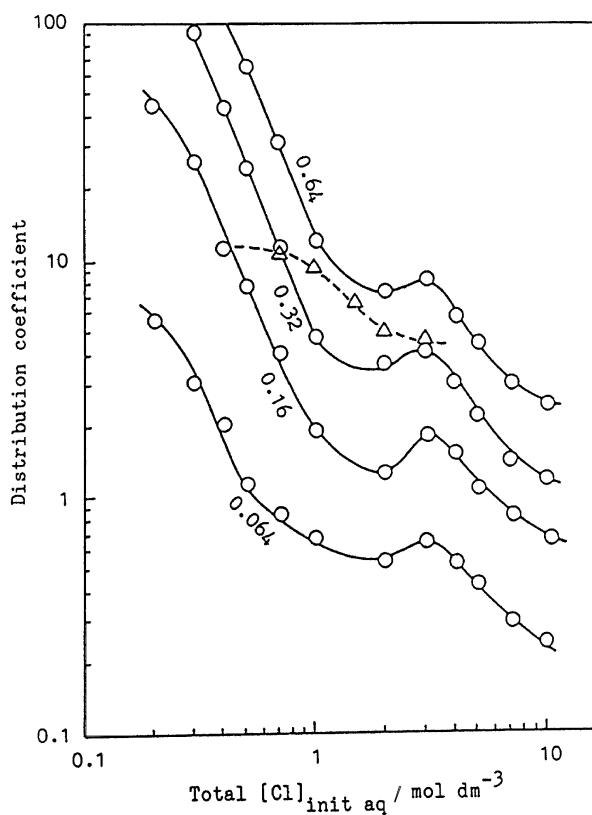

Figure 2. Extraction of zirconium(IV) from HCl solutions by LIX 63 in kerosene. Numerals upon the curves are LIX 63 concentrations /  $\text{mol dm}^{-3}$ ; continuous and broken lines represent the extraction from HCl solutions and mixed  $0.7 \text{ mol dm}^{-3}$  HCl / LiCl solutions, respectively.

### IR and NMR Spectra

The organic phases of  $0.01 \text{ mol dm}^{-3}$  LIX 63 in *n*-hexane equilibrated with 2 mol  $\text{dm}^{-3}$  hydrochloric acid solutions containing each metal salts of 1, 10 and  $25 \text{ g dm}^{-3}$  were examined by IR spectroscopy. As for all organic extracts, the C-O stretching vibration which appears at  $1030 \text{ cm}^{-1}$  for free extractant shifts to higher frequency at  $1035\text{-}1040 \text{ cm}^{-1}$ , whereas the C=N stretching vibration at  $1650 \text{ cm}^{-1}$  shifts to lower frequency at  $1610\text{-}1620 \text{ cm}^{-1}$ . From this it is deduced that the species formed in the organic phase possesses the structure in which oxime group coordinates to the metal through oxygen and nitrogen atoms. Additionally the stretching modes of Ti-Cl, Ti-O, Zr-Cl, Zr-O, Sn-Cl and Sn-O appear at 280, 515, 328, 495, 335 and  $490 \text{ cm}^{-1}$ , respectively, due to the formation of the species in Eqs. (2), (3) and (5).

*Figure 3. Extraction of tin(IV) from HCl solutions by LIX 63 in kerosene. Numerals upon the curves are LIX 63 concentration / mol dm<sup>-3</sup>; continuous and broken lines represent the extraction from HCl solutions and mixed 0.4 mol dm<sup>-3</sup> HCl / LiCl solutions, respectively.*

The organic extracts from aqueous solutions containing tin chloride in 0.4 and 5 mol dm<sup>-3</sup> HCl with 0.1 mol dm<sup>-3</sup> LIX 63 in carbon tetrachloride were examined by NMR spectroscopy. At 0.4 mol dm<sup>-3</sup> HCl, the OH resonance due to oxime at  $\tau$  5.9 exhibits the shift to higher field and the decrease in the intensity with increasing in the metal concentration in the organic phase, arising from the substitution of hydrogen ion of LIX 63 by the metal ion. At 5 mol dm<sup>-3</sup> HCl, LIX 63 shows the peak at  $\tau$  1.6, due to the compound HCl-HR [3] formed in the extraction of hydrochloric acid, shifts to higher field. Similar NMR spectra are also observed for the extracts of other metals.

#### Temperature Effect

The results for the extraction of each metals at temperature between 283-313 K are indicated in Table 2. It is seen that the distribution coefficients increase with rising temperature. Thus the value of the heat of reaction ( $-\Delta H$ , change in enthalpy) are estimated: 15.4 (Ti), 16.6 (Zr), 4.36 (Sn) and 7.93 (Sn) kJ mol<sup>-1</sup> at 2, 2, 0.5 and 5 mol dm<sup>-3</sup> HCl, respectively.

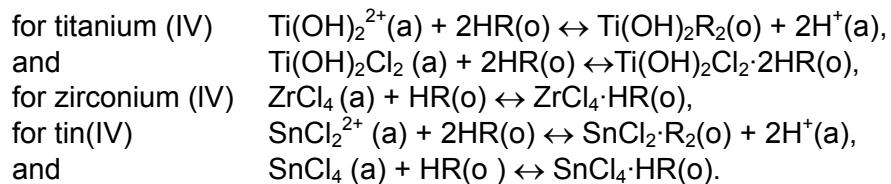

*Table 2. Temperature-dependence of the distribution coefficient for the extraction of titanium(IV), zirconium(IV) and tin(IV) from hydrochloric acid solutions with LIX 63 in kerosene.*

Metal	[HCl] <sub>init aq</sub> mol dm <sup>-3</sup>	[HR] mol dm <sup>-3</sup>	E <sub>a</sub> <sup>o</sup>			
			283 K	293 K	303 K	313 K
Ti	2	0.064	4.61	6.21	8.26	10.4
Zr	2	0.064	0.561	0.832	1.21	1.69
Sn	0.5	0.16	6.31	8.11	10.1	12.8
Sn	5	0.16	0.971	1.18	1.49	1.86

## CONCLUSION

The extraction of tetravalent titanium, zirconium and tin from hydrochloric acid solutions by LIX 63 in kerosene has been investigated over the concentration range of 0.1 to 10 mol dm<sup>-3</sup> hydrochloric acid. With increasing in the aqueous acidity, the distribution coefficient for titanium(IV) decreases gently up to 1 mol dm<sup>-3</sup> and then rises to a maximum at 2 mol dm<sup>-3</sup> and falls again; for zirconium(IV), the distribution coefficient rises to a maximum at 2 mol dm<sup>-3</sup> and then falls up to 7 mol dm<sup>-3</sup> and rises again; for tin-(IV), the distribution behaviour is analogous to that of titanium(IV) but the distribution coefficient decreases to a minimum at 2 mol dm<sup>-3</sup> and then rises to a maximum at 3 mol dm<sup>-3</sup> and falls again. When the extraction efficiency of LIX 63 is compared with each metal, its order is observed as Sn > Ti > Zr at [HCl] = < 1 mol dm<sup>-3</sup>, Ti > Zr > Sn at [HCl] = 1-3 mol dm<sup>-3</sup> and Ti > Sn > Zr at [HCl] >= 3 mol dm<sup>-3</sup>.

As a result, the extraction of tetravalent titanium, zirconium and tin from hydrochloric acid solutions by LIX 63 proceeds according to the following equations:

In conjunction with efforts to develop novel actinide extractants exhibiting solubility in supercritical carbon dioxide, the effect of adding silicon-based functionalities to diphosphonic acids has been investigated. Specifically, a series of silyl-substituted diphosphonic acids has been prepared and characterized, and their aggregation and metal ion extraction properties compared with alkyl-substituted diphosphonic acids, reagents previously demonstrated to be effective extractants of actinides from acidic aqueous media into various organic solvents. In addition, the influence of the number of methylene groups bridging the phosphorus atoms of the diphosphonic acids on their extraction behavior has been investigated. Variations in the extraction behavior of the compounds arising from differences in the number of bridging methylene groups have been shown to be attributable to a combination of factors, in particular, the aggregation state of the ligand, the size of the chelate rings formed upon complexation, the basicity of the phosphoryl group and the relative acidities of the ligands.

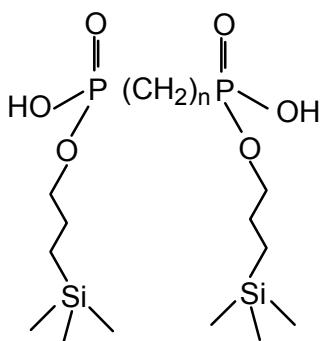

### INTRODUCTION

Partial esters of diphosphonic acids in organic solvents have been shown to be efficient metal ion extractants, exhibiting a particular affinity for tri-, tetra- and hexavalent actinides and Fe(III) [1]. In previous work, which grew out of an effort to synthesize supercritical CO<sub>2</sub>-soluble diphosphonic acid ligands, a series of silyl-substituted diphosphonic acids was investigated to determine the effect of incorporating a silicon functionality into a diphosphonic acid. While the incorporation of the silyl functionality was shown to have a relatively minor effect on the aggregation and metal ion extraction properties of the ligands, a more profound effect on these properties was observed as the length of the alkyl chain bridging the phosphorus atoms was varied. This work represents the first step toward understanding this effect, as part of a broader effort to determine the relationship between structure and function in diphosphonic acids.

### EXPERIMENTAL

All materials, instrumentation and experimental conditions used in this study were as previously described [2, 3]. The aggregation states of the ligands in toluene at 25°C were determined by vapor pressure osmometry using a Jupiter Model 833 vapor pressure osmometer. Infrared spectra were obtained by taking 64 scans at 2 cm<sup>-1</sup> resolution on a Mattson Genesis Series FTIR spectrometer. <sup>31</sup>P NMR spectra were collected on a Varian 400 MHz spectrometer, with chemical shifts reported relative to an external 85% H<sub>3</sub>PO<sub>4</sub>.

reference. Duplicate measurements showed that the reproducibility of the distribution ratio measurements was generally within five percent, although the uncertainty interval was higher for the highest and lowest D values ( $D > 10^3$ , or  $D < 10^{-3}$ ).

*Figure 1. General structure of silyl-substituted diphosphonic acids.*

## RESULTS AND DISCUSSION

### Aggregation

The aggregation state of the silyl-substituted diphosphonic acids (Figure 1) was found to vary dramatically as a function of the number of methylene groups bridging the phosphorus atoms. As can be seen in Table 1, the ligands with an odd number of bridging methylene groups exist as dimers, while those with an even number tend to form more highly aggregated species. While the origin of this even/odd effect is not fully understood in these systems, it appears to be due to the “zig-zag” pattern adopted by the alkyl chain separating the phosphorus atoms. This affects the orientation of the P=O and P-OH groups of the ligands and changes the geometry of the hydrogen bonded aggregates which can be formed between the ligand molecules. As is observed with normal “straight chain” alkanes, this even/odd effect also manifests itself in the melting points of the ligands, with the ligands containing an even number of bridging methylene groups exhibiting higher than expected melting points (Table 1). Molecular mechanics calculations are currently being performed to determine the most energetically stable conformations of these ligand aggregates.

<sup>1</sup>number of bridging methylene groups

### <sup>31</sup>P NMR and Infrared Spectroscopy

Due to the electron withdrawing effect of one phosphoryl group of the diphosphonic acid on the other, the P=O basicity and P-OH acidity of these ligands are expected to vary with the number of bridging methylene groups separating the phosphorus atoms. This is illustrated

clearly in the  $^{31}\text{P}$  NMR and infrared spectroscopy of these ligands. The  $^{31}\text{P}$  chemical shifts observed for these ligands are essentially the same as those observed for the corresponding monophosphonates in which the second phosphorus atom has been replaced by an electronegative substituent, such as chlorine [4]. As this electronegative group is separated from the phosphorus atom by an increasing number of methylene groups, the electron withdrawing effect diminishes and the P=O basicity increases, while the P-OH acidity decreases. The magnitude of this difference is expected to be the greatest between the ligands with one and two bridging methylene groups, for which the difference in  $^{31}\text{P}$  chemical shift is the greatest. When more than three methylene groups bridge the two phosphorus atoms, the  $^{31}\text{P}$  chemical shift observed is essentially the same as that for a monophosphonate, where the second phosphorus atom has been replaced by an alkyl substituent. Beyond this point, the P=O basicity and P-OH acidity are expected to remain constant with the incorporation of more bridging methylene groups, as evidenced by the constant  $^{31}\text{P}$  chemical shift observed for the ligands with four or more bridging methylene groups. Attempts are currently underway to determine the  $\text{pK}_\text{a}$ s of a series of analogous water-soluble, substituted diphosphonic acids to provide a more quantitative description of this effect.

A similar trend is observed in the infrared spectra of this series of ligands. As more methylene groups are incorporated between the phosphorus atoms of these ligands, the P=O stretching vibration is shifted to lower energy (Table 1). As in the  $^{31}\text{P}$  NMR spectra, the largest difference in energy is observed between the phosphoryl stretching bands of the ligands with one and two bridging methylene groups. The position of the stretching bands for the ligands with more than three bridging methylene groups are essentially identical. It should be noted that the position of the phosphoryl stretching band is very sensitive to hydrogen bonding. However, the same trend is also observed for the analogous series of tetraethyl diphosphonates, which do not form hydrogen-bonded aggregates, suggesting that this trend is primarily due to the electronic effect of phosphoryl groups on each other.

### Solvent Extraction

Figure 2a shows the nitric acid dependent extraction of Am(III) by 0.01 M solutions of the extractants in *o*-xylene. (For brevity, in this section, the ligands are denoted by their number of bridging methylene groups in parentheses.) Because a detailed investigation of the solvent extraction properties of this series of ligands has been described previously [2,3], for the purposes of the present discussion, it is sufficient to note that the extraction of Am(III) clearly exhibits the general trends expected as the number of methylene groups separating the phosphorus atoms is varied. A slope of negative three is exhibited by the acid dependencies of all of the extractants over at least part of the acid concentration range studied. This indicates that three protons are displaced from the extractant aggregates upon metal ion complexation, consistent with the plus three charge of the Am(III) cations. At higher acid concentrations, the extractants with more than three bridging methylene groups tend to exhibit acid dependency plots with a less negative or even positive slope. This suggests an increased importance of extraction by the neutral (fully protonated) extractant and provides evidence to support the reduced acidity of these ligands suggested by the  $^{31}\text{P}$  NMR and infrared spectroscopy experiments (*vide supra*).

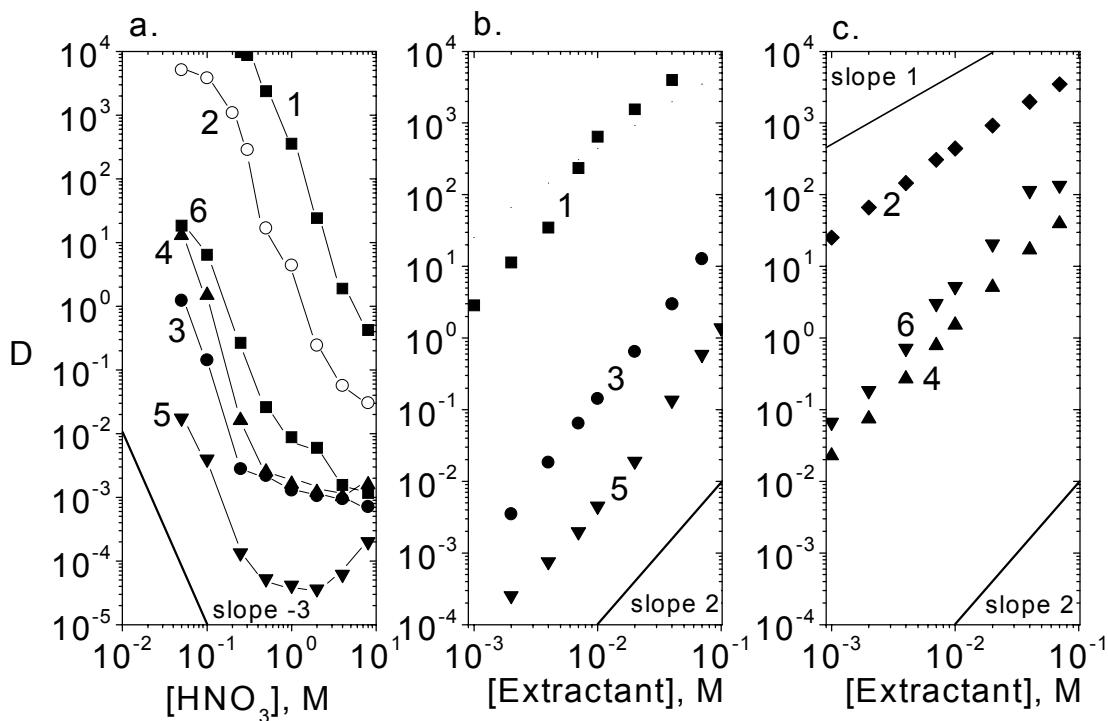

Figures 2b and 2c show the extractant dependencies for Am(III) extraction by the series of silyl-substituted diphosphonic acid ligands. The plots for the ligands with an odd number of bridging methylene groups exhibit extractant dependency slopes of two, suggesting that two dimeric ligand units participate in the extraction of each Am(III) cation. The efficiency of Am(III) extraction decreases as the number of bridging methylene groups incorporated into the ligand increases from 1 to 3 to 5, even though the basicity of the phosphoryl oxygen increases over the same series. This suggests that the chelate effect is the dominant factor in determining the differences in the efficiency of metal ion extraction observed for this series

of ligands. The six-membered rings formed upon complexation of metal ions by (1) is favored over the larger rings possible upon complexation by (3) or (5). Even though a true chelate effect is not expected to be present when considering the larger ring sizes possible upon complexation of metal ions by (3) and (5), the higher efficiency of metal extraction by (3) may be due to a small entropic advantage due to the closer proximity of two phosphoryl groups.

The ligands with an even number of bridging methylene groups exhibit Am(III) extraction dependency plots with slopes less than two, suggesting the importance of extraction by a single, highly aggregated species. Ligand (2) exhibits an extractant dependency slope of one, except at the lowest extractant concentrations, suggesting that Am(III) is primarily extracted by a single hexameric aggregate of (2). Ligands (4) and (6) exhibit extractant dependency slopes that are close to two at lower concentrations and decrease slightly as the extractant concentration increases. This agrees with the vapor pressure osmometry data, which suggests that these ligands exist as an equilibrium mixture of trimeric and hexameric species and monomeric and hexameric species in toluene, respectively. Thus, at lower extractant concentrations, Am(III) is extracted by two trimeric aggregates of (4), while at higher extractant concentrations, extraction by a single hexameric aggregate becomes important. The extraction of Am(III) by (6) involves monomeric and hexameric species. VPO data indicate that (6) is slightly less aggregated at a given extractant concentration than (2). This suggests that the ligand (6) monomer plays a more important role in metal ion extraction than the ligand (2) monomer, at a given extractant concentration, and may explain why an extractant dependency of slope one is not observed for (6). Additionally, since fitting of the vapor pressure osmometry data suggests that (6) tends to be more highly aggregated than (4) at a given extractant concentration, the slightly more efficient extraction of Am(III) observed for (6) versus (4) suggests that extraction by this single hexameric aggregate is more efficient than extraction by two trimeric species. Furthermore, extraction of Am(III) by (4) and (6) is more efficient than extraction by the dimeric ligands (3) or (5) under analogous conditions, suggesting that extraction by the single hexameric species is more efficient than extraction by two dimeric extractant units, except in the case of (1), where the chelate effect is the dominant factor in determining extraction efficiency.

#### **Comparison of Silyl-Substituted and 2-Ethylhexyl-Substituted Diphosphonic Acids**

Vapor pressure osmometry, solvent extraction and  $^{31}\text{P}$  NMR and infrared spectroscopy experiments show that incorporation of a silyl functionality into a diphosphonic acid does not adversely affect its metal ion extraction properties relative to analogous alkyl-substituted diphosphonic acids. Silyl-substituted diphosphonic acids exhibit the same aggregation behavior as and typically extract metal ions 2-3 times more efficiently than their 2-ethylhexyl-substituted analogues [2,3].  $^{31}\text{P}$  NMR and infrared spectroscopy experiments suggest that this increased extraction efficiency may be due to a slightly higher P=O basicity in the silyl-substituted diphosphonic acids [3].

(Numbers on plots refer to the number of bridging methylene groups).*

## CONCLUSIONS

The extraction of metal cations by a series of silyl-substituted diphosphonic acids has been shown to be affected by a number of factors, including the aggregation state of the ligand, the size of the chelate rings formed upon complexation, the basicity of the phosphoryl group and the relative acidities of the ligands. Metal ion extraction is most efficient when one methylene group bridges the two phosphorus atoms of the partially esterified diphosphonic acid extractant, due to the stability of the six-membered chelate rings formed upon metal ion complexation. As more bridging methylene groups are added, metal ion extraction tends to become less efficient and the aggregation state of the ligand becomes a more important factor in determining this efficiency. The incorporation of a silyl functionality into diphosphonic acids does not adversely affect the solvent extraction properties relative to analogous alkyl-substituted diphosphonic acids, with the silyl-substituted ligands typically extracting metal ions 2-3 times more efficiently, presumably due to the slightly higher basicity of their P=O groups.

## SEPARATION OF NaOH FROM SALTS BY WEAK HYDROXY ACIDS

**Tamara J. Haverlock, Peter V. Bonnesen, Gilbert M. Brown, C. Kevin Chambliss,

Promising liquid-liquid extraction chemistry has been identified for the separation of sodium hydroxide from alkaline salt solutions. Recent data show that a putative cation-exchange process using weakly acidic, lipophilic phenols or fluorinated alcohols appears especially attractive for practical use. Specific application of this concept is envisioned for treatment of nuclear waste stored at various United States Department of Energy (US DOE) sites.

### INTRODUCTION

The separation of sodium hydroxide from alkaline nuclear wastes represents significant potential value in terms of recycle to waste retrieval and sludge washing, whereupon additions of fresh sodium hydroxide to the waste can be avoided [1]. Potential savings are large because of the huge costs associated with waste disposal and the construction of new waste tanks, both of which are directly related to the net volume of the waste.

Eight fundamental approaches that could be undertaken for liquid-liquid extraction of sodium hydroxide have been conceptualized [2]. The eight approaches may be divided into two categories according to whether the underlying mechanism is ion-pair extraction or cation exchange. Ion-pair extraction involves transfer of sodium and hydroxide ions to the organic solvent and was found to be weak in the systems examined, as the selectivity of such processes tends to disfavor small, highly hydrated anions. The cation-exchange approach employs weak hydroxy acids such as phenols or fluorinated alcohols as sodium ion extractants. At the elevated pH values characteristic of alkaline tank waste, the hydroxy acids give up their protons in exchange for sodium ions. Contact of the resulting sodium phenoxide- or alkoxide-containing solvent with water results in hydrolysis, in which the protons given up by the water exchange with the organic-phase sodium ions to yield an aqueous sodium hydroxide solution and simultaneous regeneration of the neutral phenol or alcohol in the organic phase. Hence, there is no net consumption of reagent chemicals. Since only hydroxide *equivalents* and not actual hydroxide ions are extracted, the process has been termed “pseudo hydroxide extraction.” A series of experiments have demonstrated this concept with both selected phenols and novel fluorinated alcohols [2-4]. It was shown that the separation of sodium hydroxide is efficient and selective in competition with other salts present in alkaline tank waste. This paper summarizes the key findings and reports additional results toward a conceptual process.

## PROCESS REQUIREMENTS

Figure 1 depicts an idealized extraction cycle for a conceptual process. Waste containing NaOH, together with other salts and radionuclides, is passed through a multi-stage, counter-current contacting device (e.g., mixer-settlers, centrifugal contactors, or hollow-fiber dispersionless contactors) wherein NaOH is transferred to the solvent. The loaded solvent enters a multi-stage stripping section in which the NaOH is transferred to water, allowing the solvent to be recycled. The treated aqueous waste (still alkaline, but with a significantly reduced NaOH concentration) is then committed to further processing, ultimately to include a waste-immobilization process such as vitrification. The separated NaOH can then be used for further waste processing. Ideally, the entire process would require no adjustment of the waste stream, consume no chemicals, and add nothing to either the exiting partially NaOH-depleted waste or NaOH product streams. Use of water for stripping is highly compatible with such a process, necessitating extractants that release the NaOH upon contact with water. Except for perhaps simple evaporation, no further separation steps would then be needed to put the obtained NaOH product to direct use. Hence, extractant systems that are particularly attractive have adequate selectivity for NaOH, good loading directly from the waste, and good stripping into water. However, it should be kept in mind that practical extraction systems must ultimately possess other characteristics. Such characteristics include having accessible and economical extractants, good phase disengagement, good kinetics, minimal loss of the extractant to the aqueous phase, resistance to formation of third phases, and adequate chemical and radiolytic stability.

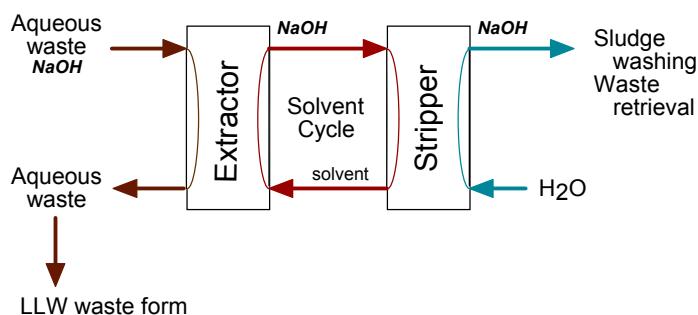

Figure 1. "Ideal" extraction cycle depicting the removal of NaOH from alkaline tank waste.

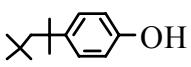

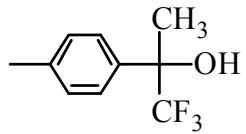

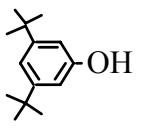

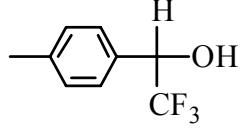

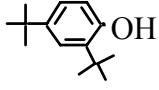

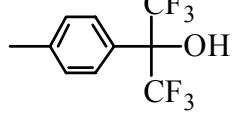

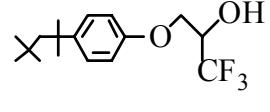

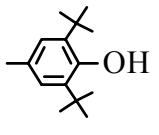

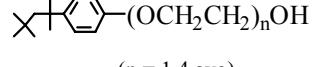

## SODIUM HYDROXIDE EXTRACTION

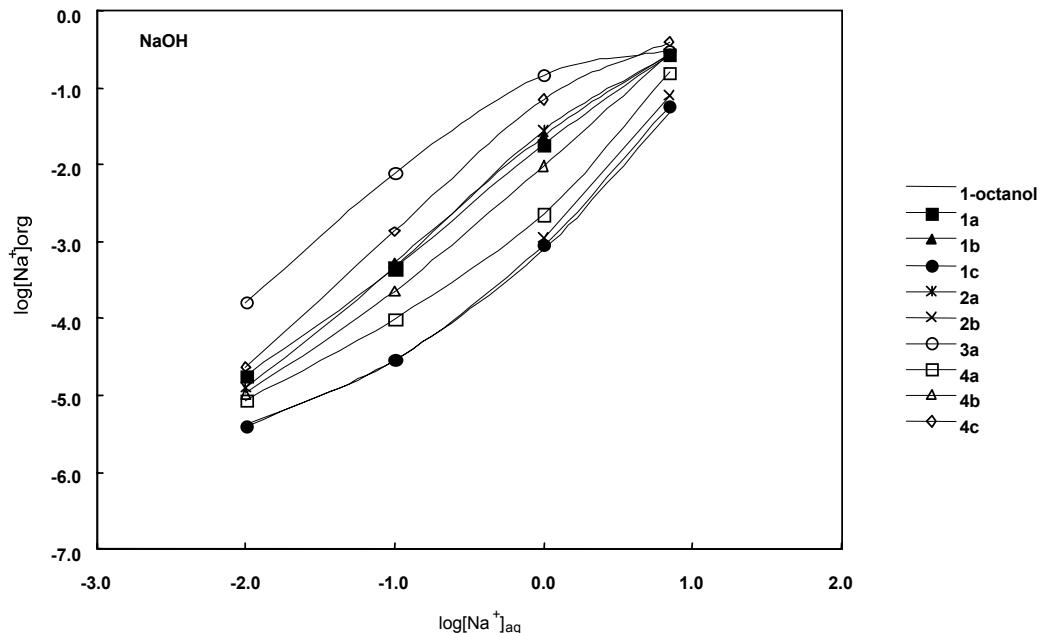

Isotherm behavior demonstrated the efficiency of sodium extraction from hydroxide solutions for the more acidic hydroxy acids tested. Table 1 lists the alkylated phenols and fluorinated alcohols used as extractants in the study. In the first set of experiments, equal volumes of an organic phase consisting of 0.2 M extractant dissolved in 1-octanol and an aqueous phase containing varying concentrations of sodium nitrate or sodium hydroxide with a spike of  $^{22}\text{Na}$  radio-tracer were gently equilibrated in vials on a rotating device at 25 °C [3]. A well-studied water-immiscible alcohol, 1-octanol, was chosen as the diluent to provide a suitable solvation environment for organic-phase sodium salts, as few alternative non-alcohol diluents compare in ability to solvate both cations and anions [5]. Plots of the equilibrium concentrations of sodium in the organic phase vs. the equilibrium concentrations of NaOH in the aqueous phase are shown in Figure 2. Most of the tested hydroxy acids significantly enhanced the extraction of sodium from aqueous NaOH over that which is extracted by 1-octanol alone. In contrast, little or no enhancement of sodium extraction from aqueous NaNO<sub>3</sub> solution by the same compounds was seen (plots not shown), an encouraging demonstration of the specificity of the tested hydroxy compounds toward hydroxide, albeit under non-competitive conditions.

Sodium hydroxide may be efficiently recovered from the solvent by stripping with water. Comparative data for the efficacy of the various hydroxy acids in extraction of NaOH together with data demonstrating the recovery of NaOH are given in Table 2. In the experiments, equal

with data demonstrating the recovery of NaOH are given in Table 2. In the experiments, equal volumes of an organic solution containing 0.20 M hydroxy acid in 1-octanol and an aqueous solution containing 7.0 M NaOH and a spike of  $^{22}\text{Na}$  radio-tracer were equilibrated at 25 °C [3]. Following extraction, the loaded solvents were stripped with an equal volume of pure water. Parallel experiments were performed with 7.0 M NaOH that did not contain the  $^{22}\text{Na}$  radio-tracer, and the total concentration of base in the aqueous strip solution was determined by titration. The data collectively demonstrate near-quantitative recovery of sodium hydroxide into water for all solvents tested, as evidenced by the near-unity values of the ratio  $[\text{base}]/[\text{Na}^+]_{\text{strip}}$ .

ND = Not determined.

Consistent with previous results on phenols [6-8], Figure 2 and Table 2 show that the strength of sodium extraction from NaOH solutions correlates directly with acidity or hydrogen-bond donor strength of the tested hydroxy acids, as perturbed by steric effects. By reference to Figure 2, relative differences in extraction efficiency for these compounds appear to become more pronounced at hydroxide concentrations less than 1 M, owing to the saturation seen for some compounds and steepened extraction by 1-octanol alone at higher hydroxide concentrations. Appreciable extraction of sodium from 7.0 M NaOH is observed for solvents containing compounds **1a**, **1b**, **2a**, **3a-c**, and **4a-c**, whereas extraction for solvents containing **1c**, **2b**, and **3d** is on the order of that observed for 1-octanol alone. The extraction of sodium from 7.0 M NaOH reveals the expected trend following the direction of decreasing extraction strength with increasing  $pK_a$  values [8]. Weak extraction by **1c** and **2b** is a reflection of this trend. Comparison of the data for compounds **4a-c** illustrates “fine tuning” of acidity within a single class of hydroxy acids by variation of a substituent -X (-X = -CH<sub>3</sub>, -H, or -CF<sub>3</sub>) in the core molecule *para*-CH<sub>3</sub>-C<sub>6</sub>H<sub>4</sub>-C(CF<sub>3</sub>)(X)-OH. The electron-withdrawing effect increases in the order -CH<sub>3</sub> < -H < -CF<sub>3</sub>, and accordingly, the resultant acidity of the alcohol as reflected by the amount of sodium extracted into the solvent phase ([Na]<sub>org</sub>, Table 2) also increases in that order. Not surprisingly, the stripping efficiency for these compounds (and also phenols **3a-d**) follows the opposite trend of the extraction efficiency. While solvents containing **3a** were impressive with respect to sodium extraction, only 82% of the extracted sodium ions were recovered as the hydroxide salt in a single contact. It may therefore be concluded that **3a** is approaching an upper limit of acidity in terms of efficient recovery of sodium hydroxide.

In order to evaluate extraction selectivity for hydroxide under competitive conditions, the extractants **1a**, **2a** and **3a** at 0.2 M in 1-octanol were equilibrated with aqueous solutions containing high concentrations of competing anions. Experiments employed solutions containing 1.75 M NaOH (typical of alkaline tank waste) plus either 3.5 M NaCl or 3.5 M NaNO<sub>3</sub>. A third aqueous solution was a complex simulant of an actual tank waste (Hanford tank AW-101 Double-Shell Slurry Feed, designated DSSF-7) that is high in hydroxide, nitrate, and aluminate ions, any of which may be co-extracted with sodium ion [3]. Extraction of OH<sup>-</sup> equivalents from the waste simulant gave very high selectivities over Al(OH)<sub>4</sub><sup>-</sup> ion with selectivity factors ranging from 280 (**1a**) to 650 (**2a**). Selectivity factors exceeded 20 for the key anion NO<sub>3</sub><sup>-</sup>. Since nitrate extraction is largely due to the background salt extraction by 1-octanol, it may be expected that selectivity will improve with use of higher, more practical concentrations of extractant.

For a process to be economical, the solvent must also prove to be recyclable as well as selective. Experiments were performed using solvent systems **1a** and **3a** at 0.2 M in 1-octanol and equilibrated with the waste simulant containing  $^{22}\text{Na}$  tracer at 25 °C to demonstrate recyclability of the extractants [3]. Both solvent systems performed consistently through four cycles with both extraction and stripping results at each cycle remaining constant, implying complete regeneration of the solvent in the stripping steps as well as negligible loss of extractant to the aqueous phases. However, recovery of the hydroxide from the phenol (**3a**) required a second strip that was not needed with **1a**. Preliminary results have shown that in the same tests, **4c** was not completely recyclable, which may be related to insufficient lipophilicity. Further work on the lipophilicity issue is in progress.

Toward maximizing solvent capacity, experiments have shown that extractant concentrations up to 1 M may be employed. In initial tests at 25 °C, it was found that when **1a** and **3b** are used at 1 M, the solvent becomes loaded with sodium exceeding 1 M. However, the viscosity increased significantly at high sodium loading, and gel formation was observed. This problem is readily alleviated at elevated temperatures, and isotherms at 60 °C are shown in Figure 3 for 1 M solutions of selected hydroxy acids [**1a**, **2a**, **3a**, **3b**] in 1-octanol. Sodium hydroxide was released from these loaded solvents on contact with water at 60 °C. To test a more complex case, 1 M **3a** was used as the extractant for hydroxide removal from a simple simulant containing 1.9 M free hydroxide, 0.70 M  $\text{NaAl(OH)}_4$ , and 3.5 M  $\text{NaNO}_3$ . The simulant was contacted successively three times at 60 °C with fresh solvent. After each contact, the simulant was analyzed for aluminum and sodium by ICAP (Thermo Jarrel Ash), while hydroxide was determined by titration. Essentially all free hydroxide was recovered, along with 24% of the sodium. Aluminum was not extracted. Subsequently, as shown by powder X-ray diffraction, Bayerite (a form of aluminum trihydroxide) precipitated in the simulant, releasing one additional recoverable mole of free hydroxide for each Al(III) precipitated.

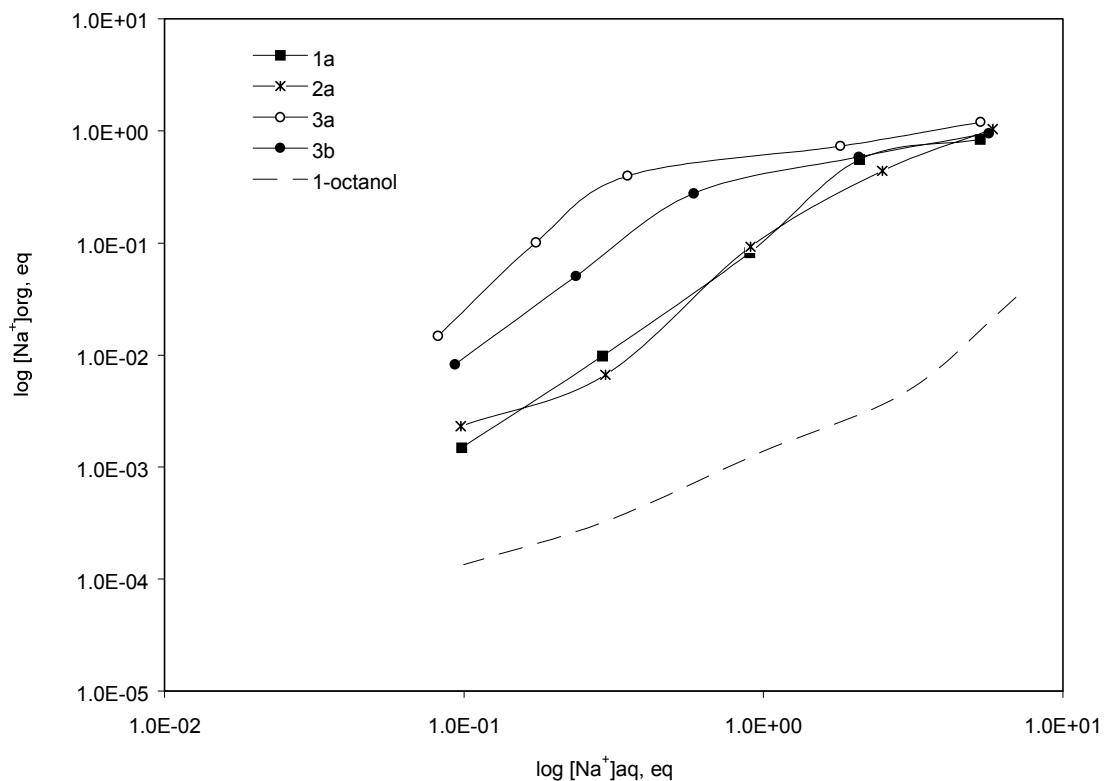

Figure 3. Equilibrium isotherms for the extraction of sodium hydroxide by selected hydroxy acids at 60 °C.

## CONCLUSIONS

Sodium hydroxide recovery adds value to the problem of tank waste remediation by enabling NaOH recycle for sludge-washing processes, thereby reducing the volume of waste that must undergo expensive vitrification. Extraction systems utilizing the concept of "pseudo hydroxide extraction" have been identified that have adequate selectivity for NaOH, good loading directly from the waste, and feasible stripping into water. A series of experiments demonstrated this concept with both selected phenols and novel fluorinated alcohols as cation exchangers for sodium ion. The majority of the hydroxy acids tested significantly enhanced the extraction of sodium from aqueous NaOH over that which is extracted by 1-octanol alone, but effected little or no enhancement of sodium extraction from aqueous NaNO<sub>3</sub> solution. These results from non-competitive extraction, as well as results from competitive extraction from a tank waste simulant are an encouraging demonstration of the specificity of the tested hydroxy compounds toward hydroxide. Furthermore, correlation between the strength of sodium extraction from NaOH solutions and the acidity or hydrogen-bond donor strengths of the tested hydroxy acids and phenols was demonstrated, as perturbed by steric effects. Not surprisingly, stripping efficiency for these compounds follows the opposite trend of the extraction efficiency, with those having the greatest extraction strength unable to release the hydroxide completely to water. Finally, in a test with an actual tank waste simulant, it was shown that over 90% of the total free hydroxide present can be extracted by a solvent containing the economical 4-*tert*-octylphenol (**3a**) at 1M, with the hydroxide subsequently recovered by stripping into water. Future research efforts are directed at testing this system with real waste at the USDOE's Hanford site.

## EXTRACTION OF SELECTED METAL CATIONS WITH THE ALKYLARYLPHOSPHINIC ACID: 2,4,4-TRIMETHYLPENTYLPHENYLPHOSPHINIC ACID

D. Nucciarone, B. Jakovljevic, B. A. Fir Medeiros, J. Hillhouse and M. DePalo

Cytec Canada, Inc., Niagara Falls, Ontario, Canada

The synthesis and physical properties of 2,4,4-trimethylpentylphenylphosphinic acid (TMPPPA) is described. Extraction of several metals, mostly from the first row transition elements, was examined and compared to that of other phosphinic acids. As a function of increasing pH the metals studied were found to extract in the order:

The metals Mn(II), Ca(II), and Cu(II) were observed to have very similar pH extraction profiles. Compared to bis(2,4,4-trimethylpentyl)phosphinic acid - the main component of CYANEX® 272 - the extraction order was similar, with the exception of Ca(II), which was observed to extract in preference to Co(II) and Mg(II). For all the metals studied extraction was observed at lower pH for TMPPPA by 1.1 to 1.6 pH units compared to CYANEX 272.

### INTRODUCTION

Organophosphorus acids of the type  $\text{R}_2\text{P}(\text{O})\text{OH}$  where R = alkyl, alkoxy, aryl or aryloxy have been extensively studied, particularly the alkyl and alkoxy derivatives. These latter two have found numerous commercial applications. To a lesser degree, diaryl and, more specifically, mixed alkyl/aryl derivatives have not been as thoroughly studied. While references to diaryl and mixed alkyl/aryl phosphoric acids and phosphonic acid esters can be found, there is little information available on the metal extraction behaviour of mixed alkyl/aryl phosphinic acids. With the advent of new synthetic methods allowing more facile preparation of this class of compounds, a more thorough investigation of these compounds was begun.

Replacement of an alkyl moiety with an aryl moiety on phosphorus would be expected to allow the introduction of unique electronic and steric effects. Compared to a saturated aliphatic substituent, an aryl group will act as an electron-withdrawing group and result in a stronger acid. The magnitude of this effect can be controlled by appropriate substitution on the phenyl ring. In addition to electronic effects the presence of a phenyl ring also permits tailoring of steric interactions between the co-ordinating ligand and the metal centre.

In an example where a mixed alkyl/aryl phosphinic acid showed improved characteristics over the dialkyl analogue, Mason *et al.*, examined octylphenylphosphinic acid and cyclooctylphenylphosphinic acid as extractants for M(III) and M(VI) cations (including selected actinides and lanthanides) [1]. They observed that the alkylphenyl derivatives were more effective extractants for M(III) cations than the dialkyl counterparts.

In this study we undertook to prepare and characterize 2,4,4-trimethylpentylphenylphosphinic acid and examine the extraction behaviour of various metal cations selected from the first row transition metals and alkali earths.

## EXPERIMENTAL

### Synthesis of TMPPPA

The general reaction of phosphine with 2,4,4-trimethylpent-1-ene under free radical initiated conditions was used to produce a blend of primary, secondary, and tertiary phosphines [2]. Isolation of the primary phosphine by distillation and subsequent reaction with bromobenzene using Pd catalysis produced a mixture containing (2,4,4-trimethylpentyl)phenylphosphine, with smaller quantities of the alkyldiphenylphosphine and unreacted primary alkylphosphine [3]. The crude mixture was washed with water to remove aqueous soluble salts. Excess bulk solvent (*o*-xylene) and unreacted primary alkylphosphine were removed to give a concentrate containing the alkylarylpophosphine as the principle component. Oxidation with 2 equivalents of hydrogen peroxide (as a 25% solution) gave, upon separation of the aqueous and organic phases, a mixture containing 88% TMPPPA, 7% (2,4,4-trimethylpentyl)diphenylphosphine oxide and 2% 2,4,4-trimethylpentylphosphonic acid.

Phosphonic acid impurities were reduced by dissolving the crude material (176 g) in methylene chloride (260 mL) and washing 3 times with 100 mL portions of 0.2 M NaOH.

Phosphine oxide levels were reduced by neutralizing the bulk organic phase with NaOH to form a micellar phase. This micellar phase was isolated, washed twice with hexanes, then converted back to the free acid by contacting with aqueous sulfuric acid.

This general procedure resulted in a purified white solid with a melting point of 66-69°C. Analysis by gas chromatography indicated a product purity of 98%. Nuclear magnetic resonance spectroscopy showed a signal for the phosphinic acid at 46.3 ppm (singlet) relative to 85% phosphoric acid as external standard.

### Metal Distribution Experiments

Single metal extraction studies were conducted as follows: A 200 mL solution containing  $1 \times 10^{-3}$  M metal sulfate and 0.5 M sodium sulfate was mixed with 200 mL of 0.1 M TMPPPA in EXXSOL D80® at room temperature (23-24°C). The pH was adjusted by dropwise addition of 50 g/L NaOH (accurately measured). At each pH value selected the mixture was allowed to agitate for 10 minutes then an equal volume of the organic and aqueous phase sampled. The aqueous phase was analyzed for metal content by atomic absorption spectrophotometry and the concentration of the metal in the organic phase determined by difference. Each experiment was done in duplicate.

### pKa Measurements

Solutions containing an accurately weighed amount of the purified phosphinic acid (0.2 g) in 75% isopropanol were titrated with standardized 0.1 N NaOH in water. The average of triplicate analyses gave a pKa of  $5.35 \pm 0.03$  at 23°C.

## RESULTS AND DISCUSSION

### General

The physical behaviour of the mixed organic and aqueous phases showed good phase separation behaviour at lower pH (< 5) with both phases separating cleanly after one minute but becoming worse at higher pH (> 5) with times increasing to up to 3.5 minutes.

Throughout these studies the aqueous phase remained clear but the organic phase was cloudy (due to the dispersion of fine droplets of the aqueous phase), the latter being easily clarified by centrifuging.

Figure 1 shows plots of % extraction versus pH for nine metal cations. The order of extraction as a function of increasing pH was seen to be:

The following general observations are noted. Fe(III) extracts at low pH and is well separated from its next nearest neighbor, Zn(II). Mn(II), Ca(II), and Cu(II) displayed overlapping extraction curves. Mg(II) and Ni(II) displayed extraction maximum near pH 4.9-5.0 with subsequent decline at higher pH. Extraction data for Mg(II) and Ni(II) above ca. pH 5.0 is not presented. At and above this pH, solids began forming which dispersed in the organic phase. This behaviour was reversible such that lowering the pH restored homogeneous liquid phases, but was otherwise not investigated further. This suggests a solubility issue of the Mg and Ni complexes which may be addressed by changing the nature of the diluent or addition of modifiers.

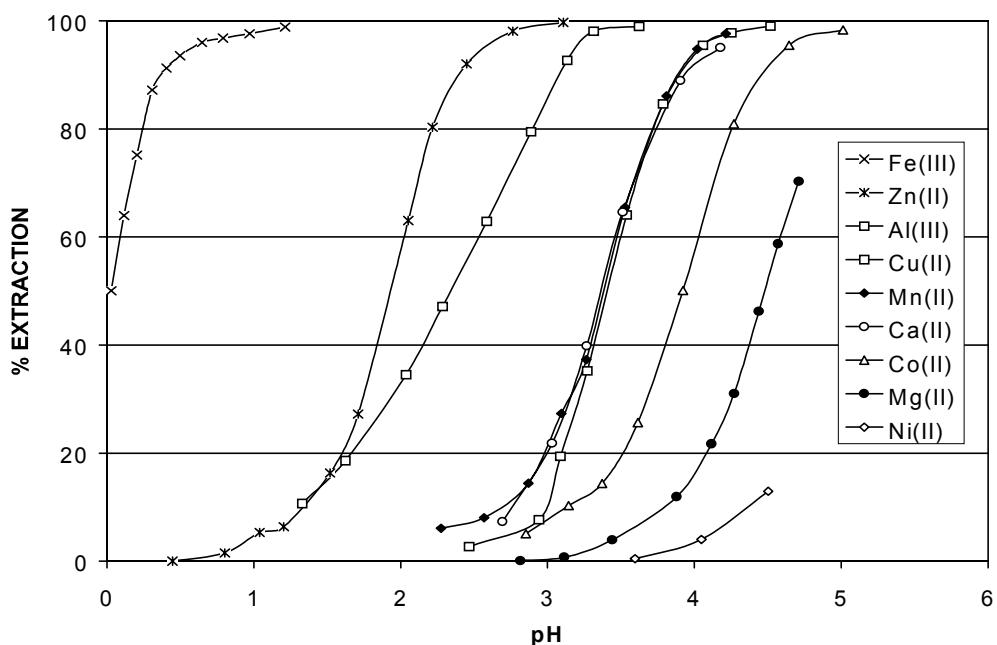

Figure 1. Extraction of metal ions by TMPPPA from sulfate solutions.

In comparison, the ordering for CYANEX 272 is:

Comparison of the order of extraction of the metals with CYANEX 272 shows a similar ordering except for Ca(II). Whereas Ca(II) extracts at higher pH than Co(II) with CYANEX 272, this element is extracted at lower pH than Co(II) for TMPPPA. The practical implication is the possibility of gypsum precipitation in SX processes having sulfate feed liquors containing Ca(II) [4].

Table 1 shows pH values at 50% extraction for the extractants TMPPPA and CYANEX 272 [5,6]. The data presented was obtained under the same conditions and allows direct comparison. Comparison with CYANEX 272 shows the extraction pH for all metals is lower by 1.1 to 1.6 pH units for TMPPPA (where data are available).

*Table 1. Comparison of  $pH_{50}$  for TMPPA and CYANEX 272.*

Metal Cation	$pH_{50}$		$\Delta pH_{50}$ (TMPPA-CYANEX 272)
	TMPPA	CYANEX 272 [5,6]	
Fe(III)	0.03	1.6	-1.6
Zn(II)	1.9	3.0	-1.1
Al(III)	2.4	3.4	-1.0
Mn(II)	3.4	4.9	-1.5
Ca(II)	3.4	-	-
Cu(II)	3.4	4.6	-1.2
Co(II)	3.9	5.2	-1.3
Mg(II)	-	5.95	-
Ni(II)	-	7.05	-

Extraction of cationic metal species by organophosphorus acids can be described by the general equation:

where  $n$  is the charge on the metal cation and  $y$  is the degree of association of the organophosphorus acid. Under the conditions studied, a value of  $y = 2$  has been observed [1], therefore Equation (1) becomes:

An equilibrium constant,  $K$ , can be defined from (2) as:

$$K = \frac{[\overline{M(H_{2x-n}A_{2x})}][H^+]^n}{[M^{n+}][\overline{(HA)_2}]^x} \quad (3)$$

Defining the distribution coefficient,  $D$ , as the ratio of the total metal concentration in the organic phase to that in the aqueous phase gives:

$$K = D[H^+]^n / [\overline{(HA)_2}]^x \quad (4)$$

and

$$\log D = n[\text{pH}] + \log K + x \log [\overline{(HA)_2}] \quad (5)$$

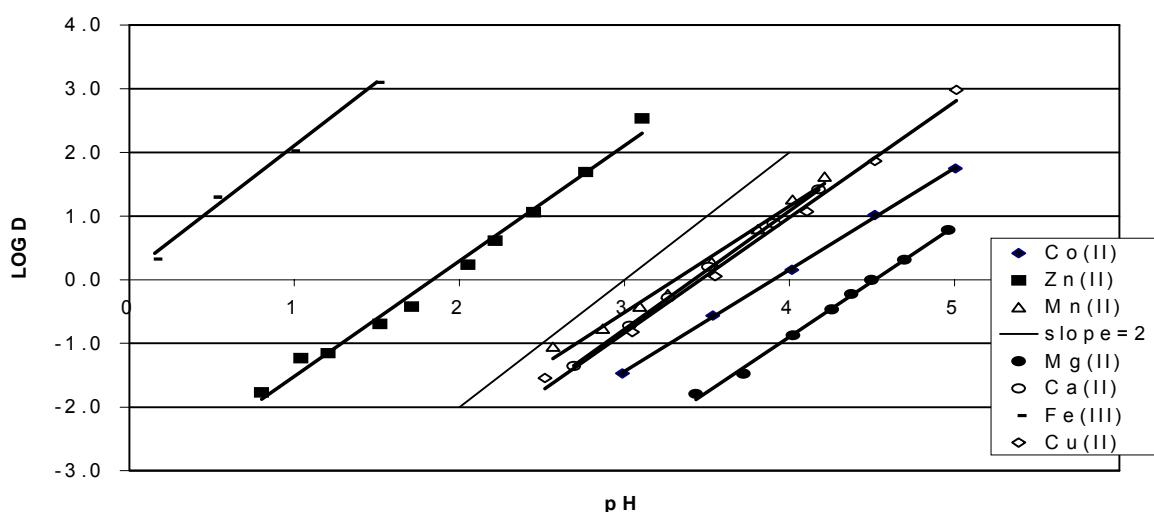

Under conditions where  $(HA)_2$  is constant, a plot of  $\log D$  versus pH should yield a straight line with slope  $n$ . Under these experimental conditions, the extractant concentration is much greater than the metal concentration, thus  $(HA)_2$  can be considered constant.

Values of  $n$  obtained from the plots of  $\log D$  versus pH are listed in Table 2. A plot of  $\log D$  versus pH for the various metals is shown in Figure 2.

Table 2. Values of  $n$  from plots of  $\log D$  versus  $pH$ .

Metal Cation	$n$	
	This work	CYANEX 272 [5,6]
Fe(III)	2.0	1.7
Zn(II)	1.8	1.8
Mn(II)	1.7	1.6
Ca(II)	1.9	-
Cu(II)	1.8	1.7
Co(II)	1.7	1.8
Mg(II)	1.7	-
Ni(II)	-	1.8

Figure 2. Plot of  $\log D$  versus  $pH$ .

Values obtained are all slightly less than two for the dipositive cations, as would be described by the stoichiometry:

Similar results were obtained for the case of CYANEX 272 [5,6]. The extraction behaviour observed for Ni(II) did not permit this type of analysis. Data for Al(III) did not show a straight line relationship for  $\log D$  versus  $pH$ . The value  $n = 2$  for Fe(III) is significantly lower than the expected value of 3 (*vide infra*).

### Iron Behaviour

A survey of the literature shows that the nature of the Fe(III) species extracted by CYANEX 272 varies markedly depending on the extraction conditions. For Fe(III) extracted with CYANEX 272 under the same conditions as reported in this study, a similar value of  $n = 2$  was observed [5,6]. With sulfate anion present in significant quantities (at 0.5 M), iron sulfate species predominate in the aqueous phase under acidic conditions [7,8]. Under these conditions, an equilibrium between ferrous and ferric has also been suggested [6]. Assuming a ferric species, then a 2:1 phosphinate:iron ratio for the extracted complex suggests that the iron species in the solvent phase may be a mixed ligand species containing both an inorganic and organic component. The nature of the extracted specie(s) in sulfate systems requires further investigation.

In a second study of Fe(III) extraction with CYANEX 272, curve-fitting models suggest that, in a nitrate medium, three species predominate having the stoichiometries  $\text{FeA}_3$ ,  $\text{FeA}_3(\text{HA})_3$ , and  $\text{Fe}(\text{NO}_3)_3(\text{HA})_3$ , where A is the phosphinate anion [9]. In the same study these authors rejected the presence of polynuclear complexes. The presence of  $\text{FeOH}^{2+}$  at  $\text{pH} < 2$  was seen as being of little significance. The extraction efficiency was found to be dependent on the nature of the anion such that extraction efficiency followed the order nitrate > chloride > sulfate at any given pH.

In a third study, where Fe(III) extraction by DEHPA, PC-88A, and CYANEX 272 was examined, results showed a phosphinate:iron ratio of 1:1 when Fe(III) was extracted by CYANEX 272 from a chloride media at 0.05 N acid strength [10]. Interestingly, a 2.8:1 stoichiometry was observed for both DEHPA and PC-88A under stronger acid conditions of 0.35 N. The phosphinate complex was postulated to be a dihydroxyphosphinatoiron(III) species,  $\text{FeA(OH)}_2$ .

## CONCLUSIONS

The extraction of several metals by the mixed alkyl/aryl phosphinic acid, TMPPPA, has shown a shift to lower pH compared to its dialkyl counterpart. Fe(III) is shifted to a low  $\text{pH}_{50}$  value of 0.03, separating it cleanly from its next neighbour Zn(II) having  $\text{pH}_{50}$  of 1.93. This may make it attractive for Fe(III) impurity removal from acidic sulfate solutions. Extraction of Ca preferable to Co makes it less attractive in Co extraction applications from sulfate media. Manganese, similar to CYANEX 272, is also extracted at lower pH than Co.

# THERMODYNAMICS OF THE EXTRACTION OF SELECTED METAL IONS BY DI(2-ETHYLHEXYL) ALKYLENEDIPHOSPHONIC ACIDS

Emmanuel O. Otu and Renato Chiarizia\*

Department of Chemistry, Indiana University Southeast, New Albany, IN, USA

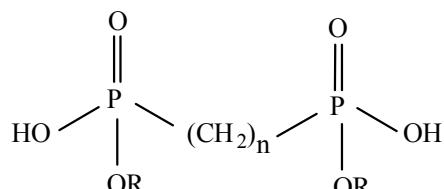

\*Chemistry Division, Argonne National Laboratory, Argonne, IL, USA

The thermodynamics of extraction of Am(III), Sr(II) and U(VI) from aqueous HNO<sub>3</sub> solutions by o-xylene solutions of P,P'-di(2-ethylhexyl) methylene- (H<sub>2</sub>DEH[MDP]), ethylene- (H<sub>2</sub>DEH[EDP]), and butylene- (H<sub>2</sub>DEH[BuDP]) diphosphonic acids has been studied by the temperature coefficient method in the 25.0 to 60.0 °C range. Both extractant aggregation and extraction stoichiometries did not change with temperature. The extraction of Am(III) by H<sub>2</sub>DEH[MDP], and that of U(VI) by all three extractants are strongly driven by both enthalpy and entropy variations. The extraction of Sr(II) by H<sub>2</sub>DEH[MDP] is enthalpy driven. The extraction of Am(III) by H<sub>2</sub>DEH[EDP] and H<sub>2</sub>DEH[BuDP] is mainly driven by entropy changes. The extraction of Sr(II) by H<sub>2</sub>DEH[EDP] and H<sub>2</sub>DEH[BuDP] is characterized by an unfavorable entropy change and is not indicative of a micellar-type extraction mechanism.

## INTRODUCTION

P,P'-di(2-ethylhexyl) alkylidendiphosphonic acids have been proposed for actinide separation and pre-concentration procedures [1]. In Structure I, n is one, two or four, for P,P'-di(2-ethylhexyl) methylene- (H<sub>2</sub>DEH[MDP]), ethylene- (H<sub>2</sub>DEH[EDP]), and butylene- (H<sub>2</sub>DEH[BuDP]) diphosphonic acid, respectively. Solvent extraction reagents containing the diphosphonic acid group, the solvent extraction equivalent of the Diphenix® resin [2], exhibit extraordinary affinity for tri-, tetra- and hexavalent actinides [3-5].

In toluene solutions H<sub>2</sub>DEH[MDP] exists as dimers [6], H<sub>2</sub>DEH[EDP] as hexamers [7], while H<sub>2</sub>DEH[BuDP] exists mainly as trimeric aggregates [5]. The effect of these aggregation states on metal extraction has been reported in previous works [3-5]. Extractant dependencies higher than one were measured for the extraction of Am(III), Sr(II) and U(VI) by either H<sub>2</sub>DEH[MDP] or H<sub>2</sub>DEH[BuDP]. However, with H<sub>2</sub>DEH[EDP], extractant dependencies equal to unity were reported for these ions indicating that, with H<sub>2</sub>DEH[EDP], extraction probably takes place through a micellar-type mechanism similar to other highly aggregated extraction systems [8-10].

The objective of this work was to gain information on the thermodynamics of metal solvent extraction by the di(2-ethylhexyl) alkylenediphosphonic acids, by using the method of the temperature coefficient of the metal distribution ratio. Given the pronounced differences in extraction processes and type of metal species formed in the organic phase, it was reasonable to expect that the extraction of metal ions by H<sub>2</sub>DEH[MDP], H<sub>2</sub>DEH[EDP] and H<sub>2</sub>DEH[BuDP] should be accompanied by different enthalpic and entropic contributions to the overall stability of the species formed.

## EXPERIMENTAL

<sup>241</sup>Am and <sup>233</sup>U were obtained from ANL stocks. <sup>85</sup>Sr was obtained from Isotope Products Laboratories (Burbank, CA). The extractants were prepared and purified as described in previous works [3-5]. All other reagents were of analytical grade.

The aggregation of the extractants in toluene at various temperatures was measured by vapor pressure osmometry (VPO) using a Jupiter Model 833 vapor pressure osmometer as described previously [5-7,11]. The extractant solutions used for the VPO measurements were first equilibrated with appropriate nitric acid solutions in order to run the VPO measurements under conditions similar to those used for distribution ratio measurements. The distribution ratios, D, defined as the ratio of metal concentrations in the organic and aqueous phase, were measured following the procedure reported earlier [11]. The measured molar D values were converted to molal values by multiplying them by the appropriate aqueous to organic phase density ratio.

## RESULTS AND DISCUSSIONS

### Aggregation

The aggregation state of the extractants redetermined at temperatures up to 60°C confirmed the results of previous studies at 25°C for concentrations up to about 0.1 M, i.e., H<sub>2</sub>DEH[MDP] is dimeric, H<sub>2</sub>DEH[EDP] is hexameric, and H<sub>2</sub>DEH[BuDP] is predominantly trimeric in toluene [5-7]. The details of the VPO results and data treatment are reported elsewhere [11].

### Extraction Equilibria

The extraction stoichiometries of the target ions by the extractants at ambient temperature have previously been determined [3-5]. Although the extractant aggregation did not change in the 25 to 60°C temperature range, it was necessary to redetermine the extraction stoichiometries at various temperatures. The temperature coefficient method for the determination of thermodynamic parameters is based on the assumption that the same equilibria are operative in the temperature range of interest. If the extraction equilibria were different at different temperatures, the temperature coefficient method would not be applicable and calorimetric measurements would be required. The acid dependencies for the three reagents were always equal to the formal charges of the metal cation being extracted. The extractant dependencies were essentially the same as those previously reported at room temperature [3-5] and are summarized in Table 1.

*Table 1. Extractant dependencies in the 25 to 60 °C temperature range.*

Ion	H <sub>2</sub> DEH[MDP]	H <sub>2</sub> DEH[EDP]	H <sub>2</sub> DEH[BuDP] trimer
Am(III)	2.0	1.0	1.5
Sr(II)	2.0	1.0	2.0
U(VI)	1.0	1.0	1.0

The extraction equilibrium of americium by the dimeric H<sub>2</sub>DEH[MDP] can be written as:

where H<sub>2</sub>A stands for the diphosphonic acid and the bar indicates organic phase species. Similar equations can be written for the other extractants and metal ions using the values of the extractant (Table 1) and acid dependencies determined experimentally. By neglecting aqueous phase nitrate ion complexation [12], the thermodynamic equilibrium constant for the exemplificative case of the Am(III)-H<sub>2</sub>DEH[MDP] system can be written as:

$$K_{\text{Am},\text{MDP}} = 4D \frac{[\text{H}^+]^3}{C_{\text{H}_2\text{A}}^2} \frac{\gamma_{\pm,\text{HN}}^6}{\gamma_{\pm,\text{AmN}}^4} \quad (2)$$

where D is the molal distribution ratio,  $\gamma_{\pm,\text{HN}}$  and  $\gamma_{\pm,\text{AmN}}$  are the mean ionic molal activity coefficients of HNO<sub>3</sub> and Am(NO<sub>3</sub>)<sub>3</sub>, respectively, and C<sub>H<sub>2</sub>A</sub> is the molal analytical concentration of the extractant. Corresponding extraction equilibria and equilibrium constant expressions can also be written for the hexameric H<sub>2</sub>DEH[EDP] and the trimeric H<sub>2</sub>DEH[BuDP], as well as for Sr(II) and U(VI) extraction by the three extractants. The mean molal activity coefficients of americium (europium was used as a stand-in), strontium and uranyl nitrates at tracer concentration level in solutions of HNO<sub>3</sub> at the relevant ionic strengths were calculated according to the method of Kusik and Meissner [13]. Other details of the equilibrium constants calculations can be found elsewhere [14]. The values of the thermodynamic equilibrium constant calculated at different temperatures are given in Table 2.

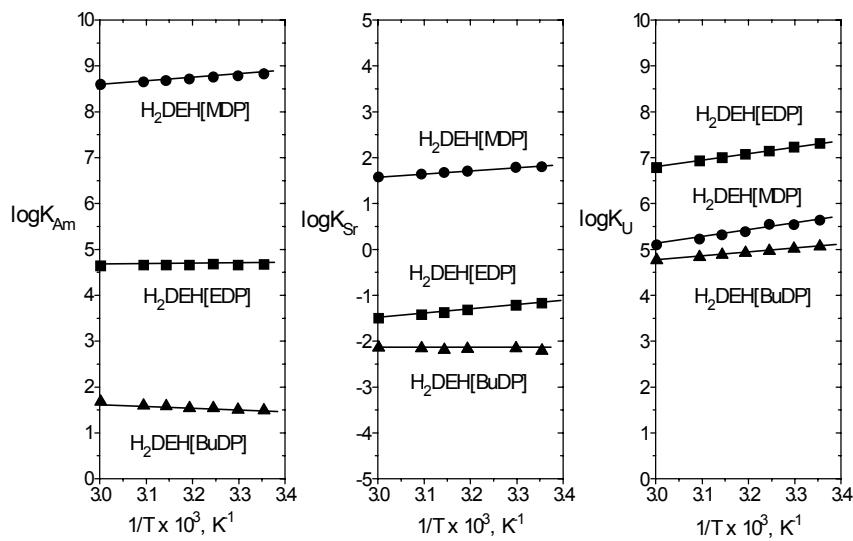

*Table 2. Equilibrium constants for the extraction of Am(III), Sr(II) and U(VI) by H<sub>2</sub>DEH[MDP], H<sub>2</sub>DEH[EDP] and H<sub>2</sub>DEH[BuDP] in o-xylene.*

T °C	logK Am(III)			logK Sr(II)			logK U(VI)		
	MDP	EDP	BuDP	MDP	EDP	BuDP	MDP	EDP	BuDP
25	8.82	4.67	1.49	1.80	-1.17	-2.21	5.63	7.31	5.06
30	8.78	4.66	1.50	1.78	-1.22	-2.16	5.54	7.23	5.01
35	8.75	4.68	1.54	-	-	-	5.54	7.14	4.96
40	8.71	4.66	1.54	1.70	-1.32	-2.17	5.38	7.07	4.92
45	8.68	4.66	1.58	1.67	-1.38	-2.19	5.32	7.00	4.88
50	8.65	4.66	1.59	1.64	-1.42	-2.16	5.22	6.93	4.83
60	8.59	4.64	1.67	1.58	-1.50	-2.15	5.10	6.78	4.76

The uncertainties in these equilibrium constant values (in log units), estimated from the statistical analysis of the logK data, are 0.05 for americium, 0.03 for strontium, and 0.08 for uranium, respectively. The logK values clearly reflect the fact that H<sub>2</sub>DEH[MDP] has the highest extraction efficiency for the three metal ions (except for U(VI)) and H<sub>2</sub>DEH[BuDP] the least [3-5].

### Free Energy, Enthalpy and Entropy Variations

The enthalpy and entropy changes of the extraction processes were calculated from the slopes (= -ΔH°/2.303R) and intercepts (= ΔS°/2.303R), respectively, of the plots of logK vs. 1/T, with R = 8.314 JK<sup>-1</sup>mol<sup>-1</sup>. Previously discussed conditions regarding the constancy of ΔH° and aqueous phase activity coefficients over the temperature range investigated apply here as well [15-17]. Plots of logK for each metal ion vs. 1/T are shown in Figure 1.

**Figure 1.** Effect of temperature on the extraction of Am(III), Sr(II) and U(VI) from aqueous  $\text{HNO}_3$  by  $\text{H}_2\text{DEH}[\text{MDP}]$ ,  $\text{H}_2\text{DEH}[\text{EDP}]$  and  $\text{H}_2\text{DEH}[\text{BuDP}]$  in *o*-xylene.

The  $\Delta H^0$  and  $\Delta S^0$  values calculated from the plots, along with the  $\Delta G^0$  values calculated from  $\Delta G^0 = -2.303RT \log K$  are given in Table 3. The uncertainties reported for  $\Delta H^0$  and  $\Delta S^0$  are the standard errors of the slopes and intercepts, respectively. Those for  $\Delta G^0$  were obtained from the standard error of  $\log K$ .

In the extraction of a metal cation by a liquid cation exchanger, the net enthalpy and entropy variations of the extraction reaction are the result of several different processes. The dehydration of the metal cation generally involves a positive enthalpy variation ( $\Delta H > 0$ ) as a result of the breakage of ion-water bonds, and a positive entropy variation ( $\Delta S > 0$ ) due to an increase of disorder in the system. The opposite will occur for the hydration of the proton. On the other hand, metal coordination by the organic ligand will result in a negative enthalpy variation ( $\Delta H < 0$ ), as a consequence of replacing relatively weak hydrogen bonds with stronger metal coordination bonds, and in a negative entropy variation ( $\Delta S < 0$ ) due to the increase of order caused by the new bonds. The deprotonation of the extractant will produce opposite effects.

Among the ions investigated, Am(III) behaves in a way which is easier to rationalize based on the arguments outlined above. The  $\Delta H^0$  values for Am(III) extraction exhibit a trend along the  $\text{H}_2\text{DEH}[\text{MDP}]$ ,  $\text{H}_2\text{DEH}[\text{EDP}]$ ,  $\text{H}_2\text{DEH}[\text{BuDP}]$  series, with the reaction being exothermic for the first, thermoneutral for the second, and endothermic for the third extractant, respectively. The trend in  $\Delta H^0$  can be interpreted as arising from the formation of progressively less stable chelate rings along the diphosphonic acids series, as the length of the alkyl chain separating the two phosphorus atoms of the molecule increases. A favorable enthalpic term is observed only for Am(III) extraction by  $\text{H}_2\text{DEH}[\text{MDP}]$ , a ligand with which the metal can form several highly stable six-membered chelate rings. In all cases, the extraction is facilitated by a favorable entropic term, as typically observed for the formation of chelate complexes [18]. The almost zero or positive enthalpy variation with a concomitant favorable entropy variation confirm for  $\text{H}_2\text{DEH}[\text{EDP}]$  and for  $\text{H}_2\text{DEH}[\text{BuDP}]$  a micellar-like type of extraction process [15,19]. The diphosphonic acids form organic phase aggregates characterized by highly ordered structures. When the metal ion is transferred to the organic phase, it becomes part of these structures adding little order to the system. Consequently, the entropy variation is mainly determined by the disorder generated by the metal ion dehydration.

*Table 3: Thermodynamic parameters for the extraction of Am(III), Sr(II) and U(VI) by H<sub>2</sub>DEH[MDP], H<sub>2</sub>DEH[EDP] and H<sub>2</sub>DEH[BuDP] in o-xylene.*

Ion	Extractant	ΔG° at 25 °C kJ/mol	ΔH° kJ/mol	ΔS° at 25 °C J/mol/K
Am(III)	H <sub>2</sub> DEH[MDP]	-50.3 ± 0.1	-12.5 ± 0.2	127 ± 1
	H <sub>2</sub> DEH[EDP]	-26.7 ± 0.5	-1.4 ± 0.5	85 ± 2
	H <sub>2</sub> DEH[BuDP]	-8.5 ± 0.7	9.5 ± 0.9	60 ± 4
Sr(II)	H <sub>2</sub> DEH[MDP]	-10.3 ± 0.1	-12.3 ± 0.4	-7 ± 1
	H <sub>2</sub> DEH[EDP]	6.7 ± 0.3	-18.2 ± 0.4	-84 ± 2
	H <sub>2</sub> DEH[BuDP]	12.6 ± 0.2	2.1 ± 1.2	-35 ± 4
U(VI)	H <sub>2</sub> DEH[MDP]	-32.2 ± 0.5	-29.9 ± 2.1	8 ± 2
	H <sub>2</sub> DEH[EDP]	-41.7 ± 0.6	-28.5 ± 0.7	44 ± 3
	H <sub>2</sub> DEH[BuDP]	-28.9 ± 0.3	-16.3 ± 0.3	42 ± 2

The extraction of Sr(II) by H<sub>2</sub>DEH[MDP] is enthalpy driven. With H<sub>2</sub>DEH[EDP] and H<sub>2</sub>DEH[BuDP], Sr(II) extraction is very inefficient, as indicated by the positive values of ΔG°, as a result of strongly unfavorable entropic terms. The H<sub>2</sub>DEH[EDP] results are indicative of strong metal-ligand coordination and attendant increased ordering. The negative entropic terms for all three extractants also suggest that the hydration of the exchanged protons predominates over the dehydration of the metal ion. Overall, in the extraction of Sr(II) by the three diphosphonic acids, the enthalpy and entropy changes do not lend themselves to indicate a micellar-type extraction mechanism.

The extraction of U(VI) by all three extractants is strongly driven by both enthalpy and entropy variations, which testifies to the extremely high affinity exhibited especially by H<sub>2</sub>DEH[MDP] and H<sub>2</sub>DEH[EDP] for U(VI). The negative enthalpy change associated with metal coordination predominates over the other opposing enthalpic factors. The increasing ΔS° values observed for U(VI) extraction in moving from H<sub>2</sub>DEH[MDP] to the other extractants may be due, at least in part, to the overlapping of a solvation mechanism with the ion exchange mechanism. Extraction of uranyl nitrate by alkylphosphoric acids as solvated complexes at relatively high aqueous acidities is well-known [20], and has been reported for alkylenediphosphonic acids as well [3-5]. In a solvation mechanism, the neutral salt is transferred into the organic phase without simultaneous transfer of protons in the other direction. Consequently, the positive entropy variation associated with the dehydration of the extracted cation and anions dominates the net entropy variation. A solvation mechanism is more likely for extractants having a more basic P=O group as observed along the H<sub>2</sub>DEH[MDP], H<sub>2</sub>DEH[EDP], H<sub>2</sub>DEH[BuDP] series (21), and would therefore explain the ΔS° trend reported for U(VI) in Table 3.

# COMPARISON OF SOLVENT EXTRACTION METHOD WITH ION-EXCHANGE METHOD FOR THE SEPARATION AMONG ALKALINE EARTH METAL IONS IN THE PRESENCE OF CRYPTANDS AS THE MASKING REAGENTS

Shigekazu Tsurubou, Shigeo Umetani\* and Yu Komatsu\*\*

Asahi University, Gifu, Japan

\* Kyoto University, Kyoto, Japan

\*\* Kanazawa Institute of Technology, Ishikawa, Japan

Synergetic solvent extraction and ion-exchange methods have been examined and compared for the selectivity among alkaline earth metal ions in the presence of cryptands as ion-size selective masking reagents. Cryptand [2.2.2] and [2.2.1] were applied as the ion-size selective masking reagents for both the synergetic solvent extraction of alkaline earth metal ions with benzoyltrifluoroaceton (BFA) and tri-n-butylphosphate (TBP) into cyclohexane, and ion exchange with the strongly acidic cation exchange resin (Amberlite 200CT). Quantitative separation between Mg and Ca was achieved in the presence of cryptand [2.2.1] by the synergetic solvent extraction method. Also, Mg and Ca were quantitatively separated from Sr in the presence of cryptand [2.2.2] by both separation methods examined here.

## INTRODUCTION

It is well known that the selectivity of metal ions in the solvent extraction and ion-exchange methods are largely governed by their ion size. Generally, the extractability of metal ions having smaller ionic radii is higher with open chain chelating reagents such as  $\beta$ -diketones. The selectivity series for divalent metal ions given by ion exchange reaction, are reverse relationship compared to that of solvent extraction. On the other hand, the stability of the complex formation between the macrocyclic ionophores such as cryptands and the metal ions especially alkali and alkaline earth metal ions exhibits a quite different tendency. Thus, combining the chelating reagents (or ion-exchange resins) and macrocyclic ionophores could possibly result in more selective or quantitative separation systems.

The stability constants of inclusion complexes between several kinds of cryptands and alkali, alkaline earth metal cations have been reported by Lehn *et al.* in 1975 [1]. Some stability constants of alkali and alkaline earths with cryptand [2.2.1] and [2.2.2] are shown in Table 1. These stability constants show the considerable differences between neighboring two metals, for example, between Mg and Ca with cryptand [2.2.1] and between Ca and Sr with cryptand [2.2.2]. In this study, the comparison of the effect of cryptands on the synergetic solvent extraction and the ion-exchange methods has been examined.

*Table 1. Formation constants ( $\log \beta$ )<sup>\*</sup> [ $M^{2+} + CR \rightarrow M(CR)^{2+}$ ].*

[2.2.2]	< 2	4.4	8.0

\* taken from [10].

## EXPERIMENTAL

### Materials

Cryptand [2.2.1] and cryptand [2.2.2] were purchased commercially from Merck, BFA and TBP from Dojindo and Nacalai Tesque, respectively, and they were used without further purification. Ion-exchange resin (Amberlite 200CT) was purchased from ORGANO, and was conditioned with dilute hydrochloric acid solution and sodium chloride solution in order to convert the resin to the sodium form. Other chemicals were reagent-grade materials. Distilled, and de-ionized water was used throughout.

### Apparatus

The metal ion concentrations in the aqueous phase were determined by an atomic absorption spectrophotometer (Shimadzu, Model AA-660). pH measurements were made with a Horiba (Model F-22) pH meter. A Taitec (Model BR-30LF) bioshaker was used to equilibrate the aqueous and organic (or the ion-exchange resin) phases at a controlled temperature ( $25\pm1^\circ\text{C}$ ).

### Procedure

#### *Solvent extraction method*

A 10 ml portion of an aqueous phase containing the required amount of metal ion (less than  $2\times10^{-4}\text{M}$ ), cryptand (0.01M) and 0.02M Good's buffer such as tris(hydroxymethyl)-aminomethane was adjusted to the desired pH with hydrochloric acid and tetramethyl ammonium hydroxide. The aqueous phase was shaken for 2-20 h until the reaction reached equilibrium with an equal volume of an organic phase (cyclohexane) containing the required amount of BFA and TBP or TOPO at  $25\pm1^\circ\text{C}$ . After centrifugation of the mixture, the pH in the aqueous phase was measured. The metal concentration in the aqueous phase was determined by atomic absorption spectrophotometry and in the organic phase was similarly measured after back-extraction with a hydrochloric acid solution.

#### *Ion exchange method*

A 5 ml portion of an aqueous phase containing the required amount of metal ion (less than  $2\times10^{-4}\text{ M}$ ), cryptand (0.02 M) and 0.02 M Good's buffer such as tris- (hydroxymethyl)-aminomethane was adjusted to the desired pH with hydrochloric acid and tetramethyl ammonium hydroxide. The aqueous phase was shaken for 3-5 h until the reaction reached to the equilibrium with required amount of ion-exchange resin (0.02-0.1g) at  $25\pm1^\circ\text{C}$ . After centrifugation of the mixture, the pH in the aqueous phase was measured. The metal concentration in the aqueous phase was determined by atomic absorption spectrophotometry and the amount of metal ions adsorbed onto ion-exchange resin were calculated from the concentrations of aqueous phase before and after the reaction.

## RESULTS AND DISCUSSION

### Synergetic Extraction of Alkaline Earth Metal Ions with BFA and TBP in the Presence of Cryptand [2.2.1] or [2.2.2] [2],[3]

The results for the extraction of magnesium, calcium and strontium with  $2.5 \times 10^{-3}$  M BFA and TBP into cyclohexane are shown in Figure 1. Logarithm of the distribution ratio of metal ions between the cyclohexane and the aqueous phase,  $\log D$ , is plotted against the pH. Alkaline earths were extracted in the order  $Mg > Ca > Sr$ , which is the same order in which their ionic radii decrease. The slopes of the straight portion of the plots are two, indicating that two protons are released through the extraction reaction.

Figure 2 shows the results for the extraction of Mg and Ca into cyclohexane with  $2.5 \times 10^{-3}$  M BFA and TBP in the presence of 0.01 M cryptand [2.2.1]. The distribution ratio of Ca decreases rapidly over pH 7.5, while that of Mg are quite similar to those in the absence of cryptand [2.2.1] as shown in Figure 1. Mg can be separated from Ca quantitatively at the pH range 8.5 - 9.5 where more than 98% of Mg ( $\log D^* > 1.80$ ) is extracted into cyclohexane with slope of +2, while more than 99% of Ca ( $\log D^* < -2$ ) remains in the aqueous phase at the same time. On the other hand, the distribution of Sr was very low ( $\log D^* < -3$ ) in the pH range 7.0 - 9.5. The application of cryptand [2.2.2] to the synergistic extraction of alkaline earths with BFA and TBP has been also examined. Figure 3 shows the results for the extraction of Mg, Ca and Sr into cyclohexane with 0.015 M BFA and TBP in the absence (blank symbols) and presence (solid symbols) of 0.01 M cryptand [2.2.2]. Very low and constant (about  $\log D^* \sim -2.0$ ) extraction of Sr was observed over pH 5.2, while that of Mg and Ca are quite similar to those in the absence of cryptand [2.2.2]. By controlling the concentration of BFA and TBP, Sr can be separated quantitatively from Mg and Ca in the pH range 6.7-8.0, where more than 99% ( $\log D^* > 2$ ) of Ca and Mg are extracted into cyclohexane with slopes of +2, while more than 99% ( $\log D^* < -2$ ) of Sr remains in the aqueous phase at the same time.

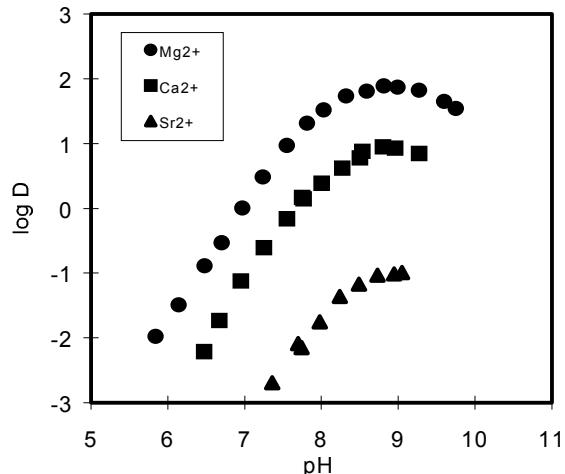

Figure 1. Extraction of alkaline earths into cyclohexane with BFA and TBP.  
 $[Mg^{2+}] = 3 \times 10^{-5}$  M,  $[Ca^{2+}] = 2 \times 10^{-4}$  M,  $[Sr^{2+}] = 10^{-4}$  M  
 $[BFA]_0 = [TBP]_0 = 2.5 \times 10^{-3}$  M.

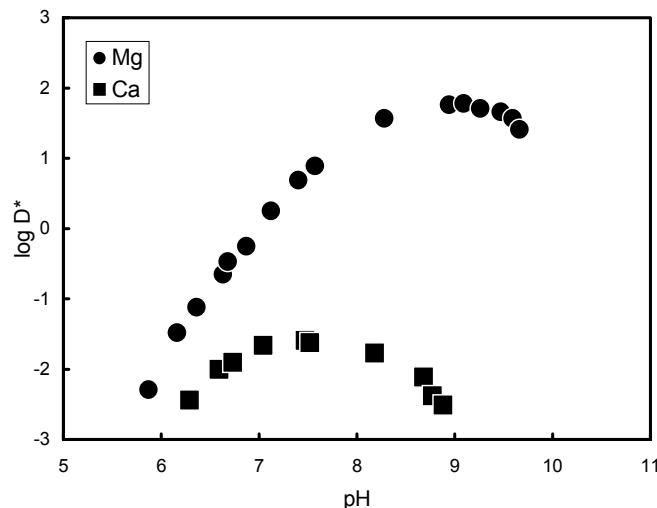

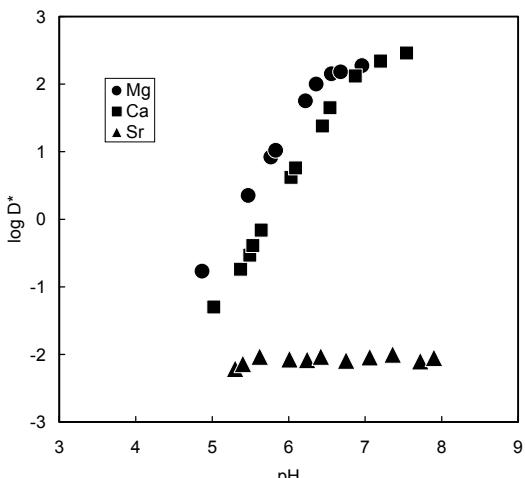

Figure 2. Extraction of Mg and Ca into cyclohexane with BFA and TBP in the presence of cryptand[2.2.1].  
 $[BFA]_0 = [TBP]_0 = 2.5 \times 10^{-3}$  M,  $[L] = 0.01$  M.

**Figure 3.** Extraction of Mg, Ca and Sr into cyclohexane with BFA and TBP in the presence of cryptand[2.2.2].  
[BFA]<sub>0</sub>=[TBP]<sub>0</sub>=0.015 M, [L]=0.01 M.

In the synergetic extraction of alkaline earths ( $M^{2+}$ ) with BFA (HA) and TBP, the extraction constant,  $K_{ex,s}$ , can be written as follows:

$$\log K_{ex,s} = \log D + 2 \text{ pH} + 2 \log [HA]_0 + 2 \log [TBP]_0 \quad (1)$$

where subscript o denotes the organic phase and D,  $[MA_2(TBP)_2]_0/[M^{2+}]$ , is the distribution ratio of alkaline earth metal ions. The distribution ratio of alkaline earth metal ions in the presence of cryptand [2.2.1] or [2.2.2] (L),  $D^*$ , can be expressed as follows:

$$D^* = K_{ex,s} [HA]_0^2 [TBP]_0^2 / [H^+]^2 \{ 1 + \beta[L] \} \quad (2)$$

where  $\beta$  is the complex formation constant of cryptand [2.2.1] or [2.2.2] with alkaline earth metal ions in the aqueous phase, defined as  $[ML^{2+}]_0/[M^{2+}][L]$ . Dividing D by  $D^*$  gives

$$D/D^* = 1 + \beta[L] \quad (3)$$

The values of  $\log K_{ex,s}$  and  $\log \beta$  for alkaline earth metal ions calculated from Eqs. (1), (2) and (3) are summarized in Table 2. These  $\log \beta$  values are in good agreement with those in Table 1.

From these results, combining the chelating reagents and the macrocyclic ionophores, such as cryptand [2.2.1] and cryptand [2.2.2], having an opposite complexation tendency has been proved to be a powerful means to separate alkaline earth metal ions each other.

**Table 2.** Extraction parameters for alkali and alkaline earth metals.

	$\log K_{ex,s}$	$\log \beta$	$\log \beta^*$
(A)	Mg	-3.50	---
	Ca	-4.60	6.85
(B)	Ca	-4.24	---
	Sr	-5.78	7.93

### **Ion-Exchange Separation of Alkaline Earth Metal Ions with Strongly Acidic cation Exchange Resin (Amberlite 200CT)**

Conventional strongly acidic cation exchange resins, such as the commercially available Amberlite 200CT and Dowex 50W, can generally adsorb alkaline earth metal ions exclusively. In the ion-exchange reaction, metal ions having smaller ionic radii exhibit lower distribution ratio. However, the separation among alkaline earth metal ions is difficult to obtain with strongly acidic cation exchange resins. Figure 4 shows the results for the adsorption of alkaline earth metal ions onto Amberlite 200CT as a function of pH in the presence of cryptand [2.2.1].

The percent adsorption of Ca and Sr decreases rapidly above pH 6, while that of Mg is almost similar to these in the absence of cryptand [2.2.1]. Mg can be separated from most of the Ca and Sr in the pH range 6–8 where almost 100% of Mg is adsorbed by the resin, while more than 75–80% of Ca and Sr remain in the aqueous phase. By adding 2-propanol to the aqueous phase, the masking effect of cryptand is enhanced, resulting in a decrease of percent adsorption of Ca and Sr. This can be explained by the fact that the lower dielectric solvents are less capable of solvating cations, thus favoring their complex formation with cryptands in the aqueous phase [4].

**Figure 4.** Adsorption of alkaline earth metal ions.  
Amberlite200CT(Na)=0.02g, [2.2.1]=0.02M, 30%-2prop.

**Figure 5.** Adsorption of alkaline earth metal ions,  
Amberlite200CT(Na)=0.02g, [2.2.2]=0.02M, 30%-2prop.

Figure 5 also shows the results for the percent adsorption of alkaline earth metal ions onto Amberlite 200CT as a function of pH in the presence of cryptand [2.2.2]. Sr can be separated from Mg and Ca quantitatively in the pH range 6–8 where more than 90% of Mg and Ca are adsorbed onto resin, while 100% of Sr remains in the aqueous phase. Effective complex formation of metal ions with cryptands can be achieved at pH 6-7 according to the stability constants, respectively. However, discussions about the increasing adsorption of metal ions in higher pH region have not been extended at this time.

## CONCLUSIONS

Highly selective separation systems for alkaline earth metal ions have been successfully developed via synergistic extraction with benzoyltrifluoroacetone (BFA) and tri-n-butylphosphate (TBP), and by ion exchange with Amberlite 200CT in the presence of cryptands [2.2.1] and [2.2.2] as the ion-size selective masking reagents. On comparison of the above two methods, under these experimental conditions, quantitative separation among alkaline earth metal ions was not obtained by ion exchange, while the synergistic solvent extraction method could achieve quantitative separation of Mg from Ca and Sr in the presence of cryptand [2.2.1] and of Mg and Ca from Sr in the presence of cryptand [2.2.2]. However, combining the chelating reagent or ion-exchange resin and cryptands has been proven to be a powerful means to separate alkaline earth metal ions. This concept is universal and is of particular interest because it generates many opportunities for analytical and separation chemistry.

## SOLVENT EXTRACTION OF METAL IONS WITH NOVEL 4-ACYL-5-PYRAZOLONES HAVING CROWN ETHER MOIETY AS INTRAMOLECULAR SYNERGIST

Shigeo Umetani, Shoko Yamazaki\* and Kaoru Ogura\*\*

Kyoto University, Uji, Japan

\* Nara University of Education, Nara, Japan

\*\*Ube National College of Technology, Ube, Japan

Novel 4-acyl-5-pyrazolones having the crown ether moiety as the intramolecular synergist have been synthesized and the solvent extraction of various metal ions are examined. It is expected that the crown ether moiety could behave as the intramolecular synergist and that the selectivity could be governed by the acylpyrazolone and the crown ether parts. These ligands are powerful and selective extracting reagents for alkali, alkaline earth and divalent transition metal ions, and the selectivity is quite unique depending on the intramolecular synergist.

Alkali metal ions are readily extracted into chloroform. The selectivity is governed primarily by the crown ether moiety depending on the cavity size. Alkaline earth metal ions are also readily extracted into chloroform, however in this case, the selectivity is governed by both the acylpyrazolone and the crown ether parts. Among the divalent transition metal ions, the extraordinarily high extractability is observed for  $Mn^{2+}$ ,  $Cd^{2+}$  and  $Pb^{2+}$ . Such anomalous extraction is also given in the synergistic extraction of  $Mn^{2+}$ ,  $Cd^{2+}$  and  $Pb^{2+}$  with acylpyrazolone and benzo-crown ethers used separately.

### INTRODUCTION

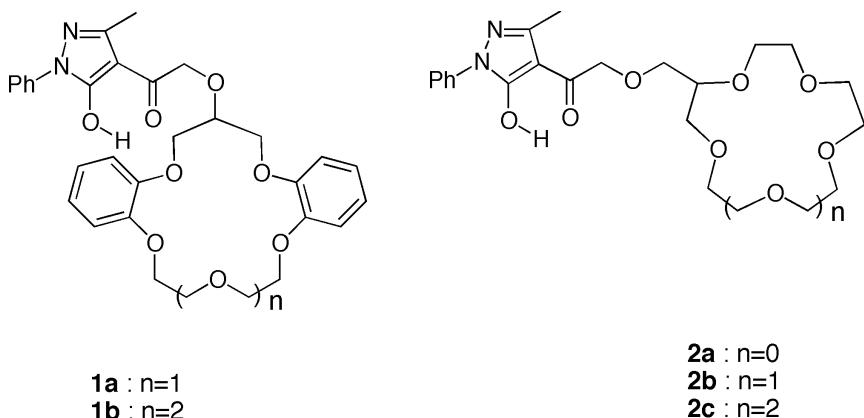

Macrocyclic ligands such as crown ethers and cryptands have been utilized in the metal ion separations [1]. Many novel macrocyclic ligands have been prepared as ion pair extraction reagents exhibiting excellent separation ability [2]. It was shown that water soluble macrocyclic ligands could enhance the separability when they were added in the aqueous phase as ion size selective masking reagents in the extraction of alkali, alkaline earth and lanthanide metal ions with the chelate extraction reagents [3, 4]. On the contrary, it is known that neutral macrocyclic ligands can work as synergists when they were added in the organic phase. In both cases, unique separability would be expected since the selectivity of the macrocyclic ligands and the chelating reagents is quite different.

In this work, 4-acyl-5-pyrazolone-substituted dibenzo-16-crown-5, dibenzo-19-crown-6 (**1a-b**), 12-crown-4, 15-crown-5 and 18-crown-6 (**2a-c**) were designed and synthesized by facile coupling reactions between  $\alpha$ -chloro 4-acyl-5-pyrazolone and the corresponding hydroxy crown ethers. It is expected that the crown ether moiety could work as the intramolecular synergist and the selectivity would be governed by the acylpyrazolone and the crown ether parts.

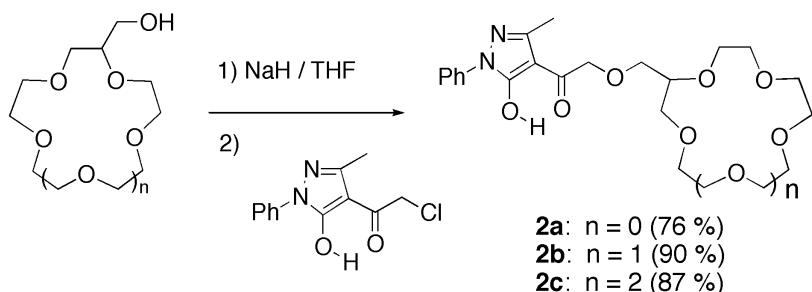

## EXPERIMENTAL

### Materials

4-Acyl-5-pyrazolone-substituted dibenzo-16-crown-5 and dibenzo-19-crown-6 (**1a-b**) were synthesized from 1-phenyl-3-methyl-4-chloroacetyl-5-pyrazolone and readily accessible hydroxy crown ethers. Hydroxy crown ethers were treated with NaH in THF at room temperature. The addition of 1-phenyl-3-methyl-4-chloroacetyl-5-pyrazolone to the mixture and stirring overnight produced **1a-b** in 48% and 95% yields, respectively. The detailed procedures, elemental analysis and spectroscopic data are available in the literature [5].

4-Acyl-5-pyrazolone-substituted 12-crown-4, 15-crown-5 and 18-crown-6 (**2a-c**) were also prepared from 1-phenyl-3-methyl-4-chloroacetyl-5-pyrazolone and commercially available hydroxy crown ethers in a similar manner. The details will be published elsewhere.

Other chemicals were of reagent-grade materials. Distilled, and de-ionized water was used throughout.

### Extraction Procedure

A  $10 \text{ cm}^3$  aliquot of an aqueous phase containing  $1 \times 10^{-4} \text{ M}$  of metal ion, 0.1 M tetramethylammonium chloride to keep the ionic strength at 0.1 and 0.01 M 2-morpholinoethanesulfonic acid as buffering component was adjusted to the desired pH with hydrochloric acid or tetramethylammonium hydroxide solution. The aqueous phase was shaken with an equal volume of chloroform containing the required amount of ligand at  $25^\circ\text{C}$  for one hour. A shaking time of 1 h was found to be long enough to reach equilibrium. After centrifugation, the pH of the aqueous phase was measured and taken as the equilibrium value. The metal concentration in the aqueous phase was determined by atomic absorption spectrometry. That in the organic phase was measured in the same way after back-extraction by stripping with hydrochloric acid solution. The sum of the metal concentrations in the two phases agreed well with the initial concentration.

## RESULTS AND DISCUSSION

### Extraction of Alkali and Alkaline Earth Metal Ions

The extraction of alkali metal ions into chloroform with 0.01 M **2a** is shown in Figure 1. 0.1 M tetramethylammonium chloride was added to the aqueous phase to keep the ionic strength at 0.1. Alkali metal ions were extracted in the order  $\text{Li}^+ > \text{Na}^+ > \text{K}^+ > \text{Rb}^+ > \text{Cs}^+$  with **2a**,  $\text{Na}^+ > \text{K}^+ > \text{Rb}^+ > \text{Cs}^+ > \text{Li}^+$  with **2b** and  $\text{K}^+ > \text{Na}^+ > \text{Rb}^+ > \text{Cs}^+ > \text{Li}^+$  with **2c**. Alkali and alkaline earth metal ions are not extractable with acylpyrazolone alone because of water molecules attached to the metal chelate that reduce the hydrophobicity remarkably. As seen in the figure, the separability and the extractability with these ligands are notable. It is clear that the crown ether moiety works as an intramolecular synergist. The extraction reaction was found to follow Eqn. (1) according to the slope analysis.

where M and HA stand for the metal ion and the extraction reagent, and the subscript o denotes the species in the organic phase. The extraction constant ( $K_{\text{ex}}$ ) can be written as follows

$$K_{\text{ex}} = [\text{MA}_n]_o [\text{H}^+]^n / [\text{M}^{n+}] [\text{HA}]^n_o = D [\text{H}^+]^n / [\text{HA}]^n_o \quad (2)$$

where D is the distribution ratio defined as  $[\text{MA}]_o / [\text{M}^+]$ . It was found that **2b** and **2c** are more powerful than the combination of 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone and benzo-15-crown-5 or benzo-18-crown-6.

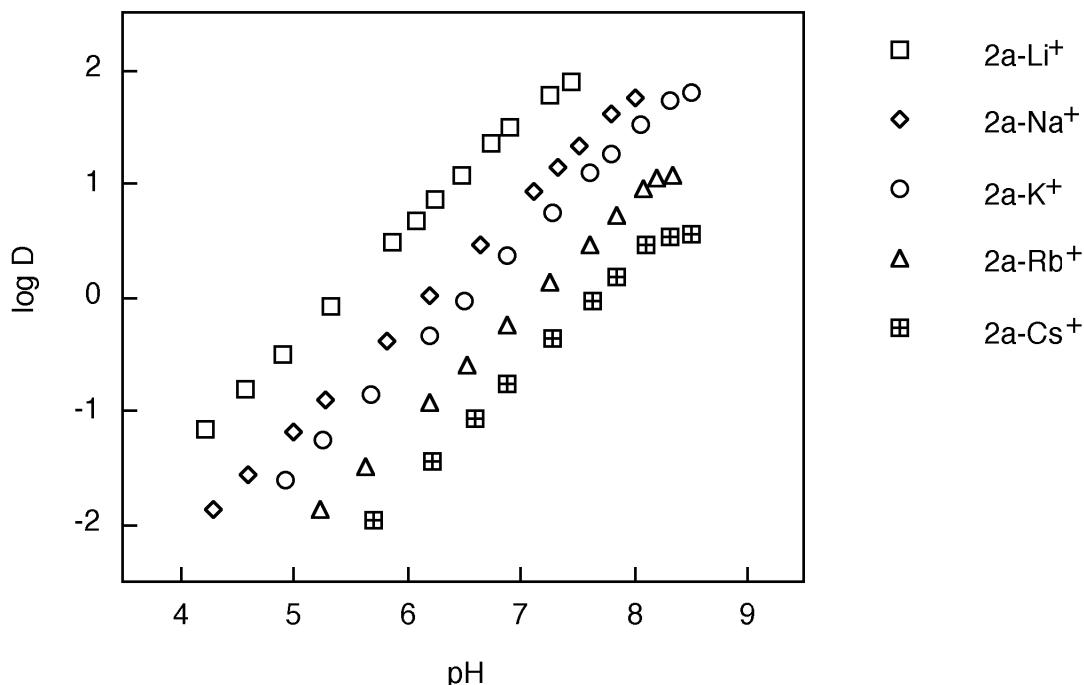

Figure 1. Extraction of alkali metal ions with **2a**.

The  $\log K_{\text{ex}}$  values for the extraction of alkali metal ions with **2a-c** are plotted in Figure 2 (a) against the  $\log K$  values which are the formation constant with 12-crown-4, 15-crown-5 and 18-crown-6 in methanol measured by conductometric titration. Fairly good linear relationship can be seen between  $\log K_{\text{ex}}$  and  $\log K$  indicating that the extraction selectivity with **2a-c** for the extraction of alkali metal ions is governed primarily by the crown ether moiety depending on the cavity size.

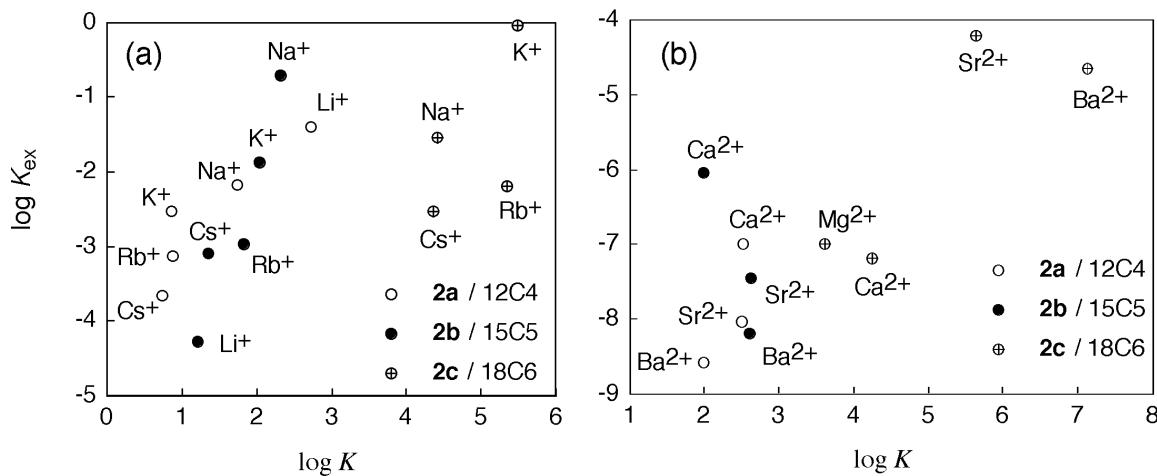

Figure 2. Relationship between the extraction constants ( $\log K_{\text{ex}}$ ) with **2a-c** and the formation constants ( $\log K$ ).

Alkaline earth metal ions were extracted in the order  $\text{Mg}^{2+} > \text{Ca}^{2+} > \text{Sr}^{2+} > \text{Ba}^{2+}$  with **2a**,  $\text{Ca}^{2+} > \text{Mg}^{2+} > \text{Sr}^{2+} > \text{Ba}^{2+}$  with **2b** and  $\text{Sr}^{2+} > \text{Ba}^{2+} > \text{Ca}^{2+} > \text{Mg}^{2+}$  with **2c**. The  $\log K_{\text{ex}}$  values for the extraction of alkaline earth metal ions with **2a-c** are plotted in Figure 2 (b) against the formation constants, the  $\log K$ , with 12-crown-4, 15-crown-5 and 18-crown-6 in methanol measured by conductometric titration. However, no good linear relationship could be seen in the figure, unlike the case for alkali metal ions, indicating that the selectivity is governed by both the acylpyrazolone and the crown ether parts.

#### Extraction of Divalent Transition Metal Ions

The extractions of divalent transition metal ions were made with 0.01 M **2c** into chloroform and are shown in Figure 3.

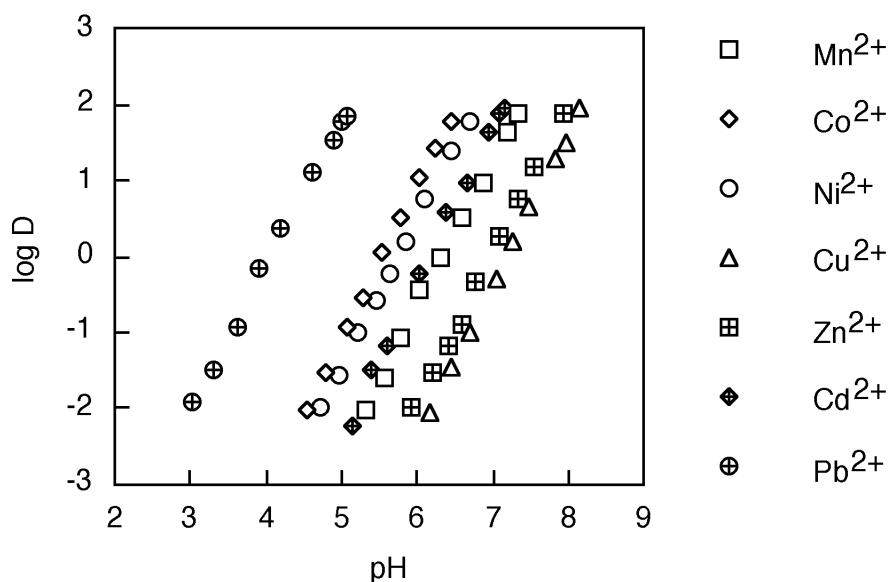

Figure 3. Extraction of divalent transition metal ions with **2c**.

Divalent transition metal ions were extracted in the order,  $\text{Pb}^{2+} > \text{Mn}^{2+} > \text{Cd}^{2+} > \text{Cu}^{2+} > \text{Zn}^{2+} > \text{Co}^{2+} > \text{Ni}^{2+}$  with **1a** and  $\text{Pb}^{2+} > \text{Cu}^{2+} > \text{Mn}^{2+} > \text{Zn}^{2+} > \text{Co}^{2+} > \text{Cd}^{2+} > \text{Ni}^{2+}$  with **1b**. With **2a-c** the orders are  $\text{Cu}^{2+} > \text{Zn}^{2+} > \text{Co}^{2+} > \text{Pb}^{2+} > \text{Ni}^{2+} > \text{Mn}^{2+} > \text{Cd}^{2+}$  with **2a**,  $\text{Pb}^{2+} > \text{Cu}^{2+} > \text{Zn}^{2+} > \text{Co}^{2+} > \text{Ni}^{2+} > \text{Cd}^{2+} > \text{Mn}^{2+}$  with **2b** and  $\text{Pb}^{2+} > \text{Co}^{2+} > \text{Ni}^{2+} > \text{Cd}^{2+} > \text{Mn}^{2+} > \text{Zn}^{2+} > \text{Cu}^{2+}$  with **2c**. The extraction orders with the present ligands are unique. Among the divalent transition metal ions, the extraordinarily high extractability was seen for  $\text{Mn}^{2+}$ ,  $\text{Cd}^{2+}$  and  $\text{Pb}^{2+}$ . It is well known that the extractability for these metal ions is much lower than the other divalent transition metal ions such as  $\text{Cu}^{2+}$ ,  $\text{Co}^{2+}$ ,  $\text{Ni}^{2+}$  and  $\text{Zn}^{2+}$  with the conventional chelating extractants. It was reported that the formation constants ( $K$ ) of divalent transition metal ions with 15-crown-5 or 18-crown-5 are low except for that of  $\text{Pb}^{2+}$  with 18-crown-6 [2]. No linear relationship can not be seen between  $\log K_{\text{ex}}$  and  $\log K$ . Such anomalous extraction was also given in the synergistic extraction with 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone and benzo-15-crown-5 or benzo-18-crown-6. The adduct formation constants ( $\beta$ ) defined as Eqn. (3) were obtained examining the effect of the benzo-crown ether ( $L$ ) concentration in the organic phase.

The  $\log \beta$  values for  $\text{Mn}^{2+}$ ,  $\text{Cd}^{2+}$  and  $\text{Pb}^{2+}$  with both benzo-15-crown-5 and benzo-18-crown-6 are considerably larger than those for the other divalent transition metal ions, which can not be rationalized considering the formation constants ( $K$ ) as described above. The extraordinarily high extractability for  $\text{Mn}^{2+}$ ,  $\text{Cd}^{2+}$  and  $\text{Pb}^{2+}$  would be attributable to the specific adduct formation reaction presumably based on the complex structure.

## A NOVEL SYNERGISM FOUND IN THE EXTRACTION OF In(III) ION WITH TTA AND TOPO IN CARBON TETRACHLORIDE

Akiko Hokura, Junji Noro\*, Satoshi Kusakabe and the late Tatsuya Sekine

Science University of Tokyo, Tokyo, Japan

\*Nissan Arc Co., Ltd., Yokosuka, Japan

Solvent extraction of indium(III) with 2-thenoyltrifluoroacetone (Htta) in carbon tetrachloride from aqueous 0.1 mol dm<sup>-3</sup> sodium nitrate solution at pH 2 was measured in the absence and presence of trioctylphosphine oxide (TOPO). Addition of TOPO enhanced the extraction, although the solvation of In(tta)<sub>3</sub> by TOPO was not found. The complexes extracted by the cooperation with Htta and TOPO was presumed to be In(tta)<sub>a</sub>(OH)<sub>3-a</sub>(TOPO)<sub>b</sub> where *a* and *b* are 2 and/or 1. The possibility of the extraction of hydroxide has been discussed.

### INTRODUCTION

Indium(III) in aqueous solutions is effectively extracted with several chelating extractants [1] such as 2-thenoyltrifluoroacetone (Htta) [2]. It is also known that In<sup>3+</sup> ion is extracted with a solvating type extractant such as trioctylphosphine oxide (TOPO) as an ion pair with a bulky anion [3]. When both a chelating and a solvating type extractant are used together, the extraction is often better than the net extraction by both extractants. This is known as synergism. Although the synergistic extraction is marked among trivalent lanthanoids as was demonstrated with 2-thenoyltrifluoroacetone (Htta) and with tributylphosphate (TBP) [2], the extraction of indium(III) with Htta was not enhanced by an addition of TBP. This observation can be explained in terms that the six coordination sites on In<sup>3+</sup> ion are fully occupied by the three molecules of bi-dentate chelate ion, and there should be no room for TBP to form the adduct compound. However, an addition of TOPO enhanced the extraction of In(III) in aqueous perchlorate solutions with Htta in carbon tetrachloride [4]. Moreover, the extracted complex seemed to contain less than three molecules of tta<sup>-</sup>. The role of anions in this extraction equilibrium was examined in the present study.

### EXPERIMENTAL

All the solvent extraction experiments were carried out in a room thermostated at 298 K. The Htta and TOPO, both supplied by Dojindo Laboratories, were crystallized from toluene and hexane, respectively. A weighed amount of Htta or TOPO was dissolved in carbon tetrachloride for each stock solution. The Htta solution was left standing overnight before use. The indium(III) nitrate was dissolved in aqueous 9.00x10<sup>-2</sup> mol dm<sup>-3</sup> sodium nitrate solution containing 1.00x10<sup>-2</sup> mol dm<sup>-3</sup> nitric acid, or otherwise an indium standard solution (contains In<sup>3+</sup> by 1000 ppm in 1 mol dm<sup>-3</sup> HNO<sub>3</sub>) for the atomic absorption spectrometry was diluted with a sodium nitrate solution. A portion of the aqueous solution and the same volume of carbon tetrachloride solution containing each or both of Htta and TOPO were placed in a stoppered glass tube of 20 cm<sup>3</sup>. The two phases were agitated by a mechanical shaker for 2 h and centrifuged off. The indium ion extracted into the organic phase was stripped by 1 mol dm<sup>-3</sup> nitric acid. The amount of indium in the stripped solution and that in the aqueous phase were determined by atomic absorption spectrometry using a Hitachi Z-6100 atomic absorption spectrometer. The pH of the aqueous phase was measured by a potentiometer using the solution containing 0.01 mol dm<sup>-3</sup> HClO<sub>4</sub> and 0.09 mol dm<sup>-3</sup> NaClO<sub>4</sub> as the standard for pH 2.

## RESULTS AND DISCUSSION

The distribution ratio of In(III) between aqueous 0.1 mol dm<sup>-3</sup> nitrate solution of pH 2 and carbon tetrachloride containing certain amounts of TOPO and Htta is shown in Figure 1. When TOPO was absent, the plot of logarithm of the distribution ratio vs. logarithm of Htta at initial concentration gave a straight line of slope +3. Thus this extraction equilibrium can be expressed by equation (1) and the formation of chelate complexes in the aqueous phase should be negligible.

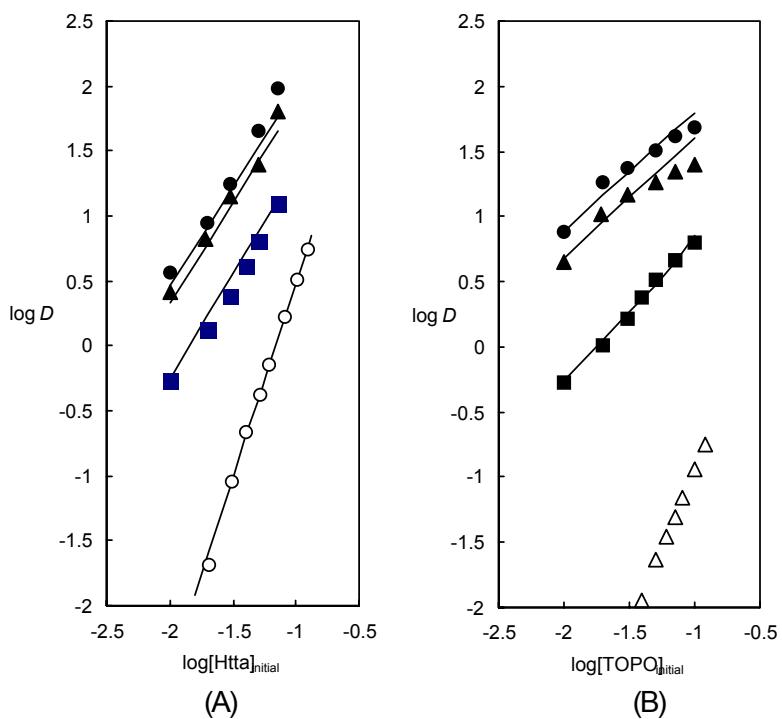

$$K_{\text{ex}30} = \frac{[\text{In}(\text{tta})_3]_{\text{org}}[\text{H}^+]^3}{[\text{In}^{3+}][\text{Htta}]_{\text{org}}^3} \quad (2)$$

The value of this constant is obtained from the data in Figure 1(A) was 10-2.53. This value is reported in the previous paper [4] as 10-2.55 by separate data. When TOPO was added, the distribution ratio was enhanced, though the slope became smaller than +3. When In<sup>3+</sup> was extracted from 1 mol dm<sup>-3</sup> aqueous NaClO<sub>4</sub> solution with TOPO only, the extracted species was found to be In(ClO<sub>4</sub>)<sub>3</sub>(TOPO)<sub>4</sub> [3]. However, Figure 1(B) shows that the slope of log-log plot for the extraction with TOPO only is approximately +2.5. Then, the chemical form of In(III) extracted with TOPO from the nitrate medium is thus expected to be In(NO<sub>3</sub>)<sub>3</sub>(TOPO)<sub>2</sub> and In(NO<sub>3</sub>)<sub>3</sub>(TOPO)<sub>3</sub>. Since the extracted amount is small compared to that with the cooperation of Htta and TOPO, this extraction is neglected in the following discussions. As is seen in Figure 1(B), the addition of Htta enhanced the extraction of In(III) but reduced the slope of the extraction curves.

The smaller slope than +3 in Figure 1(A) indicates that the extracted species contain less than three tta<sup>-</sup> ions, namely, other anion(s) should be included in them. Reduction of In(III) to In(II) or In(I) will scarcely occur, because the extraction of In(tta)<sub>3</sub> has been established and TOPO is not a reducing reagent. In order to identify the cooperating anion with tta<sup>-</sup>, indium ion was extracted from aqueous sodium nitrate or sodium perchlorate solutions of different ionic concentration. The hydrogen-ion concentration was kept at 0.01 mol dm<sup>-3</sup>. Figure 2 gives the results. The distribution ratio seems to be independent of the concentration of both anions at least below 0.1 mol dm<sup>-3</sup>. This fact excludes these anions from the counter anion.

Since highly charged cations are susceptible to hydrolysis in aqueous solutions, the effect of hydroxyl ion was examined. Figure 3 gives the extraction curves of In(III) from the aqueous solutions of various pH. Although the slopes were not always +3 exactly, the present authors assume that the extracted species may contain tta<sup>-</sup> and hydroxyl ion. Supposing that the extracted species are In(tta)<sub>3</sub>, In(tta)<sub>2</sub>OH, and In(tta)(OH)<sub>2</sub>, the number of TOPO molecules adducting to these species is assumed to be 1 or 2 from the slope of plots in Fig. 1(B). Thus the chemical form of the extracted species can be written as In(tta)<sub>a</sub>(OH)<sub>3-a</sub>(TOPO)<sub>b</sub>. The extraction constants are defined by equation (3) and the distribution ratio of indium(III) can be written as equation (4).

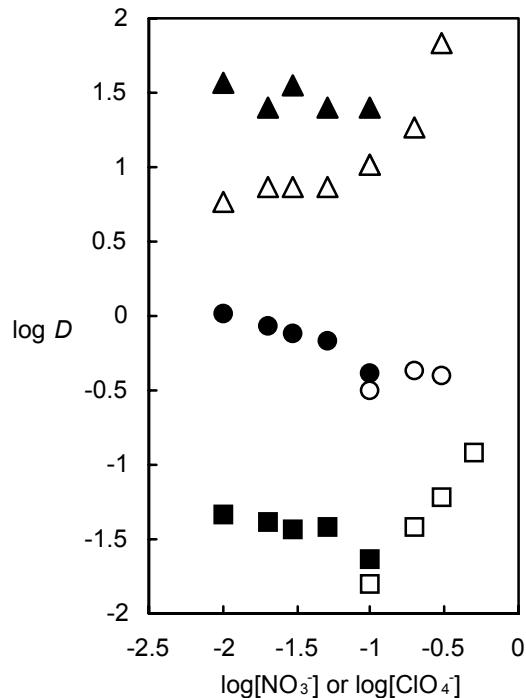

*Figure 1. Distribution ratio of indium(III). Aqueous phase: 0.01 mol dm<sup>-3</sup> HNO<sub>3</sub> and 0.09 mol dm<sup>-3</sup> NaNO<sub>3</sub> initially containing 1×10<sup>4</sup> mol dm<sup>-3</sup> In<sup>3+</sup>. Organic phase: CCl<sub>4</sub> containing (A) various amounts of Htta with; 0, 0.01, 0.0375, and 0.05 mol dm<sup>-3</sup> TOPO from bottom to top and (B) various amounts of TOPO with 0, 0.01, 0.0375, and 0.05 mol dm<sup>-3</sup> Htta from bottom to top, respectively. Solid lines are calculated by using the constants in the text on the basis of equation (4).*

$$K_{\text{exab}} = \frac{[\ln(\text{tta})_a(\text{OH})_{3-a}(\text{TOPO})_b]_{\text{org}} [\text{H}^+]^3}{[\ln^{3+}] [\text{Htta}]_{\text{org}}^a [\text{TOPO}]_{\text{org}}^b} \quad (3)$$

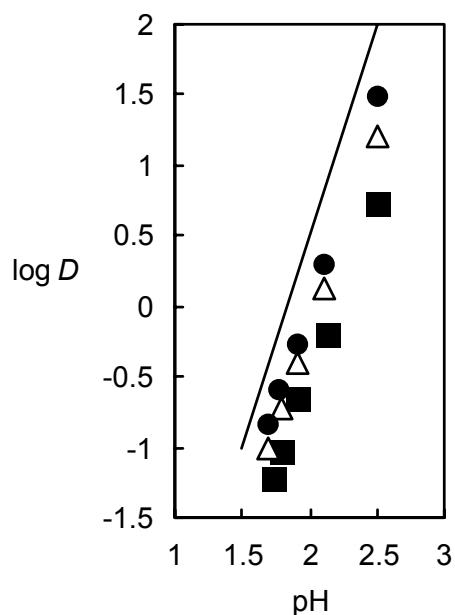

$$D = \frac{[\ln(\text{tta})_3]_{\text{org}} + [\ln(\text{tta})_2(\text{OH})(\text{TOPO})_b]_{\text{org}} + [\ln(\text{tta})(\text{OH})_2(\text{TOPO})_{b'}]_{\text{org}}}{[\ln^{3+}]} \quad (4)$$

$$= \frac{K_{\text{ex30}} [\text{Htta}]_{\text{org}}^3 + K_{\text{ex2b}} [\text{Htta}]_{\text{org}}^2 [\text{TOPO}]_{\text{org}}^b + K_{\text{ex1b}} [\text{Htta}] [\text{TOPO}]_{\text{org}}^{b'}}{[\text{H}^+]^3}$$

The Htta and TOPO associate in carbon tetrachloride. The association constant has been reported as  $K_{as} = [(\text{Htta})(\text{TOPO})]_{\text{org}} / [\text{Htta}]_{\text{org}}[\text{TOPO}]_{\text{org}} = 101$  [5]. The decrease in the concentrations of both reagents by this association equilibrium was taken into account. Curve fitting calculation based on a non-linear least squares approximation gave the constants as follows, although the accuracy is not always satisfactory;  $\log K_{ex22} = 0.97$ ,  $\log K_{ex21} = -0.30$ ,  $\log K_{ex12} = -1.09$ , and  $\log K_{ex11} = -2.93$ .

*Figure 2. The extraction of indium(III) as a function of anion concentration in an aqueous phase initially containing  $[H^+] = 0.01 \text{ mol dm}^{-3}$ . Open and filled symbols are for perchlorate and nitrate media, respectively. The organic phase is; squares = TOPO only ( $0.05 \text{ mol dm}^{-3}$  for nitrate medium and  $0.03 \text{ mol dm}^{-3}$  for perchlorate medium), circles = Htta only ( $0.05 \text{ mol dm}^{-3}$  for both media), and triangles = mixture containing the same concentration of Htta and TOPO ( $0.05 \text{ mol dm}^{-3}$  for nitrate medium and  $0.02 \text{ mol dm}^{-3}$  for perchlorate medium).*

*Figure 3. Extraction of indium(III) as a function of pH in the aqueous phase at equilibrium. The initial concentration of  $In^{3+}$  was  $8.76 \times 10^{-5} \text{ mol dm}^{-3}$  in  $0.1 \text{ mol dm}^{-3} NaNO_3$ . The organic phases initially contain;*

- (a)  $0.03 \text{ mol dm}^{-3}$  Htta and  $0.01 \text{ mol dm}^{-3}$  TOPO,
- (b)  $0.02 \text{ mol dm}^{-3}$  Htta and  $0.02 \text{ mol dm}^{-3}$  TOPO, and
- (c)  $0.01 \text{ mol dm}^{-3}$  Htta and  $0.05 \text{ mol dm}^{-3}$  TOPO

*from top to bottom. The solid line shows the slope +3.*

The hydroxyl ion is regarded as an anion of very poor extractability in the ion-pair extraction systems. Moreover, the molar ratio of these hydroxides to the  $\text{In}^{3+}$  ion in the aqueous phase of pH=2 is estimated as  $10^{-2.43}$  (3.7%) for  $\text{In}(\text{OH})^{2+}$  and  $10^{-5.35}$  (0.0005%) for  $\text{In}(\text{OH})_2^+$ , respectively, from the hydrolysis constant  $K_{11} = 10^{-4.31}$  and  $K_{12} = 10^{-9.35}$  (in 0.5 mol dm<sup>-3</sup> NaNO<sub>3</sub> medium [6], the hydrolysis constants being defined by  $K_{xy} = [\text{In}_x(\text{OH})_y]^{3x+y}[\text{H}^{+}]^y/[\text{In}^{3+}]^x$ ). Therefore, the hydroxides of In(III) ion should be negligible in both phases of the present extraction system. Although  $\text{In}(\text{OH})_3$  is scarcely extractable,  $\text{In}(\text{OH})^{2+}$  and  $\text{In}(\text{OH})_2^+$  might be stabilized in the organic phase by the aid of lipophilic ligands. As a similar case to the hydroxide, extraction of In(III) chloride complexes is reported by Brunette *et al.* [7].

Brunette *et al.* extracted indium(III) in aqueous chloride-perchlorate solutions with acylpyrazolones (HL) and TOPO in toluene [7]. The chemical form of the extracted complexes was reported as  $\text{InL}_3(\text{TOPO})_2$ ,  $\text{InClL}_2(\text{TOPO})_2$ , and  $\text{InCl}_2\text{L}(\text{TOPO})_2$ . The  $\text{InL}_3(\text{TOPO})_2$  type of complex was not found in the present study. This may be attributed to the different ability of ligand molecule to form hydrogen bonds with TOPO. Acylpyrazolone has a nitrogen atom that can form hydrogen bond with water and TOPO can also form hydrogen bond with this water molecule. Even though the Htta molecule has a sulfur atom, it may have much weaker interactions with TOPO. From [7], the extraction constant of  $\text{InL}_3$  defined by the same form with equation (2) is  $10^{1.50}$  when In(III) is extracted with 1-phenyl-3-methyl-4-benzoylpyrazol-5-one from perchlorate medium to toluene. Since this value for  $\text{In}(\text{tta})_3$  in the present study is  $10^{-2.6}$ , Htta is a poorer extractant for In(III) than HL; otherwise the extraction of hydroxides will be not recognized, hidden under a good extraction by other superior extractants.

The extraction of hydroxide is assumed to explain the unusual extraction behavior of In(III) complex in the present system and it should be proved by further studies. However, if the hydroxide is actually extracted, the present extraction system may be regarded as a new type of synergism in which three different types of extractant cooperate. Formation of poly-nuclear hydroxide in the aqueous solutions is also reported;  $K_{34} = 10^{9.29}$  (in 3 mol dm<sup>-3</sup> NaClO<sub>4</sub>) [8]. This may impair the extraction of In(III) in its higher concentrations.

## ACKNOWLEDGEMENTS

The authors thank Miss Yuko Ueno and Mr. Yohei Unno for their experimental work.

## SOLVENT EXTRACTION OF INDIUM(III) AND IRON(III) FROM SULPHURIC ACID MEDIA BY MIXTURES OF D<sub>2</sub>EHPA AND CYANEX 923

Chun Wang\*, Daxing Liu and Jin Zhang

Beijing General Research Institute of Mining and Metallurgy, Beijing, P. R. China

The extraction equilibria of In(III) and Fe(III) by di(2-ethylhexyl) phosphoric acid (D<sub>2</sub>EHPA), 2-ethylhexyl phosphonic acid 2-ethylhexyl ester (EHEHPA), Cyanex 923 and binary mixtures of D<sub>2</sub>EHPA-Cyanex 923, D<sub>2</sub>EHPA-TRPO and D<sub>2</sub>EHPA-TBP were studied. The stripping of In(III) and Fe(III) from the loaded organic phase was conducted using H<sub>2</sub>SO<sub>4</sub>. It was found that it is easier to strip In(III) and Fe(III) from D<sub>2</sub>EHPA-Cyanex 923 and D<sub>2</sub>EHPA-TRPO than from D<sub>2</sub>EHPA. 90% In(III) can be stripped from D<sub>2</sub>EHPA-Cyanex 923 by using 250 g/L H<sub>2</sub>SO<sub>4</sub> in a single stage. The In(III) loading capacity with D<sub>2</sub>EHPA-Cyanex 923 was determined. The effects of equilibrium time, phase ratio, temperature, extractant concentration were observed. The kinetics of In(III) and Fe(III) extraction and stripping were also studied to achieve a better separation of In(III) and Fe(III). Compared with D<sub>2</sub>EHPA, the mixture of D<sub>2</sub>EHPA and Cyanex 923 has the following advantages: 1) lower stripping acidity and higher stripping yield of indium(III); 2) is easier to strip Fe(III) from the loaded organic phase; 3) its loading capacity is comparable to that with D<sub>2</sub>EHPA at real leach liquor acidity.

### INTRODUCTION

Indium is one of the most important rare metals used in electronic devices and alloys. Indium consumption has been increasing significantly in recent years because of its applications in high-tech products such as InP semiconductors, and indium tin oxide (ITO) used in the LCDs of portable electronics.

Indium is recovered usually as a by-product from zinc or lead residues, or slags derived from zinc or lead smelting and refining processes. One of the important processes is to recover indium(III) from sulphuric acid leach liquors of zinc residues by solvent extraction using organophosphorus compounds. Di(2-ethylhexyl) phosphoric acid (D<sub>2</sub>EHPA, marketed as P204 in China) is used as an extractant at Laibing Smelter, Huaxi Group Co., China [1]. Toho Zinc Co., Ltd. employs a mixture of D<sub>2</sub>EHPA and tributylphosphate (TBP) [2].

Fundamental studies on the extraction of indium(III) with organophosphorus compounds have been conducted by several researchers. Sato studied In(III) extraction with D<sub>2</sub>EHPA and 2-ethylhexyl phosphoric acid 2-ethylhexyl ester (EHEHPA, marketed as PC-88A in Japan and P507 in China) from H<sub>2</sub>SO<sub>4</sub>, HNO<sub>3</sub> and HCl media [3]. Inoue compared In(III) extraction from HNO<sub>3</sub> media with D<sub>2</sub>EHPA, PC-88A and Cyanex 272. The extraction with these reagents

decreases in the order: D<sub>2</sub>EHPA > PC-88A > Cyanex 272 [4]. Bauer studied In(III) recovery from mixed hydrochloric acid-sulphuric acid media with bis(2,4,4-trimethylpentyl)-dithiophosphinic acid (marketed as Cyanex 301). In(III) is co-extracted with As(III), Cd(II), Cu(II) and Fe(III), so this reagent shows no improved selectivity for In(III) over other impurities. A high concentration of HCl, *i.e.*, 7 mol/L, is used to strip In(III) [5].

D<sub>2</sub>EHPA is still one of the most important extractants applied on an industrial scale. However, the strong extraction of In(III) and Fe(III) make the stripping of these elements very difficult, high concentrations of HCl, *i.e.*, 6-8 Mol/L, are used to conduct stripping [6]. Fe(III) will be accumulated gradually in the organic phase of the SX circuit, and this will eventually result in extractant poisoning.

Rickelton studied In(III) recovery by D<sub>2</sub>EHPA modified with Cyanex 923 (a mixture of straight-chained phosphine oxides) or Cyanex 925 (a branched chain phosphine oxide) [7]. Better stripping of In(III) and Fe(III) from the loaded organic phase can be accomplished with 2 mol/L H<sub>2</sub>SO<sub>4</sub> when D<sub>2</sub>EHPA is modified with Cyanex 923 or Cyanex 925.

In this paper, the extraction equilibria of In(III) and Fe(III) by di(2-ethylhexyl) phosphoric acid (D<sub>2</sub>EHPA), 2-ethylhexyl phosphonic acid 2-ethylhexyl ester (EHEHPA), Cyanex 923 and binary mixtures of D<sub>2</sub>EHPA-Cyanex 923, D<sub>2</sub>EHPA-TRPO and D<sub>2</sub>EHPA-TBP were studied. The effects on extraction and stripping of In(III) and Fe(III) were studied. Synthetic as well as actual leach liquors were used [8]. The purpose of this study was to evaluate the potential of D<sub>2</sub>EHPA-Cyanex 923 mixtures for indium recovery on a commercial scale.

## EXPERIMENTAL

### Reagents

Indium and ferric sulphate solutions were prepared by dissolving the analytical grade reagents in deionized water. The synthetic leach solution was prepared by mixing In(III) sulphate, Fe(III) sulphate, and sulphuric acid solutions. The actual liquor solution was supplied by a domestic zinc refinery in China, and its chemical composition is shown in Table 1.

*Table 1. Chemical composition of the real leach liquor.*

Element	In	Fe	Zn	Cd	Mn	Cu	Ca	Mg	H <sub>2</sub> SO <sub>4</sub>
Content(g/L)	0.39	49.58	11.18	0.22	2.81	0.27	0.50	0.73	19.28

Cyanex 923 was kindly supplied by Cytec Industries Inc. D<sub>2</sub>EHPA, EHEHPA, TBP and Trialkyl phosphine oxide (TRPO) were supplied by China's Chemical Plants. All extractants were used without further purification. Kerosene was used as a diluent. All other reagents were of chemical grade.

### Extraction, Stripping and Analytical Procedures

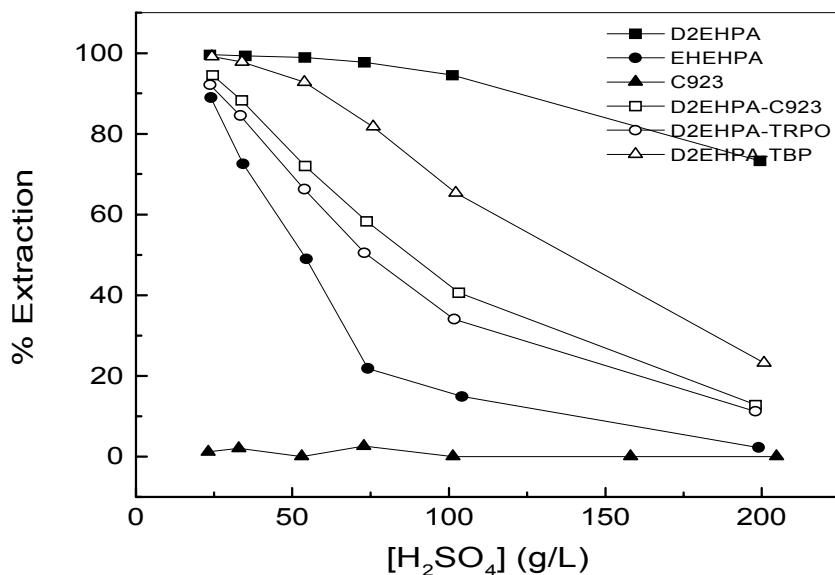

All batch experiments, including extraction and stripping, were conducted by equilibrating measured volumes of aqueous and organic phases in separating funnels and shaking for 1-10 min at room temperature.

Aqueous feed and raffinate solutions were analyzed by atomic absorption spectrophotometry (AAS) using a Perkin-Elmer model TC5100 instrument or inductively coupled plasma atomic emission spectrometry (ICP-AES) using a Perkin-Elmer model Optima 3000 instrument. The metal contents in the loaded organics were determined by mass balance. The simulated continuous counter-current tests were also conducted in a series of separating funnels.

## RESULTS AND DISCUSSION

### In(III) Extraction

In(III) extraction was conducted with 5% v/v D<sub>2</sub>EHPA, 5% v/v EHEHPA, 5% v/v Cyanex 923 and binary mixtures of 5% D<sub>2</sub>EHPA-5% Cyanex 923, 5% D<sub>2</sub>EHPA-5% TRPO and 5% D<sub>2</sub>EHPA-5% TBP under different sulphuric acid concentrations (Figure 1).

*Figure 1. Effect of aqueous acidity on the In(III) extraction. Organic Phase: 5% v/v D<sub>2</sub>EHPA, 5% v/v EHEHPA, 5% v/v Cyanex 923, 5% D<sub>2</sub>EHPA-5% Cyanex 923, 5% D<sub>2</sub>EHPA-5% TRPO or 5% D<sub>2</sub>EHPA-5% TBP; Aqueous phase: 1 g/L In(III); Phase ratio(O/A): 1.*

In the ranges of 25 g/L to 250 g/L sulphuric acid, In(III) is not extracted by Cyanex 923. The In(III) extractions with the other five solvents decrease with increasing aqueous acidity in the order: D<sub>2</sub>EHPA > D<sub>2</sub>EHPA-TBP > D<sub>2</sub>EHPA-Cyanex 923 > D<sub>2</sub>EHPA-TRPO > EHEHPA. At the real leach liquor acidity, *i.e.*, 20 g/L H<sub>2</sub>SO<sub>4</sub>, the In(III) extraction with mixtures of D<sub>2</sub>EHPA and Cyanex 923, TRPO or TBP is close to that with D<sub>2</sub>EHPA. Up to 92% In(III) can be extracted in a single stage. However, the extraction with these mixtures decrease more significantly with increasing aqueous acidity than D<sub>2</sub>EHPA does. This means the In(III) stripping from these loaded organic phases will be accomplished more easily with sulphuric acid, *e.g.*, 200 g/L H<sub>2</sub>SO<sub>4</sub>.

### Fe(III) Extraction

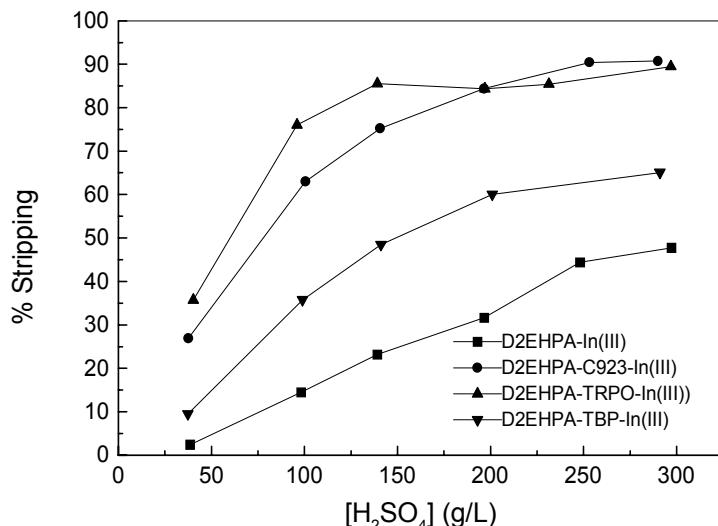

The Fe(III) extraction with with 5% v/v D<sub>2</sub>EHPA, 5% D<sub>2</sub>EHPA-5%TRPO, 5% D<sub>2</sub>EHPA-5% TBP or 5% D<sub>2</sub>EHPA-5% Cyanex 923 under different sulphuric acid concentrations was studied.

The Fe(III) extraction decreases with increasing aqueous acidity in the order: D<sub>2</sub>EHPA > D<sub>2</sub>EHPA-TRPO ~ D<sub>2</sub>EHPA-TBP ~ D<sub>2</sub>EHPA-Cyanex 923. At aqueous acidity of 20 g/L H<sub>2</sub>SO<sub>4</sub>, 25.9%, 14.6%, 10.1% and 8.9% Fe(III) are extracted, respectively. The modification of D<sub>2</sub>EHPA with alkyl phosphine oxides, therefore, can reduce Fe(III) extraction.

### In(III) Stripping

The stripping of In(III) from the loaded D<sub>2</sub>EHPA, D<sub>2</sub>EHPA-TRPO, D<sub>2</sub>EHPA-TBP or D<sub>2</sub>EHPA-Cyanex 923 was conducted using sulphuric acid of different concentrations (Figure 2).

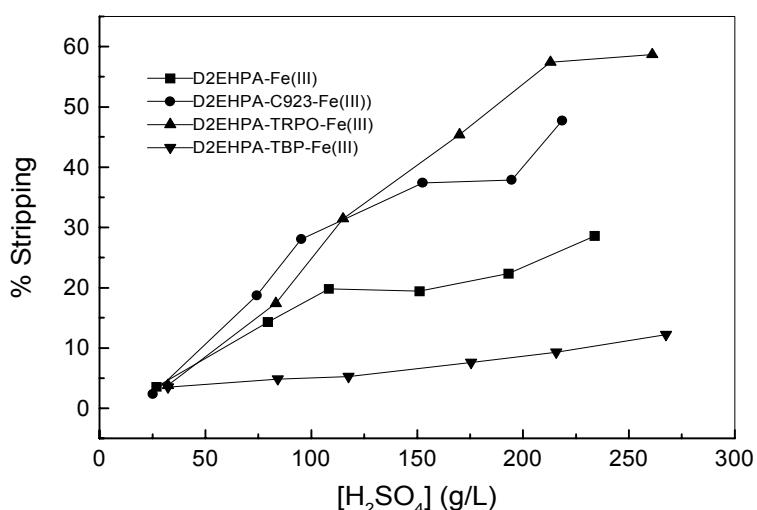

The In(III) stripping increases with increasing sulphuric acid concentration in the order: D<sub>2</sub>EHPA < D<sub>2</sub>EHPA-TBP < D<sub>2</sub>EHPA-TRPO ~ D<sub>2</sub>EHPA-Cyanex 923. In a single stage, 44.1%, 64.8%, 89.4%, and 92.2% of In(III) can be stripped, respectively, from the loaded organic phase with 250 g/L H<sub>2</sub>SO<sub>4</sub>. This result indicates that In(III) stripping can be achieved more easily with mixtures of D<sub>2</sub>EHPA and Cyanex 923 than with D<sub>2</sub>EHPA only.

*Figure 2. In(III) stripping with sulphuric acid of different concentrations. Organic Phase: 5% v/v D<sub>2</sub>EHPA, 5%D<sub>2</sub>EHPA-5%Cyanex 923, 5%D<sub>2</sub>EHPA-5%TRPO or 5%D<sub>2</sub>EHPA-5%TBP loaded with 1.9~2.0 g/L In(III); Aqueous phase: sulphuric acid solutions; Phase ratio(O/A): 1.*

### Fe(III) Stripping

Fe(III) stripping with sulphuric acid of different concentrations was also studied and shown in Figure 3. The Fe(III) stripping increases with increasing sulphuric acid concentration in the order: D<sub>2</sub>EHPA < D<sub>2</sub>EHPA-TBP < D<sub>2</sub>EHPA-Cyanex 923 < D<sub>2</sub>EHPA-TRPO. In a single stage, 12.2%, 25.6%, 47.7% and 57.4% of Fe(III) can be stripped from the loaded organic phases with 220 g/L H<sub>2</sub>SO<sub>4</sub>.

*Figure 3. Fe(III) stripping with sulphuric acid of different concentrations. Organic Phase: 5% v/v D<sub>2</sub>EHPA, 5%D<sub>2</sub>EHPA-5%Cyanex 923, 5%D<sub>2</sub>EHPA-5%TRPO or 5%D<sub>2</sub>EHPA-5%TBP loaded with 1.2~1.4 g/L In(III); Aqueous phase: sulphuric acid solutions; Phase ratio(O/A): 1.*

### In(III) Loading Capacity

5% D<sub>2</sub>EHPA, 5% D<sub>2</sub>EHPA-5% Cyanex 923 and 5% D<sub>2</sub>EHPA-5% TRPO were contacted with equal volume of a liquor containing 2 g/l In(III) and 20 g/L H<sub>2</sub>SO<sub>4</sub> in a separating funnel. After equilibrium, the raffinate was measured to determine the In(III) content, then the loaded organic phase was re-contacted with a fresh In(III) liquor. The extraction was run 3 times. The In(III) loadings are shown in Table 2. The result indicates that at the real leach liquor acidity, D<sub>2</sub>EHPA modified with Cyanex 923 or TRPO, is comparable in the In(III) loading capacity to D<sub>2</sub>EHPA.

Table 2. In(III) loading capacity

Solvents	D <sub>2</sub> EHPA	D <sub>2</sub> EHPA-Cyanex 923	D <sub>2</sub> EHPA-5%TRPO
In(III) content in organain phase(g/l)	4.71	4.43	4.26

### Effect of Contact Time on In(III) and Fe(III) Extraction and Stripping

To achieve better separation of In(III) and Fe(III) in the extraction and stripping, the effect of contact time was studied and shown in Figure 4 and 5, respectively.

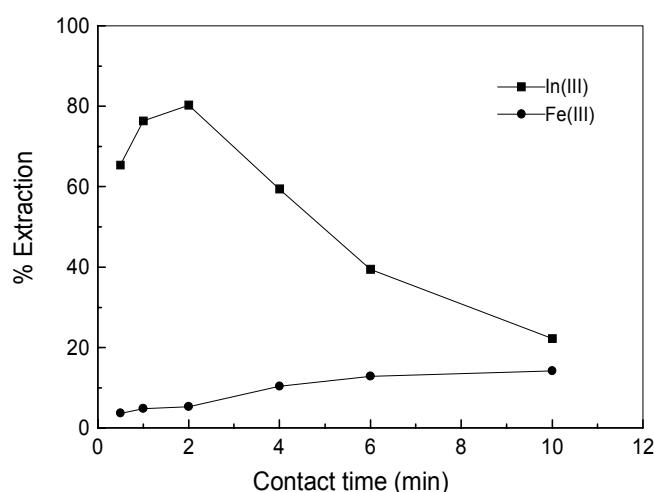

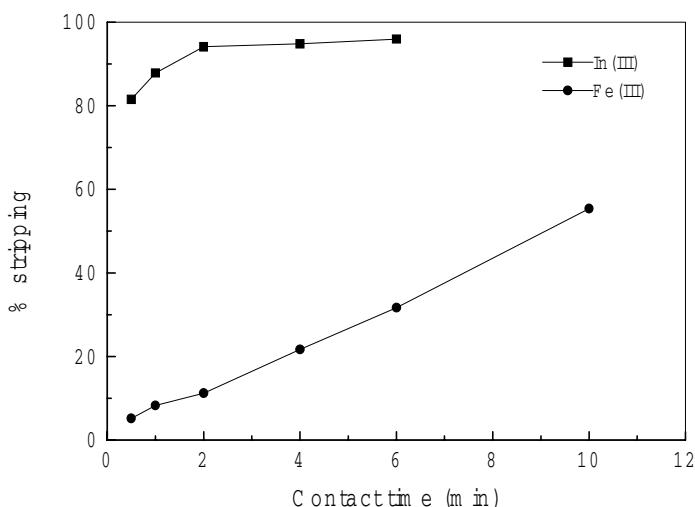

Figure 4. Effect of contact time on In(III) and Fe(III) extraction. Organic phase: 10% D<sub>2</sub>EHPA-10% Cyanex 923; Aqueous phase: real leach liquor containing 0.39 g/L In(III), 49.85 g/L Fe(III) and 19.28 g/L H<sub>2</sub>SO<sub>4</sub>; Phase ratio(O/A): 1.

The extraction of In(III) increases with increasing contact time, and up to the 80.3% In(III) is loaded at 2 min, then decreases sharply. Also, Fe(III) extraction increases with increasing contact time. 5.3% Fe is extracted at 2 min. The decrease in In(III) extraction, thus, can be ascribed to the competitive extraction of Fe(III). The contact time for extraction should be controlled at 1-2 min.

Both In(III) and Fe(III) stripping increase with increasing contact time. 94.1% In(III) can be stripped at 2 min and only up to 95.5% at 6 min. While 1.2% and 31.7% Fe(III) is stripped at 2 min and 6 min, respectively. The contact time for In(III) stripping should be 2 min.

*Figure 5. Effect of contact time on In(III) and Fe(III) stripping. Organic phase: 10% D<sub>2</sub>EHPA-10% Cyanex 923 loaded with 0.33 g/L In(III) and 0.8 g/L Fe(III); Aqueous phase: 250 g/L H<sub>2</sub>SO<sub>4</sub>; Phase ratio(O/A): 1.*

## CONCLUSIONS

In contrast with D<sub>2</sub>EHPA employed in indium recovery, the mixture of D<sub>2</sub>EHPA and Cyanex 923 has lower stripping acidity and higher stripping yield of indium(III), and same In(III) loading capacity at the real leach liquor acidity. The kinetics difference in In(III) and Fe(III) extraction and stripping should be used to achieve better separation.

It can be argued that the D<sub>2</sub>EHPA-Cyanex 923 mixture has certain potential for recovering indium from acidic leach liquors derived from zinc process residues.

## EXTRACTION OF RARE EARTH IONS BY SEC-NONAPHENOXYACETIC ACID

Y. G. Wang, S. L. Meng, D. Q. Li, M. J. Jin\* and C. Z. Li\*

Laboratory of Rare Earth Chemistry and Physics, Changchun Institute of Applied Chemistry,  
Chinese Academy of Sciences, P.R. China

\*Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences, P.R. China

The extraction of rare earths with CA-100 as a function of hydrogen ion concentration has been studied under constant ionic strength of aqueous phase. The extraction order of rare earth ions is:  $\text{Sc}^{3+} >> \text{Eu}^{3+} > \text{Sm}^{3+}(\text{Nd}^{3+}) > \text{Pr}^{3+} > \text{Ce}^{3+} > \text{La}^{3+} > \text{Gd}^{3+}(\text{Tb}^{3+}) > \text{Dy}^{3+} > \text{Tm}^{3+} > \text{Ho}^{3+} > \text{Er}^{3+} > \text{Yb}^{3+} > \text{Lu}^{3+} > \text{Y}^{3+}$ , which suggests that light lanthanides are more strongly extracted by CA-100.  $\text{Sc}^{3+}$  and  $\text{Y}^{3+}$  have the highest and lowest extractability among rare earth ions, respectively. According to the separation factors,  $\text{Sc}^{3+}$  can be separated from  $\text{RE}^{3+}$  easily;  $\text{Y}^{3+}$  can be separated from  $\text{RE}^{3+}$ , especially from light and middle lanthanides. The organic phase loaded with  $\text{Y}^{3+}$  stripped with HCl has been studied and it is obvious that the stripping acidity is low. The extraction mechanism can be written as follows on the basis of slope analysis of  $\log D$  vs. pH and  $\log D - 3\text{pH}$  vs.  $\log (\text{CA-100})_{[\text{O}]}$ :

### INTRODUCTION

The rare earth separation process using P507 and naphthenic acid solvent extraction combined with P507 extraction resin chromatography and redox, etc. has been applied widely in China [1]. This process provides industrial production of all the individual RE (except Pm) up to 99.99% or higher purity. However, the industrial practice indicates that there are some problems with the P507 and naphthenic acid extraction process. To explore some new extractants or extraction systems superior to P507 or naphthenic acid has consequently been an interesting subject for many researchers.

From a practical point of view, reagents of the carboxylic acid type are relatively inexpensive and readily available. Some application in commercial processes for the separation of rare earth metals with carboxylic acids have been found [2]. However, the extraction of the rare earth metals by carboxylic acids has not been studied in detail [3]. Alkylphenoxyacetic acid is an extractant developed by Shanghai Institute of Organic Chemistry, Chinese Academy of Science. Studies indicate that these extractants have several advantages including low solubility and stronger acidity in aqueous phase and larger distribution constant in organic solvent- water. Hence, they may be prospective extractants superior to naphthenic acid [4]. The extraction of some rare earth elements with CA-12 (sec-octylphenoxyacetic acid) from chloride medium has been studied. Li *et al.* [5] proposed HAB two solvent-extraction system on the basis of CA-12, which greatly improved the separation factors of  $\text{Y}^{3+}$  with heavy  $\text{RE}^{3+}$  elements. CA-100 (sec-nonylphenoxyacetic acid), with a larger alkyl group, has a similar structure to that of CA-12 and its molecular structure can be expressed as follows:

To date, extraction behavior of rare earth elements with CA-100 has not been reported.

There is a sharp rise in demand of lanthanides (Ln), yttrium (Y) and scandium (Sc) due to the quick growth of advanced industries such as electronics, new ceramics, metallurgy, and laser. Scandium and yttrium often co-exist with lanthanide due to the similarity in their chemical properties and the separation by solvent extraction is of practical significance [6,7]. The purpose of this paper is to explore the extraction behavior of rare earth elements in hydrochloric acid media by CA-100 and facilitate the RE hydrometallurgy process.

## EXPERIMENTAL

### Reagents and Apparatus

Before used as an extractant, CA-100 was purified by washing with  $\text{Na}_2\text{CO}_3$  and HCl twice, finally by washing with distilled water to neutrality. Stock solutions containing rare earths were prepared by dissolving the RE oxide (>99.9%) in hydrochloric acid and standardized by EDTA titration using xylenol orange as an indicator. A Shimadzu Model UV-365 spectrophotometer was used to analysis the concentration of metal ions in aqueous phase. A model pHs-3c pH meter was employed to measure pH value in aqueous phase. All other reagents were of analytical grade.

### Procedure

Equal volumes (5 ml) of organic and aqueous solutions were placed in equilibrium tubes and shaken for 20 minutes at 303K. The system was at equilibrium within this shaking time. The ionic strength ( $\mu$ ) in the aqueous phase was kept at 1 M with  $\text{NH}_4\text{Cl}$  solution. Phase were separated by centrifuging. Concentration of extractants was determined by titration with standard sodium hydroxide in an ethanol-water mixture using phenolphthalein as an indicator. The concentration of RE(III) in the aqueous phase was determined spectrophotometrically by the Arsenazo III method at 650-670 nm. The organic phase concentration of rare earth elements was determined by difference. The distribution ratio (D) of RE was defined as  $D = C_{(o)} / C_{(a)}$ .

## RESULTS AND DISCUSSION

### Effect of Equilibrium Aqueous pH

The effects of equilibrium aqueous pH on extraction equilibrium were studied under constant ionic strength of aqueous phase. The results shown in Table 1 indicate that the distribution ratios of RE increase with increasing pH with constant concentration of extractant and metal ion. The extraction order of rare earth ions is:  $\text{Sc}^{3+} >> \text{Eu}^{3+} > \text{Sm}^{3+}(\text{Nd}^{3+}) > \text{Pr}^{3+} > \text{Ce}^{3+} > \text{La}^{3+} > \text{Gd}^{3+}(\text{Tb}^{3+}) > \text{Dy}^{3+} > \text{Tm}^{3+} > \text{Ho}^{3+} > \text{Er}^{3+} > \text{Yb}^{3+} > \text{Lu}^{3+} > \text{Y}^{3+}$ , which suggests that light lanthanides are more strongly extracted by CA-100.  $\text{Sc}^{3+}$  and  $\text{Y}^{3+}$  have the highest and lowest extractability among rare earth ions, respectively. Similar results were obtained in the literature [4]. The slopes of the  $\log D$  vs. pH of rare earth elements are near three.

Table 1.  $pH_{1/2}$  value in rare earth elements extraction by CA-100.

parameter	Sc	Y	La	Ce	Pr	Nd	Sm	Eu
$pH_{1/2}$	2.14	3.01	2.78	2.76	2.75	2.73	2.73	2.71
parameter	Gd	Tb	Dy	Ho	Er	Tm	Yb	Lu
$pH_{1/2}$	2.79	2.79	2.82	2.89	2.93	2.86	2.93	2.95

From the list of separation factors of rare earths with respect to  $Sc^{3+}$  and  $Y^{3+}$  shown in Table 2, it can be seen that  $Sc^{3+}$  can be separated from  $RE^{3+}$  easily;  $Y^{3+}$  can be separated from  $RE^{3+}$ , especially from light and middle lanthanides. Compared with the data reported in literature [4], the selectivity towards  $RE^{3+}$  with CA-100 is better than that with CA-12, which may be partly due to the high steric hindrance of the former. It is suggested that CA-100 may be a useful reagent for the separation of  $Sc^{3+}$  and  $Y^{3+}$  from  $RE^{3+}$ .

Table 2. Separation factors( $\beta$ ) of  $RE^{3+}$  with respect to  $Sc^{3+}(Y^{3+})$ .

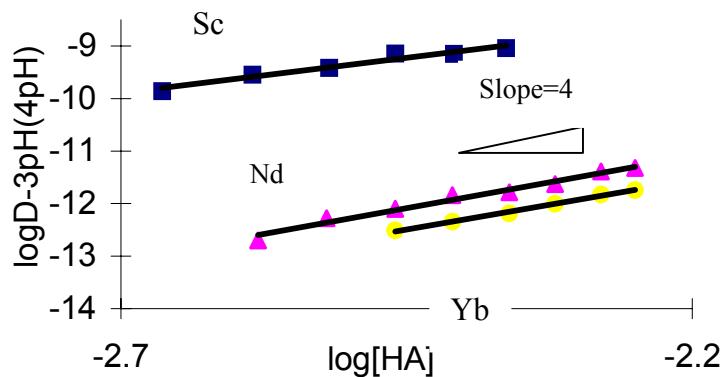

$RE^{3+}$	$Sc^{3+}$		$Y^{3+}$	
	$\bullet pH_{1/2}$	$\beta_{RE^{3+}/Sc^{3+}}$	$\bullet pH_{1/2}$	$\beta_{Y^{3+}/RE^{3+}}$
$Sc^{3+}$			0.87	407.38
$Y^{3+}$	0.87	407.38		
$La^{3+}$	0.64	83.18	0.23	4.90
$Ce^{3+}$	0.62	72.44	0.25	5.62
$Pr^{3+}$	0.61	67.61	0.26	6.03
$Nd^{3+}$	0.59	58.88	0.28	6.92
$Sm^{3+}$	0.59	58.88	0.28	6.92
$Eu^{3+}$	0.57	51.29	0.3	7.94
$Gd^{3+}$	0.65	89.12	0.22	4.57
$Tb^{3+}$	0.65	89.12	0.22	4.57
$Dy^{3+}$	0.68	109.65	0.19	3.72
$Ho^{3+}$	0.75	177.82	0.12	2.29
$Er^{3+}$	0.79	234.42	0.08	1.74
$Tm^{3+}$	0.72	144.54	0.15	2.82
$Yb^{3+}$	0.79	234.42	0.08	1.74
$Lu^{3+}$	0.81	269.15	0.06	1.51

### Effect of Extractant Concentration on the RE(III) Extraction

Figure 1 illustrates the effect of extractant concentration on the extraction of  $RE^{3+}$  in hydrochloric acid solution. Here, Nd represents light rare earth elements and Yb represents heavy rare earth elements. The distribution ratio increases with the increase of extractant concentration. The plots of  $\log D-3$  pH vs.  $\log [HA]_{(o)}$  of Nd and Yb give straight lines with slopes almost four, whereas the slope of Sc near three. It can be inferred from the results shown in Table 1 that three or four moles of hydrogen ions are released per mole of extracted metal ion. CA-100 must be ammoniated before extracting reaction to form ammoniate ( $NH_4^+A^-$ ) in order to exchange cation ions with RE(III) smoothly. Therefore it can be assumed that the RE(III) extraction with CA-100 can be expressed as follows:

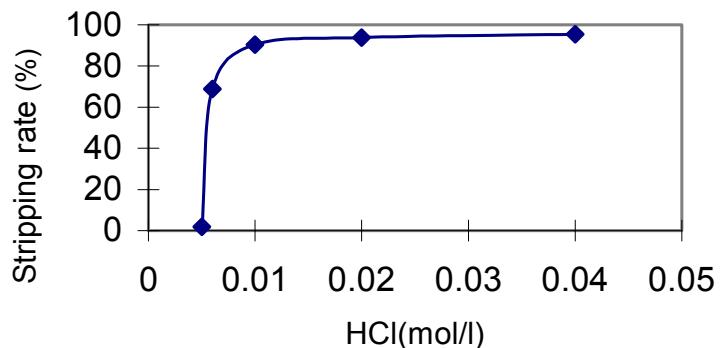

where HA represent CA-100, n equal to four or three.

*Figure 1. Effect of extractant concentration on extraction of some rare earth elements.*

### Stripping

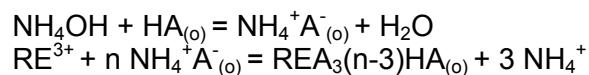

The organic phase loaded  $\text{Y}^{3+}$  was stripped with HCl. The aqueous phase concentration of Y was determined and the plot of the stripping efficiency versus different concentration of HCl is shown in Figure 2. When the concentration of HCl is large than 0.01 M, 90%  $\text{Y}^{3+}$  is stripped. The low stripping acidity is obvious.

*Figure 2. Effect of acidities on stripping of yttrium.*

### CONCLUSION

The effects of hydrogen ion concentration and extractant concentration on extraction of scandium, yttrium and lanthanides with CA-100 have been studied and the extraction mechanism can be written as follows:

According to the separation factors,  $\text{Sc}^{3+}$  can be separated from  $\text{RE}^{3+}$  easily;  $\text{Y}^{3+}$  can be separated from  $\text{RE}^{3+}$ , especially from light and middle lanthanides. Due to the higher steric hindrance, the selectivity towards  $\text{RE}^{3+}$  with CA-100 is better than that with CA-12. Hence, CA-100 may be a prospecting extractant for extraction and separation of rare earth elements.

## ACKNOWLEDGEMENTS

The authors wish to thank Shanghai Institute of Organic Chemistry, Chinese Academy of Sciences for supplying the CA-100. Project supported by State Key Project of Fundamental Research (G19980661301) and the National Natural Science Foundation of China (29771028,29801004).

# CHEMISTRY OF SOLVENT EXTRACTION OF SCANDIUM(III) FROM SULFATE SOLUTIONS BY QUATERNARY AMMONIUM SULFATES

S. I. Stepanov, A. E. Kharchev and A. M. Chekmarev

D.Mendeleev University of Chemical Technology of Russia, Moscow, Russia.

Scandium(III) extraction from sulfate solutions by methyltrialkylammonium sulfate and methylcyclohexyldioctylammonium sulfate in toluene was investigated, using the methods of distribution, slope analyses and mathematical modeling of extraction isotherms. The formation of complexes, which partially dissociate in organic phase,  $(R_4N)_3[Sc(SO_4)_3]$  with methyltrialkylammonium sulfate and  $(R_4N)_2SO_4\cdot Sc_2(SO_4)_3$  with methylcyclohexyldioctylammonium sulfate, was established. The thermodynamic constants of extraction equilibrium were calculated.

## INTRODUCTION

Scandium exists in water sulfate solutions in form of the complexes  $Sc(SO_4)_n^{3-2n}$ , where  $n = 1-3$  [1]. In a small excess of sulfate ligands, the cationic complexes  $ScSO_4^+$  are formed. When the concentration of  $SO_4^{2-}$  groups is increased, the anionic complexes  $Sc(SO_4)_2^-$  preferably with  $Li_2SO_4$  and  $Sc(SO_4)_3^{3-}$  with  $Na_2SO_4$  are formed. With sulphates of  $NH_4^+$ ,  $K^+$ ,  $Rb^+$  and  $Cs^+$  both type of complexes are observed. When the pH of the sulfate solutions is increased, hydrolysed complexes of scandium are formed, due to replacement of sulfate ligands by hydroxyl groups. Complexes of the composition  $Sc(OH)SO_4$ ,  $Sc_3O_2(OH)_3SO_4$ , and  $Sc_4(OH)_{10}SO_4$  are formed at the same time. At  $pH \geq 4.9$ , insoluble scandium hydroxysulfates are precipitated [2].  $SO_4^{2-}$  groups can be co-ordinated as monodentate or bidentate ligands in scandium anionic complexes. In this case the symmetry of  $SO_4^{2-}$  ion is decreased from  $T_d$  to  $C_{2v}$ . The highest possible number of sulfate ligands that can be included into the inner sphere of scandium anionic complexes is 3, forming the  $Sc(SO_4)_3^{3-}$  anion.

Numerous double sulfates of scandium with alkaline metals and ammonium such as  $MeSc(SO_4)_2$  and  $Me_3Sc(SO_4)_3$  were prepared. These salts can be isolated from solutions in solid phase as different hydrates [1]. So in sulfate solutions in presence of access of  $SO_4^{2-}$  groups, two anionic complexes of scandium exist preferably: less stable  $Sc(SO_4)_3^-$  and more stable  $Sc(SO_4)_3^{3-}$ . They can be extracted by quaternary ammonium salts (QAS). This work reports the solvent extraction of scandium from sulfate solutions by QAS.

## EXPERIMENTAL

For the extraction experiments  $Sc_2(SO_4)_3$ ,  $Na_2SO_4$  and  $H_2SO_4$  of analytical grade were used. As extractants, 0.1 M solutions of methyltrialkylammonium sulfate (TAMAS) and methylcyclohexyldioctylammonium sulfate (MChDOAS) in toluene were used. TAMAS and MChDOAS were prepared from methylsulfate forms of QAS by consecutive contact of the organic salts with water solutions of 50%  $H_2SO_4$ , 10% NaOH and 10%  $Na_2SO_4$ . In the case of MChDOAS, sodium sulfate, which was extracted by MChDOAS, was isolated as solid salts by

precipitation in acetone. The acetone was evaporated in a vacuum. The extraction was carried out in thermostatic separate funnels at temperature  $T = 25 \pm 0.1^\circ\text{C}$ , with initial ratio of organic and water phase volumes O:W = 1:1 and contacting time 15 min. Organic and water phases were separated and metal contents in water solutions were determined by complexonometric [3] or spectrophotometric methods with xylanol orange as indicator [4].

## RESULTS AND DISCUSSION

In Figure 1 the extraction isotherms of Sc from sulfate solutions by 0.1 M TAMAS and 0.1 M MChDOAS in toluene are presented. As one can see that the loading of the organic phase depends on extractant's structure and composition of water solution. The differences are due to the formation of various extractable complexes. The decrease of loading for Sc extraction from sulfate acidic solutions is explained by competitive distribution of sulfuric acid. At the same time,  $\text{H}_2\text{SO}_4$  addition into the initial solutions of Sc was necessary to prevent metal hydrolysis.

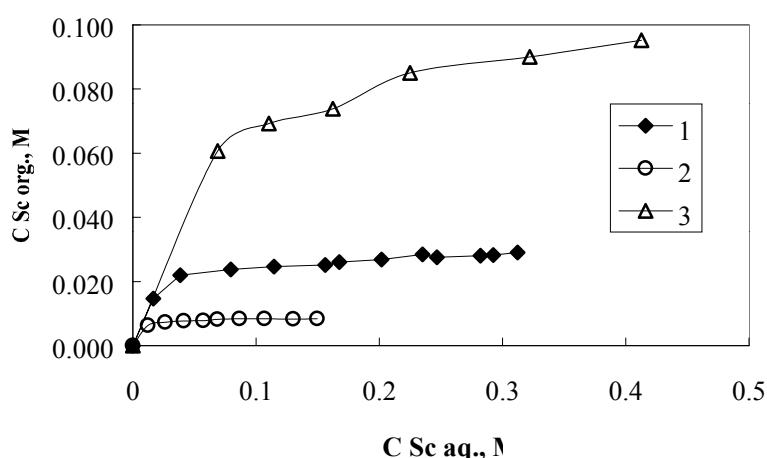

Figure 1. Scandium extraction isotherms from sulfate solutions by QAS.

- 1- $\text{H}_2\text{O} - \text{Sc}_2(\text{SO}_4)_3 - 0.1 \text{ M TAMAS} - \text{toluene};$
- 2- $\text{H}_2\text{O} - \text{Sc}_2(\text{SO}_4)_3 - 0.5 \text{ M Na}_2\text{SO}_4 - 0.2 \text{ M H}_2\text{SO}_4 - 0.1 \text{ M TAMAS} - \text{toluene};$
- 3- $\text{H}_2\text{O} - \text{Sc}_2(\text{SO}_4)_3 - 0.1 \text{ M TAMAS} - \text{toluene}.$

### Theoretical

In the present work the mathematical modelling of the extraction isotherms were carried out using software «EXTREQ». The basis for this computing program is a method that takes into account the hydration of organic components for calculation of non-ideality of organic phase, suggested by Sergievsky [5]. The following equations were used for description of scandium sulfate extraction in all cases.

Model of physical partition: chemical reaction

and constant of distribution

$$\ln K_{101}^T = \ln \frac{C_{\text{Sc.org}}}{a_{\text{Sc}}} + H_{101}(1 - a_w) \quad (2)$$

## Model of solvates formation: chemical reaction

and constant of extraction

$$\ln K_{pqv}^T = \ln \frac{C_{Sc.org}^q}{a_{Sc} C_{ext}^q} + H_{pqv}(1 - a_w) \quad (4)$$

where  $K_{pqv}^T$  is the thermodynamic constant of distribution or extraction;  $C_{Sc.org}$ , metal concentration in organic phase;  $a_{Sc}$ , metal activity in water phase;  $C_{ext}^q$ , equilibrium free extractant concentration;  $H_{pqv}$ , hydration parameter;  $p$ , number of  $Sc_2(SO_4)_3$  molecule in extractable compound;  $q$ , number of extractant molecule in extractable compound,  $v$ , stage of dissociation ( $v = 1$ , no dissociation;  $v = 2$ , first stage dissociation, etc.) In both equations (2) and (4), the hydration parameter includes non-ideality of organic phase, mainly interactions of water – organic components.

Equation (4) with  $q = 1$  will describe monosolvate extraction; equation (4) with  $q = 3$  will describe three chargeable complex extraction. The extractable compound can dissociate in the organic phase. Generally the equation for the extraction constant can be written as:

$$\ln K_{pqv}^T = \ln \frac{C_{Sc.org}^{qv}}{a_{Sc} C_{ext}^q} + H_{pqv}(1 - a_w) \quad (5)$$

In the case of extraction of two or more compounds, the equations are combined to determine all the extraction constants. The software «EXTREQ» gives the possibility of calculating extraction constants and hydration parameters for four simultaneously extractable compounds by one extractant using experimental distribution data. Relative errors between experimental and calculated isotherms and standard deviation of experimental points were used as criteria of the accuracy.

## Extraction of Scandium by MChDOAS

A molar ratio  $(R_4N)_2SO_4:Sc_2(SO_4)_3 = 1:1$  in case of MChDOAS (Figure 1) is evidence of monosolvate formation  $(R_4N)_2SO_4 \cdot Sc_2(SO_4)_3$ . Recently monosolvate formation for the extraction of Li, Na, Zn(II), Cu(II), Co(II) and Ni(II) sulfates by MChDOAS was established [6]. The mechanism of anion intercalation for explaining of this kind extraction was presented. The experimental results obtained allowed consideration of the distribution of scandium from sulfate solutions to toluene solutions of MChDOAS by anion intercalation extraction.

For confirmation of monosolvate formation of scandium sulfate with MChDOAS, mathematical modeling of extraction isotherm was carried out. In the literature, experimental thermodynamic data for binary water solutions of scandium sulfate are not found. Therefore, we calculated activity coefficients and water activity in such solutions using comparative methods and experimental data for different trivalent metals sulfates, nitrates and chlorides and scandium chloride and nitrate. Values obtained were used for simulation of all extraction isotherms.

In Table 1 the results of mathematical modeling of scandium sulfate extraction by 0.1 M MChDOAS in toluene under the assumption of physical distribution and formation of different solvates with or without dissociation into organic phase are presented. As should be seen from analysis of error values, the extractable monosolvate is partially dissociated in the organic phase. So results of mathematical modeling verify the formation of monosolvate of scandium sulfate with MChDOAS, which is partially dissociated under high values of water activity.

*Table 1. Results of mathematical modeling of Sc isotherm by 0,1 M MChDOAS in toluene.*

pqv	101	101	102	111	112	121	122	131	132
$\ln K'_{\text{pqv}}$	3.716	0.003	4.840	6.461	9.077	0.856	24.08	1.621	29.91
$H_{\text{pqv}}$	99.8	-31.71	168.1	-71.04	222.2	-5.588	136.2	-41.80	244.0
% error	68.9		8.42		3.66		6.45		51.17

So, the chemistry of scandium extraction from sulfate solutions can be presented by two equations:

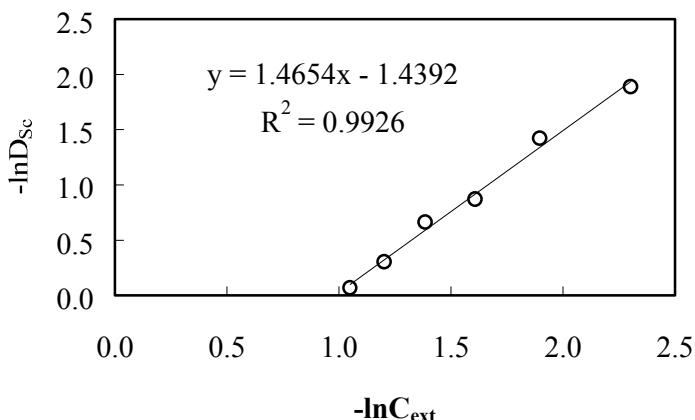

It is necessary to note, that another equation for first dissociation stage of monosolvate can be written:

Thermodynamic parameters of extraction equilibrium with MChDOAS are presented in Table 3.

### Extraction of Scandium by TAMAS

In contrast to MChDOAS, the partitioning of scandium from binary water solutions and from sulfuric solutions contained salting-out agent into toluene solutions of TAMAS is accompanied by the formation of a most stable three chargeable complex  $(\text{R}_4\text{N})_3[\text{Sc}(\text{SO}_4)_3]$ . In this case, the molar ratio  $(\text{R}_4\text{N})_2\text{SO}_4:\text{Sc}_2(\text{SO}_4)_3$  is 3:1. The distribution of this complex is confirmed by results of slope analyses (Figure 2).

*Figure 2. The dependence of  $\ln D_{\text{Sc}}$  vs.  $\ln C_{\text{ext}}$  for Sc extraction from sulfate solutions, containing 0.001 M  $\text{Sc}_2(\text{SO}_4)_3$ , 0.5 M  $\text{Na}_2\text{SO}_4$  and 0.2 M  $\text{H}_2\text{SO}_4$  by TAMAS in toluene.*

The dependence of  $\ln D_{\text{Sc}}$  vs.  $\ln C_{\text{ext}}$  is a straight line with tangent of angle equal 1.465, that corresponds to  $q = 3$  in equation (3). Mathematical modeling, which was carried out for both isotherms with TAMAS, showed adequate description only for model of three chargeable anionic complex extraction with its partial dissociation under high values of water activity. In Table 2, the results of the mathematical calculations of the extractable complexes concentrations in frame of selected model for  $\text{Sc}_2(\text{SO}_4)_3$  extraction by TAMAS are presented.

The chemistry of Scandium extraction from sulfate solutions by TAMAS can be described the following equations:

In Table 3 thermodynamic data for extraction equilibrium of scandium sulfate with MChDOAS and TAMAS are presented.

*Table 3. Thermodynamic parameter of Sc extraction from sulfate solutions by QAS.*

Composition of water phase	Composition of extractable compounds	Num. of points	ln K <sup>T</sup> <sub>pqv</sub>	H <sub>pqv</sub>	% error

Sc <sub>2</sub> (SO <sub>4</sub> ) <sub>3</sub> , 0.5 M Na <sub>2</sub> SO <sub>4</sub> , 0.05 M H <sub>2</sub> SO <sub>4</sub> , a <sub>w</sub> = 0.9755	(R <sub>4</sub> N) <sub>3</sub> [Sc(SO <sub>4</sub> ) <sub>3</sub> ] (R <sub>4</sub> N) <sub>2</sub> [Sc(SO <sub>4</sub> ) <sub>3</sub> ] + R <sub>4</sub> N <sup>+</sup>	9	26.567 29.958	102.5 250.0	1.16

The scandium extraction from binary solutions is accompanied by formation of three chargeable complex in organic phase too. But under these conditions, when the salting-out agent is absent in water solutions, the distributed species can be the neutral molecule Sc<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub> only. So, in this case formation of anionic complex is the result of complexing reaction or replacement of water molecule on sulfate groups in organic phase. These reactions embodied high values of the hydration parameters. The negative value of H<sub>111</sub> for scandium extraction by MChDOAS corresponds to more hydration number of extractant in comparison with extractable monosolvate.

For the isotherm obtained in the presence of  $\text{Na}_2\text{SO}_4$ , the extrapolation of the function  $\ln K_{\text{pqv}}^T$  vs.  $(1-a_w)$  at  $a_w = 0.9755$  was made. This water activity corresponds to the standard condition of "indefinitely dilute solution" of scandium sulfate in 0.5 M  $\text{Na}_2\text{SO}_4 + 0.05$  M  $\text{H}_2\text{SO}_4$  water solution. The calculated value of  $\ln K_{\text{pqv}}^T$  shows that the addition of the salting-out agent increases the extraction constant of non-dissociated sulfate complex of scandium up to 4 orders of magnitude and the dissociated complex up to 5 orders. The extraction constant of scandium from nitrate solutions by TAMAN is up to 12 orders less than from sulfate media [7]. So, sulfate media are preferable for recovery scandium by QAS.

## CONCLUSIONS

Scandium(III) can be extracted from water sulfate solutions as the neutral salt or anionic complexes by quaternary ammonium sulfates. Extraction of  $\text{Sc}_2(\text{SO}_4)_3$  by MChDOAS is accompanied by the formation of the monosolvate  $(\text{R}_4\text{N})_2\text{SO}_4 \cdot \text{Sc}_2(\text{SO}_4)_3$ , presumably by the mechanism of anionic intercalation. Extraction of  $\text{Sc}_2(\text{SO}_4)_3$  by TAMAS is accompanied by the formation of three chargeable anionic complex  $(\text{R}_4\text{N})_3[\text{Sc}(\text{SO}_4)_3]$ . This process is due to a complexing reaction or replacement of water molecule on sulfate groups in the organic phase. From sulphate solutions with excess salting-out agent, the more stable anionic complex  $(\text{R}_4\text{N})_3[\text{Sc}(\text{SO}_4)_3]$  is extracted by an anion-exchange mechanism. The above compounds can be partially dissociated in the organic phase under conditions of high water activity.

## EXTRACTION OF URANIUM(VI) FROM PHOSPHATE MEDIA IN POLY(ETHYLENE GLYCOL) SOLUTIONS

Alfia M. Safiulina, Oxana A. Sinegribova and Valerii M. Shkinev\*

D. Mendeleev University of Chemical Technology of Russia, Moscow, Russia

\*Vernadsky Institute of Geochemistry and Analytical Chemistry,  
Russian Academy of Sciences, Moscow, Russia

Extraction of uranium(VI) from concentrated phosphate media using aqueous poly(ethylene glycol) (PEG) solutions with different molecular masses (1500, 4000, 6000, 20 000) was studied. The phase diagram for the PEG/phosphate salts/water system has been examined and the causes of phase formation from the position of the theory of regular solutions was explained after a theoretical analysis of the PEG/water and phosphate salt/water systems. A study of the distribution coefficients of uranium(VI) between the phases as a function of pH indicated that uranium extraction increased with the pH of the salt phase. Extraction of uranium at pH 13.6 and 20°C was studied as a function of its concentration in the salt phase. The separation coefficients of uranium from Ca, Cr, Cu, Mg, B, Zn, Co, and Ni were greater than 100.

### INTRODUCTION

Liquid-liquid extraction systems based on water-soluble polymers are used for the separation of biomolecules in biotechnology [1]. The studies, first initiated at the Vernadsky Institute in Moscow in 1983, have shown that not only biomolecules but common metal ions as well are unevenly distributed between the two phases in Aqueous Biphasic Systems (ABS), one of which is the salt-rich phase and the other is the PEG-rich phase [2-5]. Pioneering research has been done on the application of ABS to the separation of actinides [2-5]. The experiments indicated that such systems are suitable for the extraction of various metals, including actinides [2-7]. This system usually contains two aqueous phases: either two solutions of two-water soluble polymers, or one solution of water-soluble polymer and a solution of an inorganic salt. The components of the systems are distributed between these two aqueous phases. Poly(ethylene)glycol (PEG) is popular polymer for such systems. The advantages of polymer systems, as compared with traditional extraction systems, are the following: PEG systems are cheap; the components are readily available; they are non-toxic in nature, inflammable, and contain no organic diluent.

The aim of our work is to study the extraction of uranium(IV) from higher pH solutions and provide a thermodynamic description of the phase formation in ABS from a study of the PEG/water and salt/water systems.

## EXPERIMENTAL

### Reagents and Methods

The inorganic salts were of chemical purity grade. PEG from Loba Chemie with different molecular masses from 1500 to 20 000 was used in the extraction experiments. 2 ml of 40 mass % solution of potassium phosphate, uranium solution aliquot and 2 ml of 40 mass % PEG solution were diluted with water to a volume of 6 ml. The mixture was shaken for 7 min. After phase separation, aliquots of each phase were withdrawn and analysed by x-ray fluorescence analysis. Measurements of solution pH were made on a LPU-01 pH meter after phase separation.

The distribution coefficients were calculated as the ratio of the uranium concentration in the PEG-enriched phase (PEG-phase) to that in the phosphate salt-enriched phase (salt phase).

## RESULTS AND DISCUSSION

### Phase Diagrams

Some phase diagrams of phosphate salt/PEG systems are given in Figure 1.

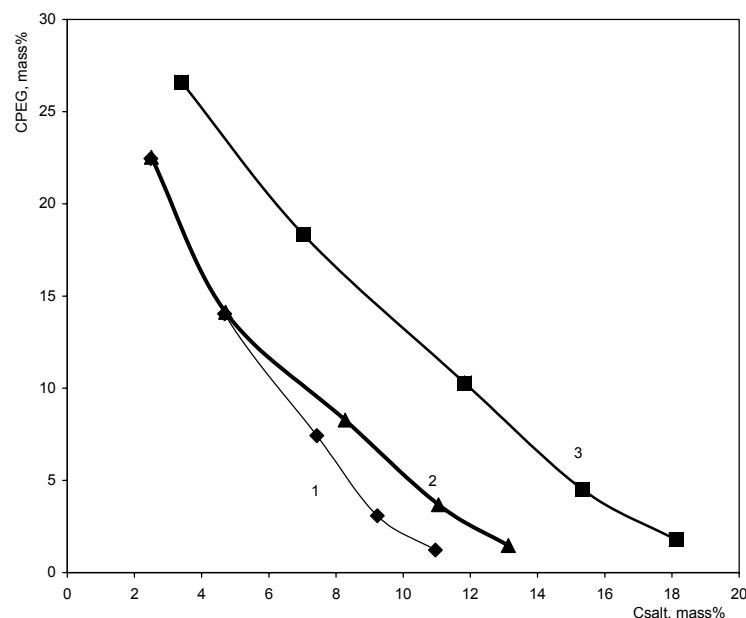

Figure 1. Phase diagrams: (1)  $\text{PEG1500} / \text{K}_3\text{PO}_4 / \text{H}_2\text{O}$ ; (2)  $\text{PEG1500} / (\text{NH}_4)_2\text{SO}_4 / \text{H}_2\text{O}$ ; (3)  $\text{PEG1500} / \text{K}_2\text{HPO}_4 / \text{H}_2\text{O}$ .

The heterogeneity areas are situated above the corresponding lines in the diagrams. The system chosen for the investigation of uranium extraction contained 12 mass % PEG 1500 and 12 mass % phosphate salts. Comparison of the phosphate and sulfate systems indicated that order of affinity of the salt for phase formation is  $\text{K}_3\text{PO}_4 = (\text{NH}_4)_2\text{SO}_4 > \text{K}_2\text{HPO}_4$ . The molecular mass of PEG influences the viscosity and phase separation rate of the systems. It is practically convenient to work with PEG of a molecular mass between 1500 and 4000, at a polymer concentration lower than 40 %.

The phase separation rate of such systems was faster than 5 min. The pH of the salt systems influences the phase separation rate. For concentrated solutions, the phase separation is better.

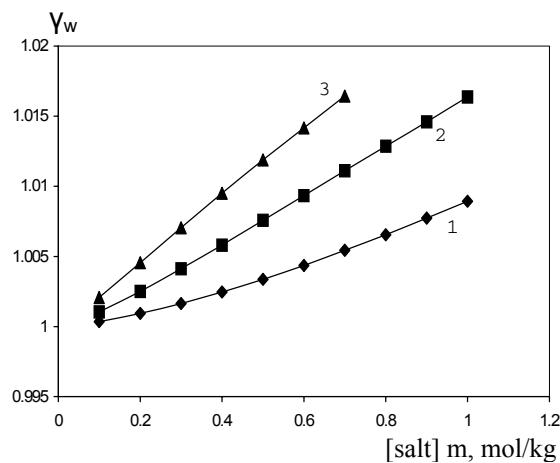

### Thermodynamic Description

To studying the three component system (water/soluble polymer/inorganic salts), two bi-component systems (water/inorganic salt and water/water-soluble polymer) were considered. The bi-component system water/inorganic salt was analyzed from the point of view of the theory of electrolyte solutions. It was found that salts containing anions ( $\text{PO}_4^{3-}$ ,  $\text{CO}_3^{2-}$ ,  $\text{HPO}_4^{2-}$ ,  $\text{SO}_4^{2-}$ ,  $\text{SCN}^-$ ), capable of creating two-phase equilibria in the three-component system, are characterized by weak interactions with water (negative hydration energy  $\Delta G > 0$  in Table 1) and by positive deviation from Raoult's law ( $\gamma_w > 1.0$ ) (Figure 2) in the water/inorganic salt binary system.

*Table 1. Hydration energies of salts.*

Salt	$\Delta G_{\text{hydr}}$ (kcal/mol)	Salt	$\Delta G_{\text{hydr}}$ (kcal/mol)
$\text{Na}_3\text{PO}_4$	7,85	$\text{Cu}(\text{NO}_3)_2$	-3.09
$\text{Na}_2\text{HPO}_4$	4,04	$\text{Zn}(\text{NO}_3)_2$	-3.7
$\text{NaH}_2\text{PO}_4$	-0,74	$\text{NH}_4\text{NO}_3$	-1.46
$\text{Na}_2\text{SO}_4$	3,22	$\text{NaF}$	0,67
$\text{NaHSO}_4$	2,06	$\text{KF}$	-3,46
$(\text{NH}_4)_2\text{SO}_4$	1,27	$\text{LiBr}$	-7,24
$\text{Na}_2\text{CO}_3$	1,96	$\text{LiI}$	-6,27
$\text{K}_2\text{SO}_4$	4,22	$\text{CsF}$	-8,65
$\text{KHSO}_4$	1,99	$\text{Ca}(\text{NO}_3)_2$	-1,82
$\text{KH}_2\text{PO}_4$	0,76	$\text{Li}_2\text{SO}_4$	0,11
$\text{K}_2\text{CO}_3$	-4,2		

The negative derivation from Raoult's law ( $\gamma_w < 1.0$ ), exhibited by the interaction of salts with water, characterize the salts of metals with anions, in the presence of which two phases are not formed (for example,  $\text{LiCl}$ ,  $\text{NaCl}$ ,  $\text{NaNO}_3$ ). The ability of salts to achieve phase formation is connected, as a rule, with the negative hydration energy, and hence with more intensive interaction of cations and anions between themselves than with water.

*Figure 2. Activity coefficients of water in the system potassium phosphate salts/ $\text{H}_2\text{O}$ . (1)  $\text{KH}_2\text{PO}_4$ , (2)  $\text{K}_2\text{HPO}_4$ , (3)  $\text{K}_3\text{PO}_4$ .*

In the present work, the experimental data concerning the dependency of water activity on the concentration and molecular masses of PEG for the temperatures 298, 313, 323, and 333 K [8] were treated and discussed from the point of view of the theory of polymer solutions (Figure 3).

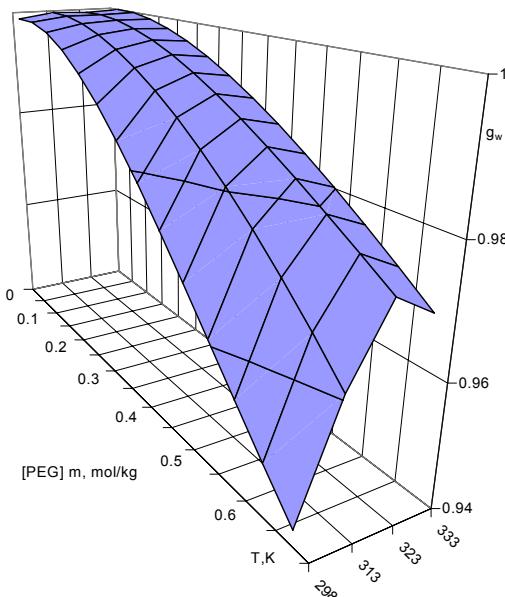

Figure 3. Activity coefficients of water in the system PEG1500 /  $H_2O$ .

It was shown that these dependencies can be explained by a thermal effect, namely by an entropy increase on mixing of molecules with different sizes (Flory-Huggins theory). Quantitative description is possible if one takes into account the value of the coordination number. The Van-der-Waals force effect was described and  $\gamma_{vw}$  was estimated in the approximation to the theory of regular solutions:  $\gamma_{vw} = \exp(2T_c/T)$ . The value of  $\gamma_{hydr}$  was determined from  $\gamma_{hydr} = 1/\gamma_{vw}$ . If the pure substance was considered as the standard condition,  $\gamma_{hydr} = \exp(-2T_c/T)$ . The hydration number ( $h$ ) was found, which was equal to 2 at the cloud-point temperature for the binary solution; at lower temperatures, it is equal to 4 according to the equation  $1/\gamma_{hydr} = \exp(h)$ , where  $h = 2T_c/T$ . So the influence of Van-der-Waals forces on phase separation is important.

It was shown earlier [9] that some phase diagrams for polymer systems contain two cloud points. The upper part of diagram, corresponding to upper cloud point, is a result of the influence of Van-der-Waals forces. The appearance of the lower critical point may be caused by the formation of crystallohydrates in these systems. It corresponds with the temperature effect on the phase separation process: for such systems, when temperature rises the expansion of the two-phase field is typical. So it can be concluded from the investigation of PEG/water systems that the properties of solutions are determined by the entropy factor.

### Extraction of Uranium

For practical purposes, it is important to study the distribution of species in multi-component systems. The distribution of uranium(VI) in the phosphate salts/PEG system was studied (Figure 4). There are conditions for the selective recovery of uranium.

The distribution of uranium has been examined at different pH values of the equilibrium salt-phase. Earlier, the distribution coefficients of some common and actinide metals were examined for PEG/ammonium sulphate systems [2-5] and for the phosphate system at pH values lower than 11 [2].

Optimal conditions for uranium extraction from phosphate solutions are pH 11 to 14. Distribution coefficients are near 2.0 for molecular masses of PEG from 1500 to 4000. For higher molecular masses of PEG (6000, 20 000), the distribution coefficients increased (Figure 5).

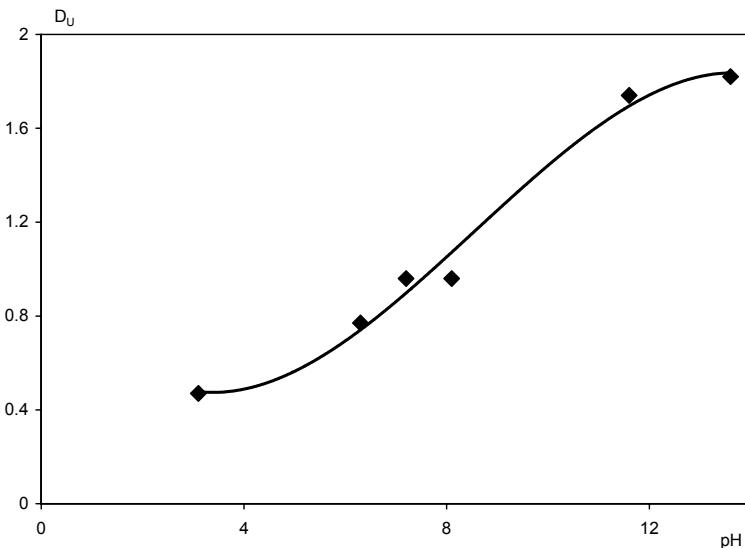

Figure 4. Influence of pH the on distribution coefficient of U(VI) in the system PEG1500 (12 mass %) / potassium phosphate salts (12 mass %) /  $H_2O$ .

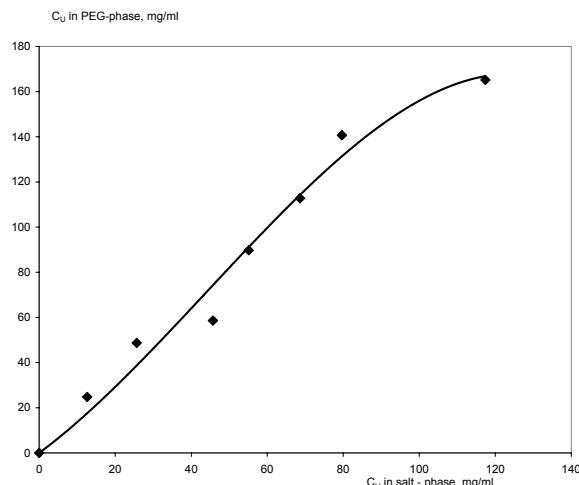

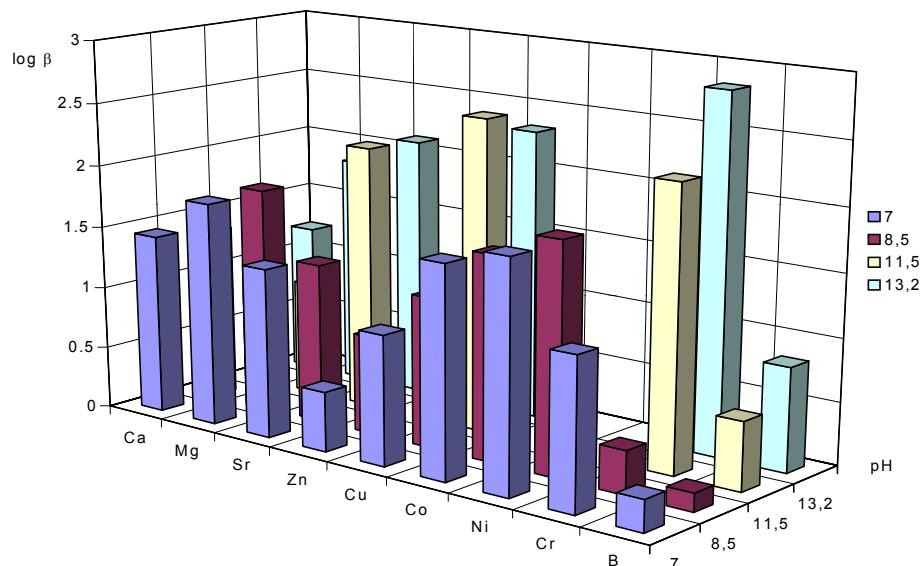

Figure 5. Distribution of uranium (VI) in the system PEG1500 (12 mass %) / potassium phosphate (12 mass %) /  $H_2O$ . pH = 13.6 and  $20^{\circ}C$ .

The extraction of uranium at these conditions is very selective. The separation coefficients of uranium from Zn, Cu, Cr, Ni and other elements are higher than 100 and it is possible to separate uranium from common metals (Figure 6).

## CONCLUSIONS

Conditions for optimal extraction of uranium from concentrated phosphate solutions were selected. A theoretical description of the PEG/water and phosphate salt/water systems was carried out. Selective extraction of uranium was shown.

*Figure 6. Separation coefficients ( $\beta = \log D_U/D_{me}$ ) for the system PEG1500 (12 mass %) / potassium phosphate salts (12 mass %) /  $H_2O$ .*

## DEVELOPMENT OF ENVIRONMENTALLY BENIGN NEW SOLVENT EXTRACTION REAGENTS FROM CHITOSAN, A NATURAL POLYSACCHARIDE

Katsutoshi Inoue, Kazuharu Yoshizuka, and Keisuke Ohto

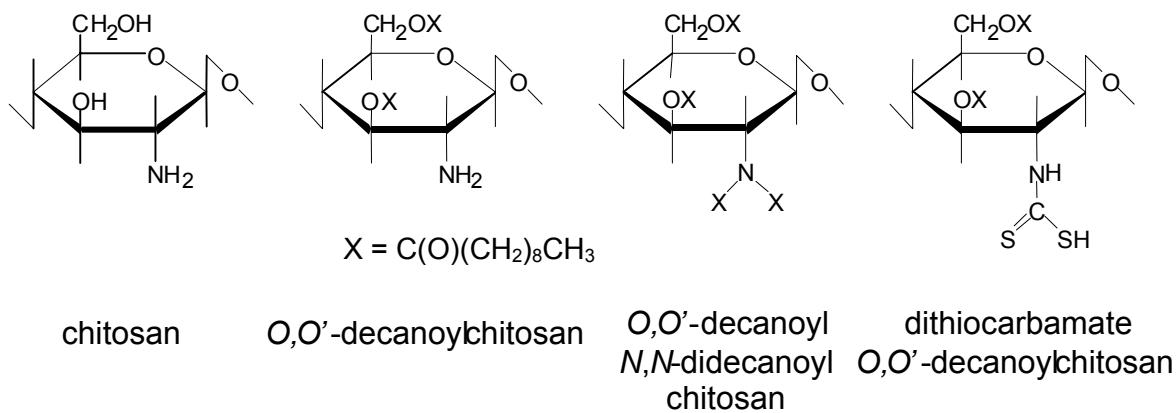

Department of Applied Chemistry, Faculty of Science and Engineering,  
Saga University, Japan

Two types of lipophilic chitosan, O,O'-decanoyl chitosan (1) and O,O'-decanoyl N,N-didecanoyl chitosan (2) as well as that chemically modified with functional groups of dithiocarbamate (3) were synthesized as solvent extraction reagents for metal ions from chitosan, which is a natural polysaccharide produced from shells of crabs, shrimps, prawns and so on, a biomass waste discharged from marine food industries. Although the reagent (1) was soluble in toluene, the reagents (2) and (3) were soluble not only in toluene but also in kerosene and hexane. In the solvent extraction with the reagent (1), Cu(II) was selectively extracted while only negligible amount of Fe(III) was extracted though it was selectively extracted over Cu(II) in the extraction with the reagent (2). On the other hand, in the extraction with the reagent (3), Cu(II) and Ni(II) were selectively extracted over Fe(III).

### INTRODUCTION

Chitosan is a basic polysaccharide containing primary amino groups. It is produced from shells of some Crustacean such as crabs, shrimps, prawns etc. as discharged from marine food industries in large amount as biomass wastes. It is currently being used for various purposes such as coagulating reagent in waste water treatments or as raw materials for cosmetics, reagents for improving soils for agriculture and so on. Although chitosan itself is hydrophilic solid powder, it is possible to make it lipophilic and soluble in some organic diluents by means of some chemical modifications of hydroxyl groups, for example, by acylating them by using chloride of some carboxylic acids with long-chain alkyl radicals [1]. In addition, the primary amino groups of chitosan are reactive and suitable for various chemical modifications. Thus it is possible to immobilize a variety of functional groups with high affinity to specified metal ions, suggesting the possibility of the development of very new solvent extraction reagents from chitosan, environmentally benign natural polysaccharide.

From the viewpoints as such, we prepared O,O'-decanoyl chitosan which has the free primary amino groups and O,O'-decanoyl N,N-didecanoyl chitosan in which the primary amino group is also acylated with two decanoyl groups as well as O,O'-decanoyl dithiocarbamate chitosan the primary amino groups of which are chemically modified with dithiocarbamate to test their solvent extraction behaviors for some metal ions (see Figure 1).

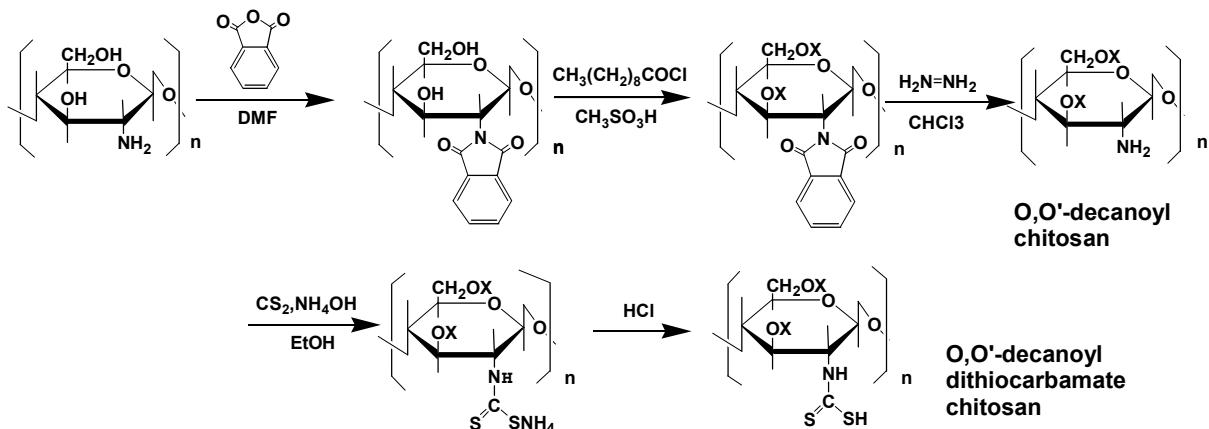

*Figure 1. Chemical structures of chitosan and some lipophilic chitosan employed in the present work.*

## EXPERIMENTAL

$O,O'$ -decanoyl chitosan was synthesized according to the method proposed by Nishimura *et al.* [1] as shown in Scheme 1. Here, prior to the acylation of hydroxyl groups of chitosan with decanoyl chloride, primary amino groups were protected against the attack by the decanoyl chloride by interacting phthalic acid anhydride which was deprotected by using hydrazine after the acylation. The product was soluble in chloroform and toluene, but insoluble in kerosene.  $O,O'$ -decanoyl  $N,N$ -didecanoyl chitosan was prepared by directly interacting decanoyl chloride with chitosan according to the method of Fujii *et al.* [2]. The product was soluble not only in chloroform and toluene but also in hexane and kerosene.

$O,O'$ -decanoyl dithiocarbamate chitosan was synthesized by interacting  $O,O'$ -decanoyl chitosan with carbon disulfide. The sulfur content was measured by using a Mitsubishi Chemicals model TOX-10 total halogen analyzer, from which the extent of the immobilization of the functional groups of dithiocarbamate onto glucosamine unit of  $O,O'$ -decanoyl chitosan was evaluated as high as 96 % [3] while it was only 25 % in the case of immobilization onto chitosan, the solid feed material [4]. It was soluble not only in chloroform and toluene but also in hexane and kerosene.

### Preparation of the Reagents

*Scheme 1. Synthetic route of  $O,O'$ -decanoyl chitosan and  $O,O'$ -decanoyl dithiocarbamate chitosan.*

## Procedure

All experiments of solvent extraction and adsorption were carried out batch wise at 30 °C. Aqueous metal solutions for solvent extraction or adsorption tests were prepared by dissolving metal sulfate or nitrate in 0.1 M aqueous HEPES (2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid) buffer solution the pH of which was adjusted by adding small amount of nitric acid or sulfuric acid. Initial metal concentration was 0.1 or 0.2 mM for all metal ions in the cases of solvent extraction tests and adsorption tests, respectively. In the solvent extraction tests with O,O'-decanoyl chitosan, chloroform and toluene was used as diluents while, in those with O,O'-decanoyl N,N-didecanoyl chitosan and O,O'-decanoyl dithiocarbamate chitosan, kerosene was used.

Equal volumes (5 ml) of organic and aqueous phases were contacted for 12 h to attain equilibrium in the solvent extraction tests while 30 mg chitosan powder was shaken in 10 ml aqueous metal solution for 24 h in the adsorption tests. Metal concentration in the aqueous phase was measured by using Seiko model SAS 7500 or Shimadzu model AA-6650F atomic absorption spectrophotometer. Metal concentration in the organic phase and amount of metal adsorption on chitosan was calculated by mass balance.

## RESULTS AND DISCUSSION

### O,O'-Decanoyl Chitosan

Figure 2 shows the plot of % extraction against equilibrium pH in the extraction of some metal ions with O,O'-decanoyl chitosan in chloroform. As seen from this figure, iron(III) is not practically extracted with this solvent while copper(II) is highly selectively extracted over all of other metal ions. Similarly, also in the case of toluene as the diluent, only copper(II) was extracted with this reagent while other metals including iron(III) were not practically extracted.

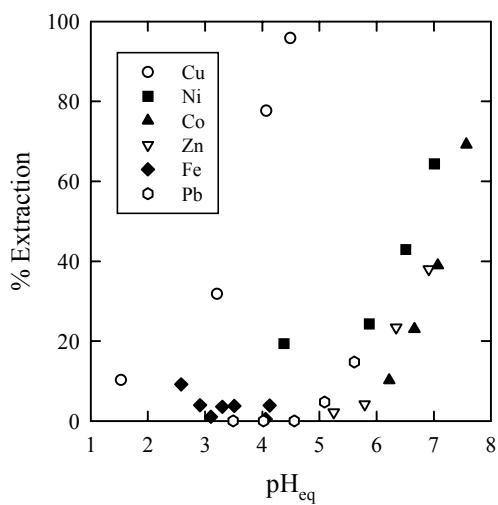

Figure 2. Percentage extraction of some metal ions with O,O'-decanoyl chitosan in chloroform.

Figure 3 shows the plot of % adsorption against equilibrium pH in the adsorption of the same metal ions on chitosan itself. Very different from the result shown in Figure 2, iron(III) is selectively adsorbed over other metals including copper(II). In addition, the extraction with O,O'-decanoyl chitosan takes place at pH greater than 2, which is lower than that at which adsorption on chitosan takes place by 1 pH unit; that is, copper(II) is more strongly extracted with O,O'-decanoyl chitosan than chitosan itself by making chitosan lipophilic. It may be inferred that only the nitrogen atom of primary amino group takes part in the coordination with metal ions in the extraction with O,O'-decanoyl chitosan while oxygen atom of the hydroxyl

group adjacent to the primary amino group also take part in the coordination in the adsorption on chitosan itself as was suggested in the previous paper [5]. In these respects, further works should be necessary in future to elucidate the exact and detailed mechanisms of solvent extraction and adsorption reactions.

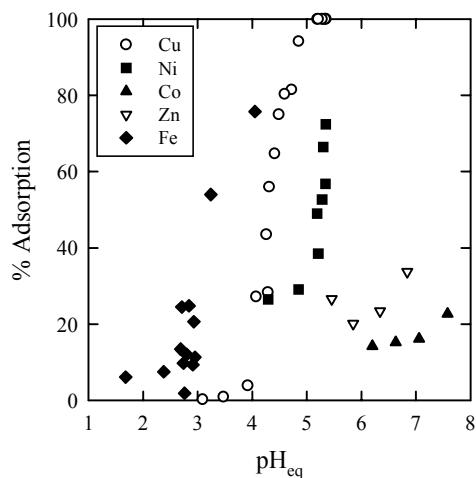

Figure 3. Percentage adsorption of some metal ions on chitosan.

#### O,O'-Decanoyl N,N-Didecanoyl Chitosan

Figure 4 shows the plots of % extraction of metal ions with O,O'-decanoyl N,N-didecanoyl chitosan in kerosene. In this case, iron(III) is selectively extracted over copper(II), which is much more selectively extracted over other divalent metal ions. In the solvent extraction with lipophilic N,N-diacyl chitosan which have two carbonyl groups at the  $\alpha$ -position adjacent to nitrogen atom, it is very natural to consider that oxygen atoms of the two carbonyl groups take part in the coordination, which may be responsible to the high selectivity to iron(III) over copper(II) different from the extraction with O,O'-decanoyl chitosan. Remarkable differences between chloroform and kerosene were not observed in this case.

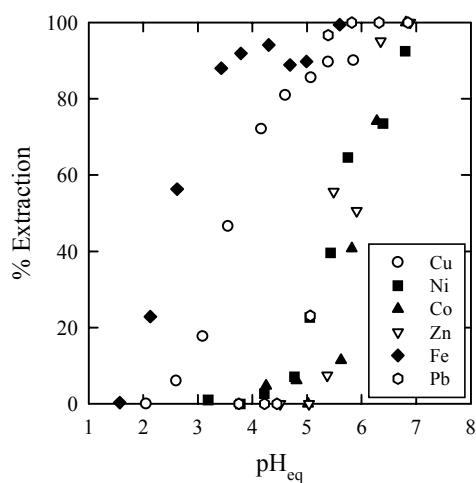

Figure 4. Percentage extraction of some metal ions with O,O'-decanoyl N,N-didecanoyl chitosan in kerosene.

#### O,O'-Decanoyl Dithiocarbamate Chitosan

Figure 5 shows the plot of % extraction against equilibrium pH in the extraction of some metal ions with 2.3 kg/m<sup>3</sup> O,O'-decanoyl dithiocarbamate chitosan in kerosene. As seen from this figure, copper(II) is nearly quantitatively extracted over the whole pH greater than 1, very selectively over other metal ions tested. Although nickel(II) is extracted at pH higher than that

at which the extraction of copper(II) takes place, it is much more selectively extracted over other metal ions including iron(III), which is selectively extracted over cobalt(II) and zinc(II). The sequence of the selectivity among metal ions in this extraction system is also different from that in the adsorption on chitosan chemically modified with dithiocarbamate groups the extent of immobilization of which was about 25 % on glucosamine unit of chitosan. That is, the order of the selectivity among metal ions in the adsorption on the dithiocarbamate chitosan was as follows: Cu(II) > Fe(III) > Ni(II) ~ Co(II) [4].

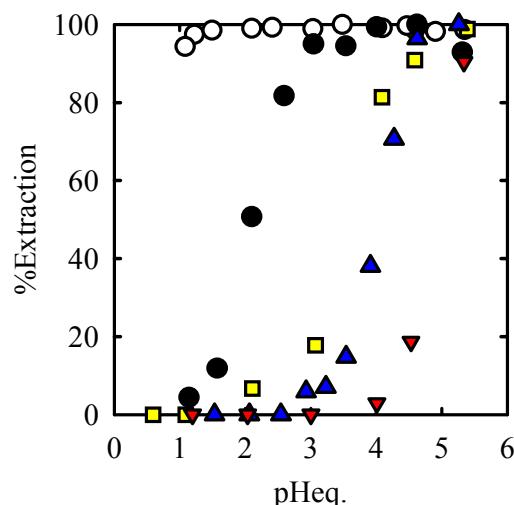

Figure 5. Percentage extraction of some metal ions with O,O'-decanoyl dithiocarbamate chitosan in kerosene. ○: Cu(II), ●: Ni(II), □: Fe(III), ▲: Co(II), ▼: Zn(II).

It should be considered that the extent of the immobilization of the functional groups and its characteristics as a soft base are much enhanced by making polymer matrices of chitosan lipophilic.

## NOVEL ELECTROCHEMICAL PROCESSING USING CONVENTIONAL ORGANIC SOLVENTS

T. O'Keefe, M. O'Keefe, R. Fang, J. Sun and E. Dahlgren

Department of Metallurgical Engineering and Graduate Center for Materials Research,  
University of Missouri-Rolla, Rolla, MO, USA

Recent research studies have demonstrated the feasibility of conducting spontaneous electrochemical displacement or redox reactions in conventional solvent extraction organic solutions. Even though the solvents are poor electrolytic conductors, local oxidation/reduction reactions are possible. The patented process was initially designed to use solid metals to remove ferric or ceric ions or metal cation impurities such as copper, lead, cadmium and silver directly from the organic phase. Examples of organic solvents that were successfully used includes D2EHPA, TBP, LIX, Dipex and Alamine. One promising application identified during these studies was Fe<sup>3+</sup> removal from a zinc electrowinning circuit utilizing zinc or iron metal powder in D2EHPA. This process is being evaluated in laboratory pilot tests, with emphasis on producing a usable iron product.

Based on similar chemistry, a unique new process has been developed for the metallization of surfaces in the fabrication of integrated circuits on silicon wafers. After the initial chip surface is coated with Al or a similar barrier metal, an adherent seed layer of Cu, Pd or Au is selectively deposited onto the substrate metal from a suitable organic solution. Once in place, the deposited layer provides an anchoring intermediate film for subsequent build-up of other metals using standard commercial electroless or electrodeposition processes to complete the circuitry. The organic solution process is currently under evaluation for a number of potential commercial semiconductor manufacturing applications. Initial feasibility tests have shown that deposition from the organics has certain advantages over similar aqueous based cementation metallization systems currently used in the electronics industry, but the systems must be optimized.

The basic process and nature of the reactions involved, as well as possible commercial applications of spontaneous electrochemical reactions in organics, will be discussed. The influence of various operating parameters on the reaction rates and efficiencies of these processes, as well as a possible electrochemical model of the process, are presented. Overall, the potential for incorporating electrochemical concepts into the development of new processes or enhancing existing solvent extraction systems seems promising.

### INTRODUCTION

The purification and concentration of leach solutions is a necessary step in most hydro-metallurgical processes because of the adverse effects of trace metal impurities on product quality, recovery and efficiency. Some of the more common treatment options include precipitation, crystallization, electrolysis, cementation, ion exchange and solvent extraction.

Each of these unit operations has certain unique characteristics and advantages, but the ability to provide a favorable distribution of the chemical components between the reacting phases with good, selective separation is essential. From this perspective, solvent extraction is particularly attractive in providing a wide range of options for use in metal production from either primary or waste sources.

The solvent extraction process is based on the ability to control the chemical equilibria operative in an organic/aqueous system. The vast majority of the reactions do not involve electron transfer, but in recent years the use of gaseous reducing agents such as hydrogen as well as photochemical reduction have been proposed, in selected cases, as alternatives to conventional chemical stripping. The concept of incorporating oxidation/reduction reactions to supplement the bulk chemical stripping reactions has been expanded to include the use of solid metals as the reducing agents [1]. Even though the electrical resistances of the organic solutions used were extremely high, it was demonstrated that spontaneous, short range, heterogeneous electrochemical reactions directly in the organic media were possible. Thus, cementation type reactions, similar to those carried out in aqueous solutions, were shown to also be feasible in organic solvents.

A brief overview of direct electrochemical reactions in organic media, termed galvanic stripping, will be presented. Two examples of the use of galvanic stripping will be described. One involves the removal of  $\text{Fe}^{3+}$  from acid zinc sulfate process streams. In a second application area, a completely new form of solid metal deposition that could be used in the electronics industry is presented. The nature of the reactions occurring and the general role that electrochemical reactions may have in organic solvent systems is discussed. A possible model for the mechanism of the reactions is also presented.

### GALVANIC STRIPPING - PROCESS DESCRIPTION

Aqueous solution purification and concentration that involve electrochemical reactions are utilized in a variety of hydrometallurgical operations. While the representation of these displacement or cementation reactions is relatively simple, the specific mechanisms involved may be considerably more complex [2]. The basis for the cementation reaction is the ability of a less noble metal ( $M_2$ ) to serve as the reducing agent for a more noble cation ( $M_1^+$ ) present in an aqueous electrolyte as depicted in Eq. (1).

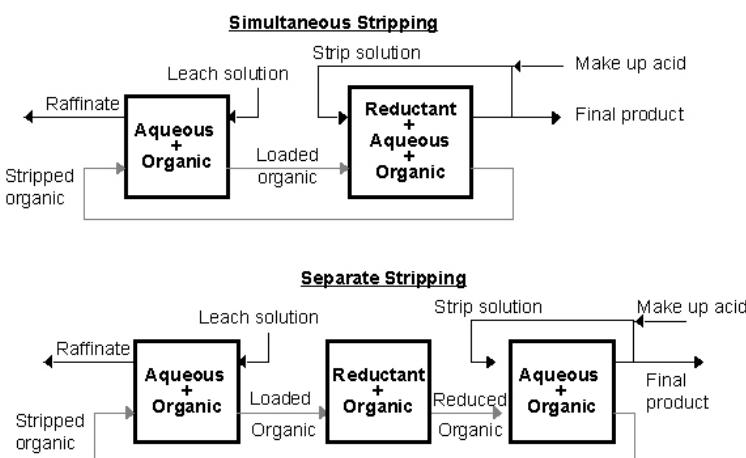

The equilibrium potentials for  $M_1^+/M_1$  and  $M_2^+/M_2$  reflect the relative driving force for oxidation and reduction and each can be written as a separate, half cell reaction, a condition which is unique to electrochemical reactions. While the thermodynamics of the cementation reactions can be used to theoretically predict reaction tendencies, in actual practice the reactions are often strongly influenced by the system kinetics. As a result, the degree and types of polarization inherent to the systems often dictate the extent and efficiency of the reactions. One outcome of this behavior is that a wide range of chemical and operating modifications may be employed to control the cementation reactions and provide a broader range of separation options.

In principle, the galvanic stripping process to be described in this paper is a cementation reaction. The major difference is the nature of the liquid media in which the reactions occur. In this particular variation of the reaction, organic solvents are used instead of aqueous electrolytes. While some organics are good conductors and capable of sustaining electrochemical reactions, the particular organics employed in galvanic stripping are poor electrolytic conductors. This condition imparts a high degree of polarization to the system and forces the spontaneous reactions to occur over a relatively short range because of the high solution resistivities.

The galvanic stripping reactions might be written using the chemical format given previously for aqueous cementation. Though not indicated in Eq. (1), the metal cations are complexed with water in a hydration sheath. In galvanic stripping the chelation or primary solution structure is an organic entity, probably similar to that encountered in standard solvent extraction. Examples of reactions involving either complete or partial reduction of an  $M_1$  cation by the less noble metal  $M_2$  using a suitable organic ligand L are:

Two process variations can be used to carry out the galvanic stripping reactions and are referred to as simultaneous or separate stripping as illustrated in Figure 1. In simultaneous galvanic stripping the loaded organic, the solid metal reductant and the aqueous stripping phase are allowed to react before settling and separating. This arrangement seems more efficient for partial reduction separations, for example reducing  $Fe^{3+}$  to  $Fe^{2+}$  or  $Ce^{4+}$  to  $Ce^{3+}$  that then easily transfer into the aqueous stripping phase. In separate stripping the reduction reaction and stripping reactions are conducted in two steps. For low concentration cation impurity removal, metal deposition or seed crystal nucleation for microelectronic applications, the separate stripping process has been more effective. An example of the latter is the cementation of Cu on Al, Pd on Al, or Au on Cu.

## GALVANIC STRIPPING APPLICATIONS

### Feasibility Studies

The first successful demonstration of galvanic stripping was the deposition of copper onto zinc powder from a LIX reagent. Next a broader range of combinations of organic solvents and metal/metal ion systems was investigated to determine if the reactions occurred only in isolated instances or were more generic in nature [3]. Somewhat surprisingly, reactions were observed to occur in a variety of organic solvents such as D2EHPA, TBP, Acorga, Cyanex, Alamine and Dipex. In total,  $Ag^+$ ,  $Cd^{2+}$ ,  $Cu^{2+}$ ,  $Co^{2+}$ ,  $Pb^{2+}$ ,  $Au^{3+}$ ,  $Fe^{3+}$ ,  $Ce^{4+}$ ,  $Pd^{2+}$  and  $Ni^{2+}$  were reduced using Al, Fe, Zn, Cd, Cu and Mn as the solid metal reductants. Of course, the correct combination of organic/ion/metal is necessary and the selection criteria are based on solubility and reactivity in the organic and the thermodynamic driving force generated by the two metal/ion half cells.

Attempts to measure the potentials of the metal/ion half-cells had limited success because of the lack of a stable reference electrode in the low conductivity organic solutions. Another observation regarding the possibility of obtaining a redox reaction in the organic phase was the dependence on the metal ion used for loading. For example, in some cases where copper sulfate was used, no reaction occurred, but deposition was possible with copper chloride. Obviously, the operating conditions as well as the thermodynamic stability and reducibility of the components themselves must be considered, as is often the case for aqueous cementation reactions.

### FERRIC ION REMOVAL - ZINC ELECTROLYTES

The application of galvanic stripping that involves the selective removal of  $\text{Fe}^{3+}$  from zinc sulfate electrolytes appears to offer some attractive advantages [4]. Di(2-ethylhexyl) phosphoric acid (D2EHPA) was the organic solvent of choice and either metallic zinc or iron was used to reduce  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$ , the latter then being easily removed into an aqueous stripping phase. Extensive fundamental and applied studies have been made on both systems. The critical operating parameters were identified and correlated with the efficiency, recovery and kinetics of the anodic and cathodic reactions of interest. A recent article surveyed the removal and recovery of  $\text{Fe}^{3+}$  from sulfuric acid processing solutions using solvent extraction and ion exchange [5]. Though promising, the conclusion was that no commercially proven system is available, considering both the extraction and stripping aspects to produce a "useful" iron product. When galvanic stripping was used it was possible to recover the iron in various forms that could have commercial value.

Initially, batch screening tests were made on  $\text{Fe}^{3+}$  separation using either simultaneous or separate galvanic stripping at a beaker scale. Once the feasibility of using galvanic stripping in this application was demonstrated, a small, continuous pilot apparatus was designed and operated. The schematic flow sheet for the continuous galvanic stripping of  $\text{Fe}^{3+}$  is shown in Figure 2. The results from the small continuous pilot run were reasonably successful and in good agreement with the previous batch tests. Some of the pertinent operating parameters and results are given in Table 1.

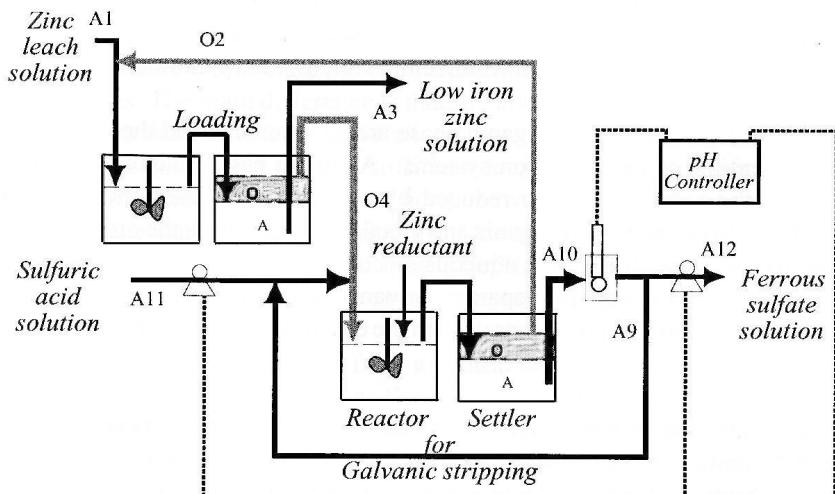

Figure 2. Flow sheet for continuous galvanic stripping of  $\text{Fe}^{3+}$  from a Zn leach solution.

*Table 1. Simultaneous galvanic stripping for Fe<sup>3+</sup> removal.*

Conditions	Results
30 vol% D2EHPA SX-12 Diluent (A/O) 1.0 Loading (A/O) 2.0 Striping Strip pH 1.5 – 2.1 Zn Powder Reductant Fe <sup>3+</sup> 5 – 11 g/L	Fe <sup>3+</sup> removal 50% (one stage) Rate 75 µg/cm <sup>2</sup> /min @40°C Stoichiometry 1.3 – 4 Fe <sup>2+</sup> Strip 90 – 110 g/L Electrolytic Fe Product Crystallized FeSO <sub>4</sub> Product

A complete impurity distribution chemical analysis between the initial zinc sulfate electrolyte and processed organic was made. A number of undesirable impurities such as Ni, Co, Ge and Ti did not extensively load into the organic, but small concentrations of Sn, In, Cu, Cd and Pb did load into the organic. The two major impurities that reported to the final aqueous iron product stream were Zn and As. The Zn can be controlled by using a proper strip solution pH and As may be eliminated by a pre-treatment of the organic prior to reduction. The most promising aspects of the continuous runs were the reasonably efficient elimination of Fe<sup>3+</sup> and a the production of a concentrated Fe<sup>2+</sup> solution as a final iron product. The Fe<sup>2+</sup> concentration in the final aqueous strip solution was in the range of 100 g/L. Assuming the As levels could be decreased, this solution might be used in water treatment applications. In other tests it was demonstrated that electrolytic iron could be won from the solution. In a separate study, a very pure ferrous sulfate product was crystallized that resulted in a final solid salt with a very low impurity content [4].

In summary, galvanic stripping offers some potentially attractive alternatives for removing Fe<sup>3+</sup> from process streams while simultaneously producing a useful final iron product. Other options have also been evaluated, such as using scrap steel as the reductant and operating in a separate rather than a simultaneous mode. Each has advantages and disadvantages that must be considered for the intended application.

## ELECTROCHEMICAL MODEL

Even though it was clear that spontaneous electrochemical reactions could be conducted directly in high resistance organic media, the actual mechanistic path for galvanic stripping was less evident. With simultaneous stripping and an abundance of water as a second phase it is arguable that the electron transfer steps might occur in the aqueous phase. This mechanism appeared less likely for metal deposition from organics using the separate stripping mode because the amount of water was very limited, often in a range of 1% or less. The availability of some water definitely enhanced the reaction rates. One assumption is that water is acting as an intermediate component in the metal/ion electrochemical step at the interface between the solid metal and the organic phase.

In order to gain more insight into the fundamental aspects of the reactions, Electrochemical Impedance Spectroscopy (EIS) measurements were made using zinc electrodes in dehydrated D2EHPA. The Nyquist plot generated is shown in Figure 3a. A simple two-element model was derived from the two capacitive semi-circles present in the plot. The water content was increased to saturation and the EIS curves that resulted are shown in Figure 3b. The first large semi-circle decreased significantly and the second small semi-circle was no longer evident as water was added. Each semi-circle was assumed to represent a reaction layer. The large capacitive loop with 74 MΩ resistance and 7 pF capacitance being the bulk or solution layer. The second small capacitive loop with 1.6 MΩ

resistance and  $10^4$ F capacitance was thought to represent the interface or charge transfer layer. From a high value of  $1.6\text{ M}\Omega$  the second loop is seen to decrease to a value too low to measure, an indication that the reaction resistance decreased with increased water content. The water does increase the bulk conductivity, which may assist the reaction, but the critical function is to decrease the charge transfer resistance at the electrode interface. Therefore, the presence of water would be expected to improve zinc dissolution in D2EHPA, a condition that was observed in the galvanic stripping experiments. Though these results are very preliminary in nature, the tests show that there is a definite opportunity to conduct fundamental studies on organic solvents using electrochemical techniques.

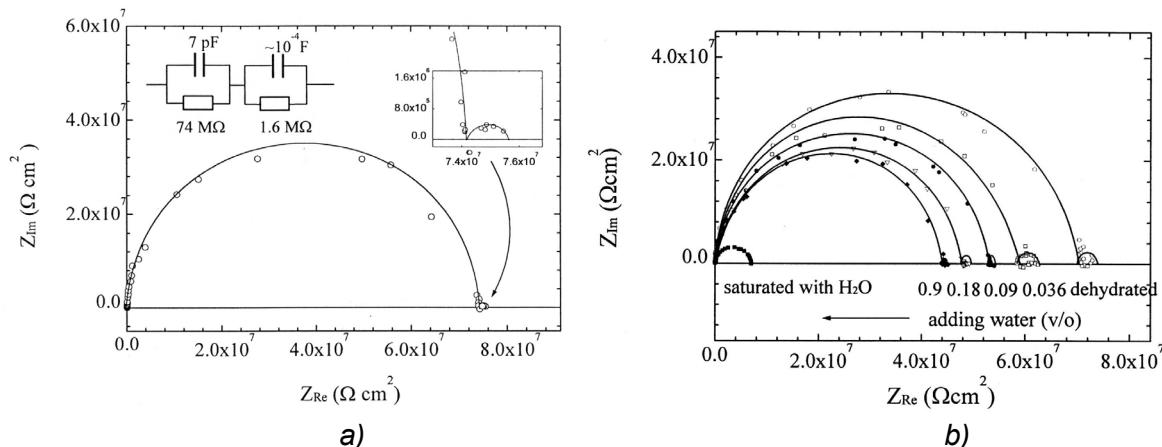

Figure 3. a) Nyquist plot of Zn-Zn cell in dehydrated D2EHPA with simulation of a two layer mechanism. b) Effect of water on zinc dissolution in D2EHPA at 25°C measured by the Zn-Zn cell at open circuit potential in the frequency range of  $10^6$  to  $10^{-2}$  Hz.

## METAL DEPOSITION FOR MICROELECTRONIC APPLICATIONS

The separate galvanic stripping process depicted in Figure 1 can be utilized for metal deposition from organics if the more noble ions loaded into the organic phase are brought into contact with a less noble metallic substrate. As shown in Figure 4a, deposition of more noble ions (e.g., Cu<sup>2+</sup>) on the surface of the less noble substrate (e.g., Al) occurs by a process similar to immersion plating in aqueous solutions. Dissolution of the active substrate into the organic phase is accompanied by an electrochemical reduction of the ions that leads to the formation of metallic seed crystals or nuclei on the surface of the substrate. An inherent part of the process is that deposition occurs only on electrochemically active surfaces and not on electrically non-conducting materials or more noble metals.

There are number of microelectronic applications that might benefit from the organic solution selective area deposition process. Many microelectronic manufacture processes require a sequence of deposition, patterning and etching to fabricate multilayer structures with the required electrical functionality. Integrated circuits on silicon wafers, printed circuit boards made of copper on an insulating dielectric, and microelectromechanical systems (MEMS) all require deposition, print and etch processing steps. Typically, metals and insulating films are deposited over the entire surface and the film is then patterned and etched to remove unwanted material.

Since the deposition of metals from organic solutions is a selective process the seed layers (Figure 4b) will plate only in the patterned areas that are metallic. Subsequent build up of metal thickness to complete the circuits can then be accomplished using conventional aqueous electroless and electrolytic plating processes.

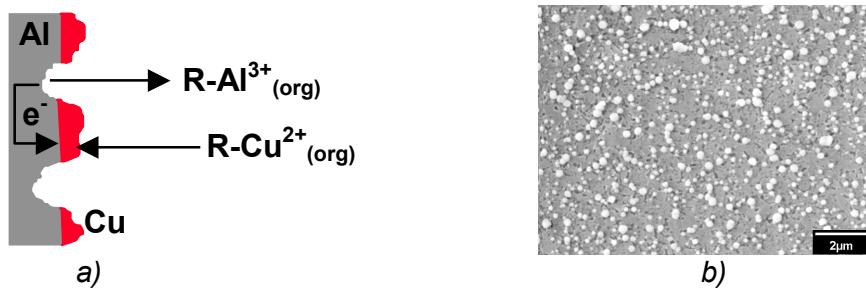

Figure 4. a) Schematic drawing of deposition of Cu onto Al from organic solutions.  
b) Scanning electron micrograph of Cu seed crystals (white) on an Al substrate.

Previous work on the deposition of metals from organic solutions focused on the deposition of metals onto the Al bond pads of silicon integrated circuits (ICs) [6-8]. In some cases, it is desirable to deposit copper or nickel onto the bond pads to facilitate solder attachment of the IC during packaging. Selected area deposition of Cu or Pd from organic solutions acts as a seed layer for the subsequent deposition of electroless copper or nickel from aqueous solutions eliminates the need for subsequent patterning steps. In addition, the process can be scaled to accommodate individual die (on the order of a few mm on a side) or entire wafers (up to 200mm in diameter). The studies found that metal loaded organic solutions could be used to deposit adherent Cu and Pd nuclei that were able to act as seed layers for subsequent metallic copper build-up directly onto Al bond pads. Attempts to deposit copper directly from aqueous plating baths onto the aluminum bond pads were not successful as either no deposition occurred or the film that was deposited did not adhere to the bond pad.

Deposition onto thin (500Å) metal films such as Ta, TaN, Ti, and TiN used as diffusion barriers between copper and low-k dielectric insulators on advanced integrated circuits [9] and the deposition of Au onto Cu for MEMS applications has also been investigated (Figure 5). The feasibility of depositing Cu and Pd seed layers from organic solutions on barrier metals has demonstrated that organic solution processing offers many advantages over aqueous processing. Due to the tenacity of the native oxides on tantalum and titanium based alloys, aqueous electrochemical processes for depositing seed layers onto these materials has proven to be very difficult, if not impossible. Utilizing the unique properties of conventional organic solvents in conjunction with electrochemically driven deposition has the capability to extend the technology to these and other applications as well.

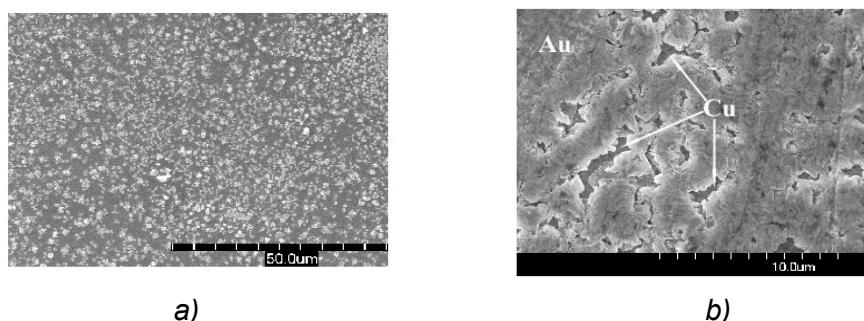

Figure 5. a) Au seed crystals on a Cu substrate. b) Semi-continuous Au film on a Cu substrate.

## CONCLUSIONS

Localized electrochemical reactivity in poorly conducting organic solvents has been demonstrated. The unique aspect of the galvanic stripping and deposition from organics described is the use of solid metals as the reducing agents. Displacement, or redox, reactions were possible in a substantial number of organic/ion/metal systems. Several promising commercial applications have been identified and development efforts continue in these areas. From a more fundamental standpoint, these complex heterogeneous reactions offer some interesting possibilities for extending the utilization of electrochemical principles to advance solvent extraction and organic solution processing.

## ADVANCED LIQUID-LIQUID EXTRACTION SYSTEM USING PHOTOCHEMICAL REDUCTION FOR METALS

Syouhei Nishihama, Takayuki Hirai, and Isao Komasawa

Department of Chemical Science and Engineering, Graduate School of Engineering Science,  
Osaka University, Toyonaka, Japan

An advanced liquid-liquid extraction system using photochemical reduction for metal ions has been investigated. The distribution of the target metals between the aqueous and organic phases in the extraction system can be controlled by the reduction of the metals, and selective extraction or stripping processes. Kinetic studies for such extraction systems revealed that the photochemical reduction of the metals is the rate-determining step. The photochemical reduction of the metals mainly progressed at the interface and in the organic phase, following photoabsorption at the absorption band for the metal extracted. The technique can be applied to the cobalt-poisoning problem in the hydroxyoxime-type extractant systems.

### INTRODUCTION

Liquid-liquid extraction is a major method employed for separation of metals on an industrial scale. Such extractive separation processes are generally based on differences in the complex formation abilities between metals and their extractants. Separation of some metals is, therefore, difficult when using a conventional extraction system. For the development of more effective separation processes, introduction of functional chemical reactions to the system has been investigated [1]. Redox reactions for the target metal has also been investigated as the reaction to the extraction system. This system is based on the principle that ions with different valencies behave differently with respect to their extractability [2]. There are three possible ways for producing the redox reaction: (1) chemical reaction, (2) electrochemical reaction, and (3) photochemical reaction. In these reactions, the photochemical reaction has the advantages of little discharge of waste and good integration with the extraction system. The photochemical redox reaction can be introduced to both the metal ion in the aqueous phase [3,4] and to the extracted species in the organic phase [5-8], and high selective separation can be carried out. There are, however, relatively few reports concerning the mechanism for such extraction systems.

In the present work, the mechanism of advanced liquid-liquid extraction systems combined with the photochemical reduction of target metals has been investigated. The photoreductive stripping of Fe(III) [9] and photoreductive extraction of V(V) [10] were investigated as case studies. The photochemical reduction of Fe(III) and V(V) in separate aqueous or organic phases was first investigated. The photochemical reduction was then applied to the extraction (stripping) system, and the mechanism of extraction was investigated based on kinetic studies. The advanced extraction system was then applied to the cobalt-poisoning problem in hydroxyoxime extractant systems [11].

## EXPERIMENTAL

The commercial extractants 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester (EHPNA), bis(2-ethylhexyl)phosphoric acid (D2EHPA), 2-hydroxy-5-nonylacetophenone oxime (LIX-84I), and 2-hydroxy-5-nonylbenzophenone oxime (LIX-65N) were used as extractants, without further purification. In the cases of the Fe and Co systems, aqueous feed solutions were prepared by dissolving each metal chloride in dilute HCl solutions. In the case of the V system, the aqueous feed solution was prepared by dissolving either NaVO<sub>3</sub> or VOSO<sub>n</sub>H<sub>2</sub>O into dilute H<sub>2</sub>SO<sub>4</sub>. The organic solutions were prepared by diluting each extractant with *n*-dodecane.

The extraction equilibrium data were obtained by conventional procedures, at an organic/aqueous (O/A) volume ratio of 1, at 298 K. The photochemical reaction of metals in both single aqueous and organic solutions and photoreductive stripping or extraction were carried out using a beaker-type glass bottle (32 mm in diameter). A 500 W xenon lamp with an irradiation intensity of 580 kW/m<sup>2</sup> was used as the light source for the Fe and V systems, and a 500 W halogen lamp with an irradiation intensity of 706 kW/m<sup>2</sup> was used for the Co system. The wavelength of irradiated light was adjusted by the Pyrex glass material of the reaction bottle (greater than 300 nm) or by using appropriate cut-off filters. The concentrations of metals in the aqueous solutions were analyzed using an inductively coupled argon plasma atomic emission spectrophotometer.

## RESULTS AND DISCUSSION

### Extraction Equilibrium Formulations

Figure 1 shows the effect of the equilibrium pH value on the distribution ratios in Fe/EHPNA and V/D2EHPA systems. Generally, the distribution ratios for the metals having larger valencies are larger than those for metals having smaller valencies. For the Fe system, the distribution ratio for Fe(II) is much lower than that for Fe(III) over the pH range investigated, thus indicating that selective stripping of Fe may be expected to progress by reduction during the stripping process. The slope analysis method revealed that the extraction equilibria for these metals could be expressed as in Eqs. (1) and (2).

For the V system, however, the distribution ratio for V(V) is smaller than that for V(IV), which is contrary to the valences, since, in an acidic solution with a pH value of 0-2, V(V) and V(IV) exist as VO<sub>2</sub><sup>+</sup> and VO<sup>2+</sup>, respectively. Selective extraction of V is thus expected by reduction, especially at high pH. The slope analysis method revealed that the extraction equilibria for these metals could be expressed as in Eqs. (3) and (4).

### Photochemistry of the Metals in Aqueous and Organic Solutions

In the case of Fe(III), no photochemical reduction occurs without a radical scavenger in both aqueous and organic solutions. In aqueous solution, however, the reaction progresses in the presence of a radical scavenger, such as formic acid. This is because the photochemical reduction of Fe(III) in aqueous solution occurs by electron donation from water, and the OH radical produced, which promotes the reverse reaction, is scavenged by formic acid. In the case of V(V), photochemical reduction occurs in both aqueous and organic solutions without

a radical scavenger. The rate of photochemical reduction was investigated following Ar bubbling in order to purge dissolved oxygen. A pseudo-first order kinetic plot for the variation in the concentration of V(V) revealed that the rate of photochemical reduction of V(V), in both aqueous and organic solutions, is first order with respect to V(V) concentration and is independent of pH, sulfuric ion concentration, and extractant concentration.

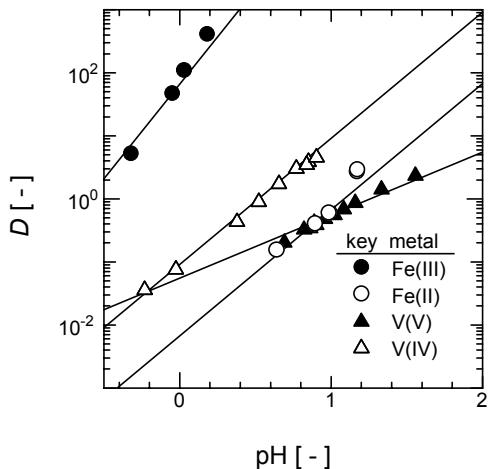

Figure 1. Effect of the aqueous pH on the distribution ratio for Fe with EHPNA and V with D2EHPA.  $[(RH)_2]_{feed} = 0.5 \text{ mol/l}$  and  $[M]_{feed} = 0.01 \text{ mol/l}$ .

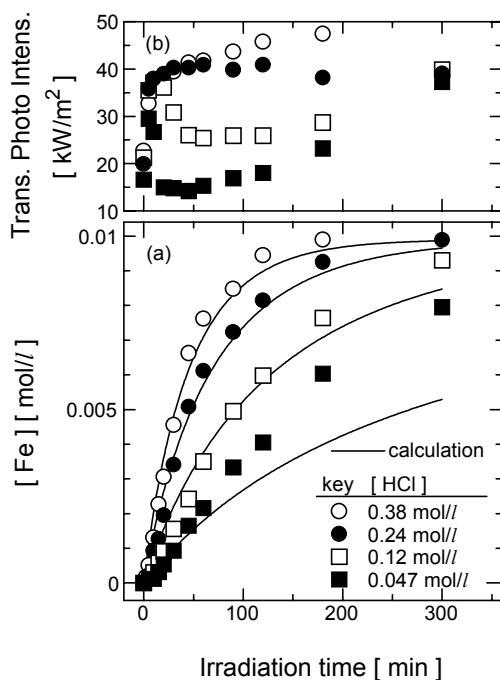

Figure 2. Effect of irradiation time on (a)  $[\text{Fe(III)}]$  and (b) the transmitted photointensity. Comparison of observed data with prediction shown by solid lines.  $[(RH)_2]_{feed} = 0.1 \text{ mol/l}$  and  $[\text{Fe(III)}]_{feed} = 0.01 \text{ mol/l}$ .

### Photoreductive Stripping of Fe(III)

The organic solution following extraction of Fe(III) was contacted with a dilute HCl solution at O/A = 1, which was not expected to strip Fe(III), and then photoirradiated with the Xe lamp with vigorous agitation by a magnetic stirrer. The photoreductive stripping of Fe(III) progresses by photoirradiation following an initial induction period caused by dissolved oxygen in the extraction system. In addition, the photoreductive stripping of Fe(III) progressed when only organic phase was irradiated. Because photochemical reduction is found not to occur in the organic solution, Fe(III) is likely to be photoexcited in the organic phase and to be reduced at the interface by electron donation from water. A kinetic study revealed that the rate of photoreductive stripping is expressed by Eq. (5):

$$r_{\text{Fe}} = -\frac{d[\overline{\text{Fe}}]}{dt} = k_{\text{Fe}} \frac{[\overline{\text{Fe}}][\text{H}^+]}{[(RH)_2]^{0.5}} \quad (5)$$

where  $k_{\text{Fe}} = 0.0275 \text{ l}^{0.5} \text{ mol}^{-0.5} \text{ min}^{-1}$ . Figure 2(a) shows the effect of photoirradiation time on the concentration of Fe in the aqueous phase, as compared with the calculated value based on Eq. (5). The experimental values agree well with the calculated values during the initial part of the run, but with increasing irradiation time the deviations become notable in the run with the solution of lower HCl concentration. Figure 2(b) shows the variation with time on the photointensity of transmitted light. In the case of HCl concentration of 0.047 mol/l, the transmitted light intensity increased as the photoreductive stripping of Fe(III) progressed, and the photoreaction progressed more effectively than that predicted based on the initial photoreductive stripping rate.

The overall reaction mechanism for the photoreductive stripping of Fe(III) can be divided into two reaction stages, the photochemical reduction of extracted species of Fe(III) to Fe(II) at the interface, followed by the stripping of Fe(II) into the aqueous phase, as follows:

This reaction scheme is deduced on the assumptions that the rate-determining step is the photochemical reduction of Fe(III), as shown by Eq. (6), and that the rate of distribution of the reduced Fe(II) is fast. The Fe(III)-extractant complex is found to be excited in the organic phase and to be donated an electron from the water at the aqueous/organic interface. Assuming the extractant to exist as a monomeric species at the interface, the elementary reaction of Eq. (6) can be expressed in more detail as in Eqs. (8)-(13):

If the rate-determining step is the photochemical reduction of Fe(III) as shown by Eq. (12), the overall reaction rate equation can be expressed by Eq. (14).

$$r = -\frac{d[\overline{\text{Fe}}]}{dt} = k_1 [\overline{\text{FeR}_2(\text{RH})_3}^+] = \frac{k_1 K_2 K_3 K_4}{K_1^{0.5}} \frac{[\overline{\text{FeR}_3(\text{RH})_3}][\text{H}^+]}{[(\overline{\text{RH}})_2]^{0.5}} \quad (14)$$

This agrees with the result from the experimental kinetic study, as shown by Eq. (5), indicating that the mechanism of photoreductive stripping of Fe(III) is expressed by the proposed scheme.

### Photoreductive Extraction of V(V)

The extractant D2EHPA in *n*-dodecane was contacted with the aqueous solution, containing NaVO<sub>3</sub>, at O/A = 1, under the photoirradiation following Ar bubbling with agitation by a magnetic stirrer. Figure 3 shows the effect of photoirradiation time on the distribution ratio for V. The variation with time of the distribution ratio can be predicted by assuming that the rate of the reaction is dominated by the photochemical reduction of V in the aqueous and organic phases, which were obtained otherwise. Such predictions, which are shown by dotted lines in Figure 3, however, lead to much lower values for the distribution ratio than the experimental results. This difference may be caused by photochemical reduction of V at the interface between the aqueous and organic phases, as was also found in the case for the photoreductive stripping of Fe(III). The prediction lines, considering the photochemical reduction of V(V) at the interface, can express the experimental data, thus indicating that the photochemical reduction of V progresses in the aqueous phase, in the organic phase, and at the interface. However, the reduction in the aqueous phase hardly contributes to the overall photoreductive extraction.

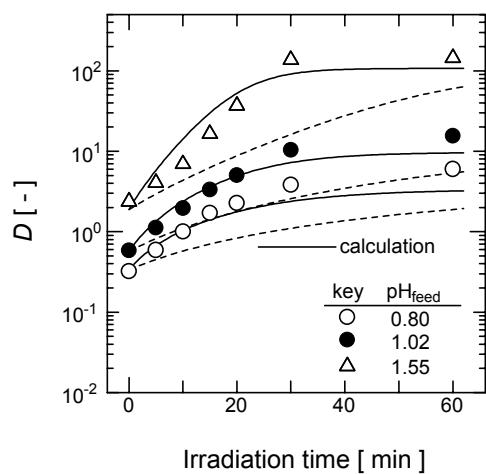

Figure 3. Effect of the irradiation time on the distribution ratio for V. Solid lines: photochemical reduction at the interface only, dotted lines: photochemical reduction only in the aqueous and organic phases.  $[(RH)_2]_{feed} = 0.5 \text{ mol/l}$  and  $[NaVO_3]_{feed} = 0.01 \text{ mol/l}$ .

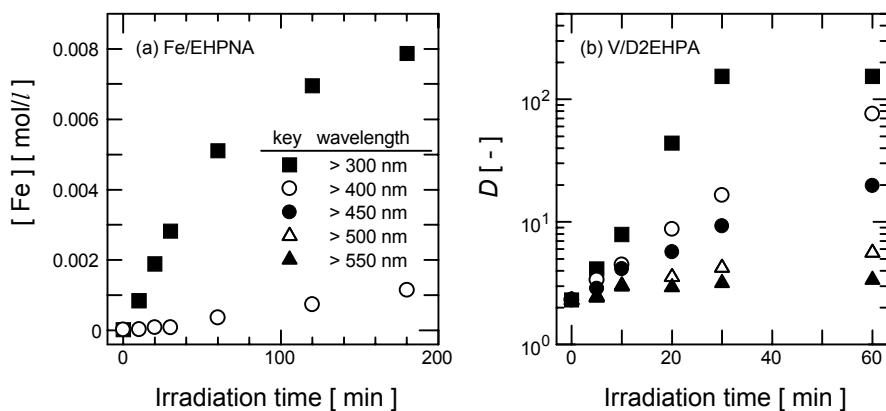

Figure 4. Effect of the wavelength of the light source on the rate of (a) photoreductive stripping of Fe(III) and (b) photoreductive extraction of V(V). (a) Fe/EHPNA system,  $[(RH)_2]_{feed} = 0.1 \text{ mol/l}$ ,  $[\overline{Fe}]_{feed} = 0.0088 \text{ mol/l}$ , and  $[HCl]_{feed} = 0.24 \text{ mol/l}$ , and (b) V/D2EHPA system,  $[(RH)_2]_{feed} = 0.5 \text{ mol/l}$ ,  $[NaVO_3]_{feed} = 0.01 \text{ mol/l}$ , and  $pH_{feed} = 1.52$ .

### Effect of the Wavelength of the Irradiated Light

Figure 4 shows the effect of the wavelength of the irradiated light, when varied by the use of appropriate cut-off filters, on the variation with time in the photoreductive stripping of Fe(III) and photoreductive extraction of V(V). The reaction hardly occurs when irradiated light of less than 400 nm is cut off in the Fe system, and hardly occurs when irradiated light of less than 500 nm is cut off in the V system. This may be caused by the ability for photoabsorption of the extracted species. In the case of Fe(III), the absorption band, caused by Fe(III) extracted species, appears at 200-350 nm. In the case of V(V), the absorption band, caused by V(V), appears at 300-500 nm. These results thus indicate the photochemical reduction of the metals in the organic phase and at the interface progresses following photoabsorption at the absorption band for the metal extracted.

### Reusability of the Organic Phase

The reuse of an organic solution following photoirradiation was also investigated. In the case of Fe, the aqueous feed solution and organic solution were contacted at O/A = 1. The Fe loaded organic solution was then contacted with 0.36 mol/l HCl solution at O/A = 1 and the phases photoirradiated for 300 min. In the case of V, the aqueous and organic solutions were contacted at O/A = 1 and were photoirradiated for 60 min. The resultant organic solution was then stripped using 6 mol/l HCl at O/A = 0.5. These resultant organic solutions were then used for repeated processing after washing with 3 mol/l HCl and then water. Figure 5 shows the concentration of Fe or V in the organic phase during the repeated extraction-stripping processing. The results thus show that the organic phase possesses sufficient loading and stripping capacity for use in repeated processing and confirm the possible reuse of the organic phase following photoirradiation.

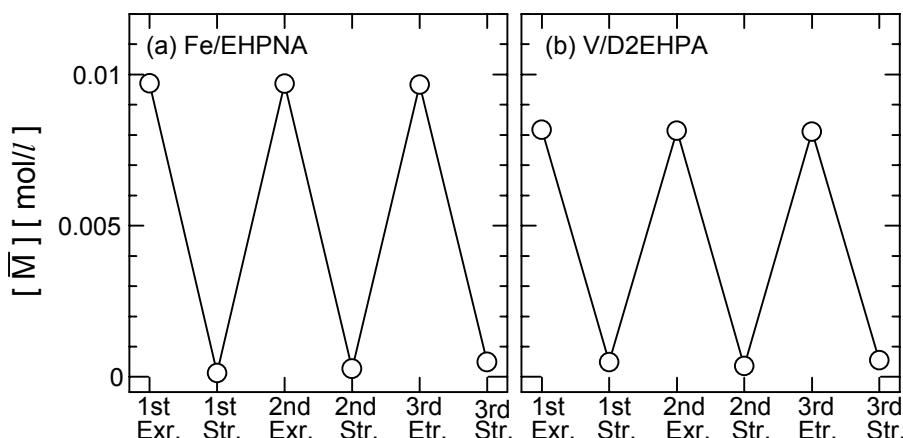

Figure 5. The concentration of (a) Fe and (b) V in the organic phase following the repeated extraction-stripping processing.  $[(RH)_2]_{\text{feed}} = (a) 0.1 \text{ mol/l}$  and  $(b) 0.5 \text{ mol/l}$ ,  $[M]_{\text{feed}} = 0.01 \text{ mol/l}$ , and  $pH_{\text{feed}} = (a) 1.47$  and  $(b) 0.86$ .

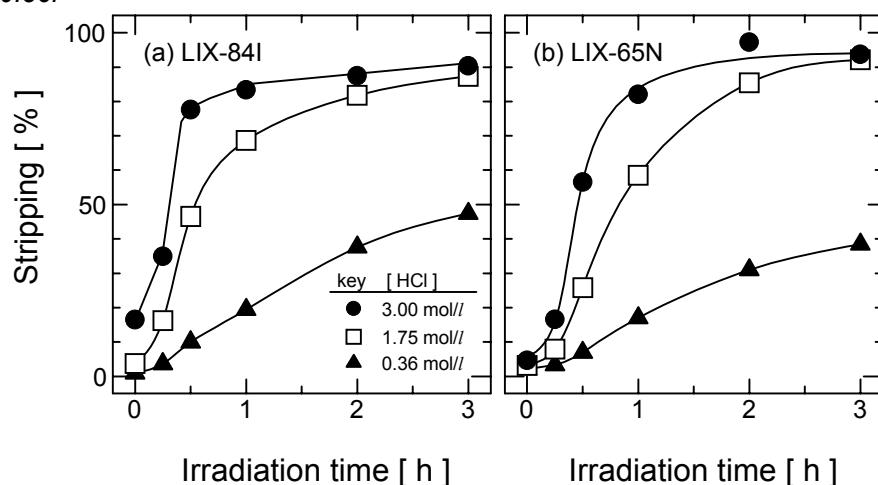

Figure 6. Effect of the HCl concentration on rate of photoreductive stripping in (a) LIX-84I and (b) LIX-65N systems.  $[RH]_{\text{feed}} = 10 \text{ vol\%}$ , and  $[Co]_{\text{feed}} = (a) 6.53 \text{ mmol/l}$  and  $(b) 9.37 \text{ mmol/l}$ .

### **Application for the Cobalt-Poisoning Problem**

It is well known that Co(II) when extracted via commercial chelating extractants, such as hydroxyoxime type extractants, is difficult to recover by conventional stripping procedures, owing to cobalt poisoning. This poisoning is because Co is oxidized to the trivalent state by oxygen in the extraction system, and is then stabilized in the organic phase, which suppresses quantitative stripping. Effective stripping is therefore expected to be carried out, if the oxidized Co(III) complex can be photoreduced within the organic phase. The photoreductive stripping of Co was then carried out by a similar procedure to the photoreductive stripping of Fe using a halogen lamp. Only visible light with a wavelength greater than 550 nm was irradiated, since Co-LIX 84I has a large absorption band at 400-800 nm. Figure 6 shows the effect of HCl concentration on the photoreductive stripping of Co in LIX-84I and LIX-65N systems. Successive stripping can be carried out in both systems using the photoreductive stripping technique. The photoreductive stripping of cobalt is improved by increasing the concentration of HCl in both systems, and a stripping efficiency of about 90 % can be achieved with 3 mol/l HCl following photoirradiation for 3 h. The organic phase in this process also possesses sufficient loading and stripping capacity for use in repeated processing, as for the Fe and V systems.

### **CONCLUSION**

Advanced liquid-liquid extraction systems using photochemical reduction for metal ions have been investigated, with the following results: (1) The distribution ratio of metals can be controlled by photochemical reduction of the metals. The mechanisms of the extraction system combined with photochemical reduction were elucidated based on kinetic studies, in which the photochemical reduction of the metals is the rate-determining step. (2) The photochemical reduction of the metals in the organic phase and at the interface takes place following photoabsorption at the absorption band for the extracted metal. The organic solution following photoirradiation is reusable for repeated extraction-stripping processing. (3) The photoreductive stripping technique can solve the cobalt-poisoning problem in hydroxyoxime extractant systems.

## ROOM TEMPERATURE IONIC LIQUIDS AS ALTERNATIVES TO TRADITIONAL ORGANIC SOLVENTS IN SOLVENT EXTRACTION

Ann E. Visser, John D. Holbrey, and Robin D. Rogers

The Department of Chemistry and Center for Green Manufacturing,  
The University of Alabama, Tuscaloosa, AL, USA

We describe a new class of solvents comprised of low melting salts known as room temperature ionic liquids. Recent interest has focused on their unique properties as alternative solvents in synthesis and separations. The properties of both hydrophobic and hydrophilic ionic liquids reveal how water content, density, viscosity, surface tension, melting point, and thermal stability are affected by changes in the nature of both cation and anion. Applications for ionic liquids, with particular attention to their solvating ability and utilization as replacements for organic solvents in liquid/liquid separations, are described.

### INTRODUCTION

Much of the interest surrounding Ionic Liquids (IL) has centered on their unusual properties for catalysis [1] and, recently, as solvent alternatives for synthesis [2] and liquid/liquid separations [3-6]. Performing ordinary chemical processes using alternative reaction media demonstrates the basis for a shift in manufacturing paradigm towards “green chemistry,” and an aim to reduce or eliminate hazards and risks involved with current processes that rely heavily on volatile organic compounds (VOCs) as the solvent medium. Incorporating green chemistry to provide benign conditions or processes will promote the research, development, and implementation of innovative chemical technologies to achieve pollution prevention [7].

#### Ionic Liquids

In the current understanding, IL are composed of large, organic cations (Figure 1) which, when appended with alkyl groups and combined with various anions, result in low melting salts [8].

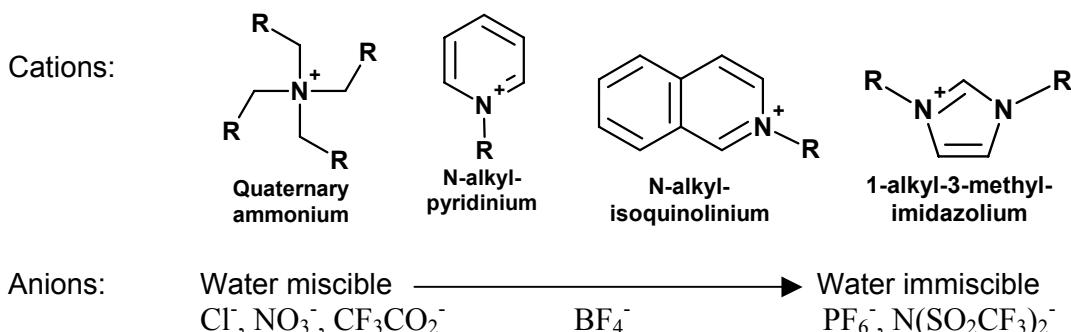

Figure 1. Representative IL compositions.

These novel compounds are, thus, ionic and melt at or below 150 °C (an accepted upper temperature limit). In contrast to molten ionic melts (*i.e.*, NaCl at 800 °C), the asymmetric organic cations in IL interrupt the crystal packing and can substantially lower the melting points. Room Temperature Ionic Liquids (RTIL) are a subdivision of IL that are liquid at room temperature and, thus, facilitate their use at ambient temperatures.

## SUMMARY

Depending on composition, IL can be hydrophobic or hydrophilic [8,9]. An inherent property of many IL is their minuscule volatility and easily manipulated properties, characteristics of a unique class of solvents. IL principally have an organic cation, usually among ammonium [10-12], phosphonium, pyridinium [13,14], pyrrolidinium [15], or imidazolium [8,9], each with the possibility for attaching various alkyl groups to the ring or quaternary onium cation. Depending on the type of cation investigated and the length of the alkyl chain, the resulting IL may have a melting point above room temperature and several crystal structures have been reported [16].

We have initially focused on IL incorporating the 1-alkyl-3-methylimidazolium ( $[C_n\text{mim}]^+$ ) cation [3,4], where the alkyl group is usually an *n*-alkane and increasing the length of the alkane chain affects the resulting properties (*e.g.*, viscosity, hydrophobicity, and melting point) [8,9]. For example,  $[C_8\text{mim}][\text{PF}_6^-]$  is a liquid at room temperature with a glass transition temperature at -75 °C [9] and  $[C_{10}\text{mim}][\text{PF}_6^-]$  melts at 38 °C [3]. IL composed of several different cations or anions (*i.e.*, multi-component mixtures) can also be envisaged to further expand the family of ionic liquids.

Choice of cations and anions can be used to control the IL water miscibility with the nature of the anion having the greatest effect on hydrophobicity. The anions may also impart unique chemistry to the systems, rendering the IL capable of digesting materials such as nuclear fuel components [17] and kerogens [18]. For liquid/liquid separations,  $\text{PF}_6^-$  and  $\text{N}(\text{SO}_2\text{CF}_3)_2^-$  produce water immiscible IL useful for partitioning both organic and inorganic solutes [3-6]. Our previous results [9] indicate water content has a profound effect on physical properties and, in liquid/liquid separation systems, IL analyses after equilibration with water provide the most accurate analysis of the IL properties under those conditions. Table 1 presents some physical properties of water-equilibrated  $[C_n\text{mim}][\text{PF}_6^-]$  IL which illustrate the cation effect.

*Table 1. Physical properties of water-equilibrated IL [9].*

Parameter	$[C_4\text{mim}][\text{PF}_6^-]$	$[C_6\text{mim}][\text{PF}_6^-]$	$[C_8\text{mim}][\text{PF}_6^-]$
Water content (ppm)	11700	8837	6666
Viscosity (cP)	397	452	506
Density (g/mL)	1.35	1.24	1.16
Melting point (°C)	4		
Glass transition (°C)	-83	-75	-75
Thermal decomposition (°C)	360	390	374
Surface tension (dyn/cm)	49.8	36.8	34.2

Even ‘hydrophobic’ RTIL incorporating the  $\text{PF}_6^-$  anion contain significant amounts of water. Previous partitioning results show that an increase in the alkyl chain length produces higher distribution ratios [3,9] for more hydrophobic solutes which is consistent with the decreasing water content. The rheological properties hinge largely on water content.

For comparison, Table 2 lists some physical properties for IL composed of the  $[C_4mim]^+$  cation and various anions. Since both hydrophobic and hydrophilic IL are represented, the properties listed here are those for IL that have been ‘dried’ on a vacuum line for 4 hours while heating to 70 °C.

*Table 2. Physical properties of related dried IL [9].*

Parameter	$[C_4mim]-[Cl]$	$[C_4mim]-[BF_4]$	$[C_4mim]-[PF_6]$	$[C_4mim]-[N(SO_2CF_3)_2]$
Water content (ppm)	2200	4530	590	474
Viscosity (cP)	na	219	450	69
Density (g/mL)	1.08	1.12	1.36	1.43
Melting point (°C)	41	na	10	na
Glass transition (°C)	na	-97	-80	-104
Thermal decomposition (°C)	254	403	349	439
Surface tension (dyn/cm)	na	46.6	48.8	37.5

### Solvent Properties

IL are generally considered to be highly polar, yet non-coordinating solvents. Solvatochromatic studies have shown that IL have polarities similar to those of short-chain alcohols and other polar, aprotic solvents (e.g., DMSO, DMF, etc.) [8,19-21]. Some IL are immiscible with several organic solvents (e.g., alkanes). Primary solvent features of IL are the ability for H-bond donation from the cation to polar or dipolar solutes. H-bond accepting functionality in the anion can vary from  $Cl^-$ , which is a good H-bond acceptor, to  $PF_6^-$ , which is poor. In addition, cations containing  $\pi-\pi$  or  $CH-\pi$  interactions may serve to enhance aromatic solubility.

From empirical observation, most IL tend to be immiscible with non-polar solvents. Thus, IL can be washed or contacted with either diethylether or hexane to extract non-polar reaction products. On increasing solvent polarity, esters (e.g., ethylacetate) exhibit variable solubility with IL depending on the nature of the IL. Polar or dipolar solvents (chloroform, acetonitrile and methanol) appear to be totally miscible with all IL (excepting tetrachloroaluminate IL and the like, which are reactive).

We have recently shown that hydrophobic  $PF_6^-$  IL can, in fact, be made totally miscible with water by the addition of alcohols [22]. Ethanol forms biphasic mixtures with  $[C_4mim][PF_6]$ ,  $[C_6mim][PF_6]$ , and  $[C_8mim][PF_6]$ , depending on temperature, although mixtures containing ethanol, water, and IL may be totally miscible at specific compositions as shown in Figure 2. Successful solubilization of IL has many potential uses for washing and removal of ionic liquids from products and reactors or catalysis supports, and has important implications in designing IL/aqueous extraction systems.

### Liquid/Liquid Separations

Water immiscible RTIL (e.g.,  $PF_6^-$  salts) have been pursued as a class of alternative solvent media to illustrate how their unique properties encourage their use in place of traditional organic solvents in liquid/liquid separations [3,9,23]. Some of our recent results are summarized below.

### Organic solutes

Our initial results [23] for aromatic solute partitioning between water and  $[C_4mim][PF_6]$  indicated that neutral, hydrophobic, aromatic solutes have an affinity for the ionic liquid phase and that traditional hydrophobicity parameters (*i.e.*, 1-octanol/water log P) can be a guide to predicting IL affinity. With charged or ionizable solutes, a change in the aqueous phase pH results in certain ionizable solutes exhibiting pH-dependent partitioning such that their affinity for the RTIL decreases upon ionization [23] (*e.g.*, the pH dependent partitioning of thymol blue, Figure 3 [3]).

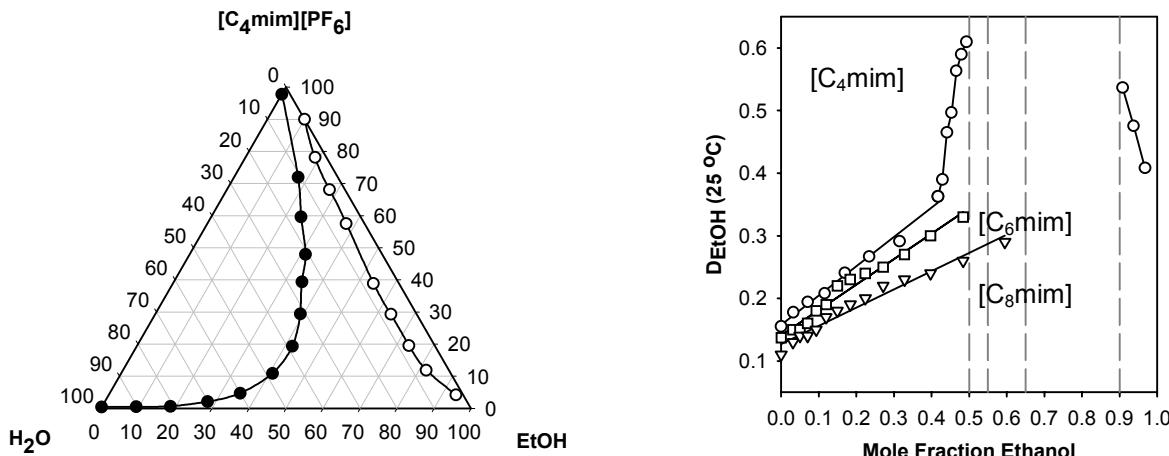

Figure 2. Ethanol/water/[ $\text{C}_4\text{mim}][\text{PF}_6]$  ternary phase diagram and solute distribution in IL.

Extraction efficiency and selectivity can be controlled by changing IL components: for example, IL/aqueous systems containing alkyl-isoquinolinium cations show increased distribution ratios [24] for organic solutes in comparison to imidazolium-based IL, as shown in Figure 4.

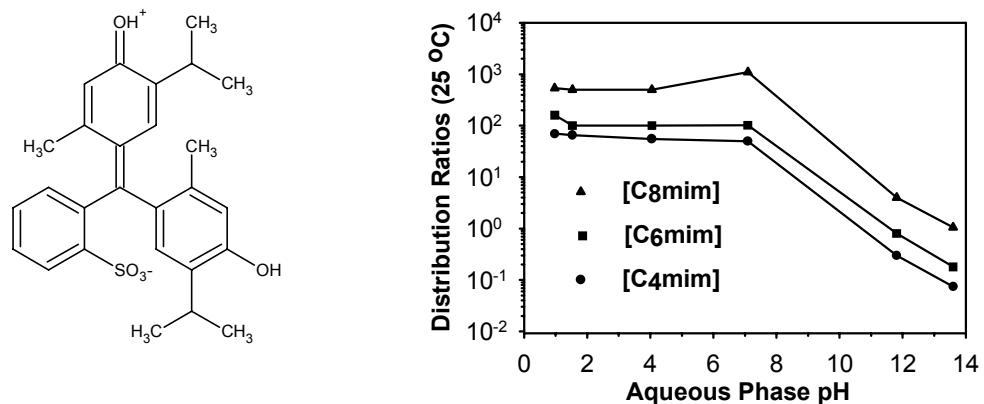

Figure 3. pH switchable partitioning of thymol blue in  $[\text{C}_n\text{mim}][\text{PF}_6]$ /aqueous biphasic systems.

### Metal ions

There is considerable interest in replacing organic extracting phases with IL for recovery of metals from waste water, mining, nuclear fuel, and waste reprocessing, and immobilizing transition metal catalysts. The hydrated nature of most metal ions lowers their affinity for the IL phase, thus, in the typical  $[\text{C}_n\text{mim}][\text{PF}_6]$ /water system, hydrated metal ions do not partition to IL from water. Enhancing the affinity of metal ions for the less polar phase can be achieved by changing the hydration environment of the metal ion using either organic ligands [4,5] which provide a more hydrophobic region around the metal, or with inorganic anions [5] that form softer more extractable anionic complexes with the metal. The challenges in adapting IL to traditional separations include finding extractants which quantitatively partition to the solvent phase and can still readily complex target metal ions, or finding conditions under which specific metal ion species can be selectively extracted from aqueous streams containing inorganic complexing ions.

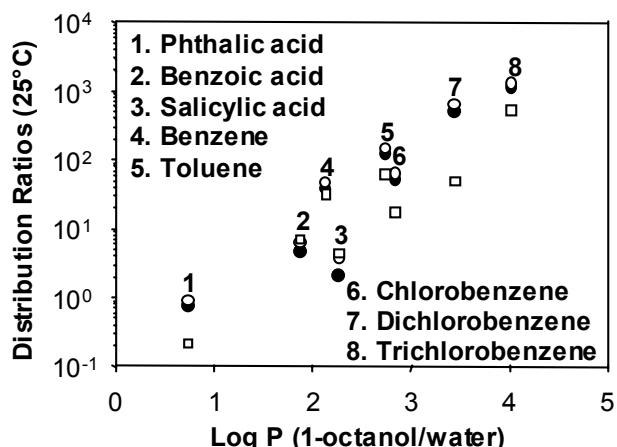

Figure 4. Organic solute distribution ratios in  $[C_{14}isoq][BETI]$  ( $\circ$ ),  $[C_8isoq][BETI]$  ( $\bullet$ ), and  $[C_4mim][PF_6]$  ( $\square$ ).

### Anionic extractants

The distribution ratios from aqueous to IL phases of some metal ions may be enhanced in the presence of coordinating anions such as halides or pseudohalides. Metal ions such as  $Hg^{2+}$  have large formation constants with halides, and their effect has been observed on the partitioning of  $Hg^{2+}$  in other systems [25]. Halides, cyanate, cyanide, and thiocyanate have been studied [5] as anionic extractants in  $[C_4mim][PF_6]$ /aqueous systems. The results appear to indicate that the metal ion transfer to the IL phase depends on the relative hydrophobicity of the metal complex;  $Hg-I$  complexes having the highest formation constants and highest distribution ratios [5].

### Organic extractants

Macrocyclic ligands such as crown ethers have been widely used for metal ion extraction. A series of 18-crown-6 ligands were investigated as extractants for  $Sr^{2+}$  and  $Cs^+$  in  $[C_nmim][PF_6]/HNO_3$  [4] with unexpected results which highlight the complexity of IL-based liquid/liquid systems and other system factors which have a dramatic effect on metal ion extraction and the stability of the IL.

Ionizable extractants can also be used to complex metal ions and increase lipophilicity. The azo dyes 1-(2-pyridylazo)-naphthol (PAN) and 1-(2-thiazolyl)-2-naphthol (TAN) are conventional metal extractants which quantitatively remain in  $[C_6mim][PF_6]$  when contacted with an aqueous phase between pH 1 – 13. Distribution ratios for  $Fe^{3+}$ ,  $Co^{2+}$ , and  $Cd^{2+}$  show that the metal ions can be extracted from the aqueous phase at basic pH and stripped from the IL under acidic conditions [5].

### Task Specific Ionic Liquids

Task Specific Ionic Liquid (TSIL) can be designed to incorporate a complexing functionality as an integral part of an IL [6]. These TSIL can be used as the extracting phase, or may be mixed with a second, more conventional IL to modify rheological properties. Figure 5 demonstrates the utility of one such TSIL prepared by tethering a ligating moiety to an imidazolium cation [6].

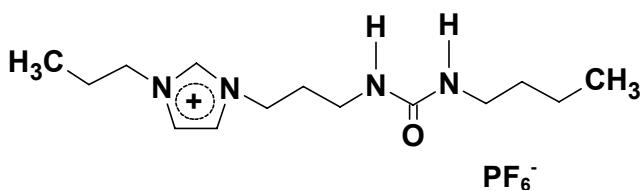

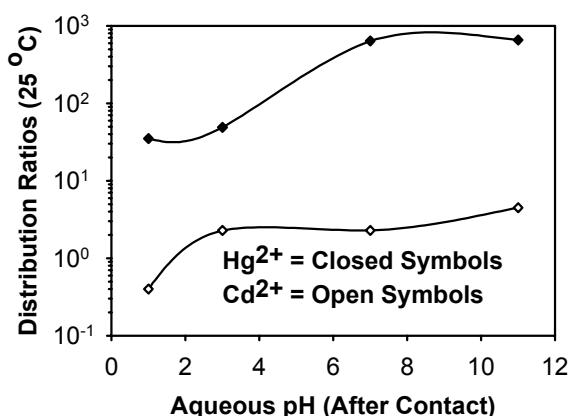

Figure 5.  $\text{Hg}^{2+}$  and  $\text{Cd}^{2+}$  distribution ratios with 1:1 TSIL: $[\text{C}_4\text{mim}][\text{PF}_6]$  as the extracting phase.

## CONCLUSIONS

At an early stage in a rapidly developing field of separation science, RTIL have clearly demonstrated versatility and promise for design of facilitated separation schemes. From the “green chemistry” standpoint, the chemical and physical properties of RTIL warrant their further study and exploration. The potential for RTIL is great, but these results must be considered with a certain degree of caution; there is a necessary, yet missing, fundamental understanding of these systems and cation-anion-solute interactions. There is, however, every reason for optimism; the number of new and exciting examples of RTIL separations schemes is limited only by time and imagination.

## TOWARDS "*IN SILICO*" DESIGN OF NEW POTENTIAL EXTRACTANTS USING CHEMICAL INFORMATICS METHODS

Alexandre Varnek, Georges Wipff and Vitaly P. Solov'ev\*

Université Louis Pasteur, Strasbourg, France

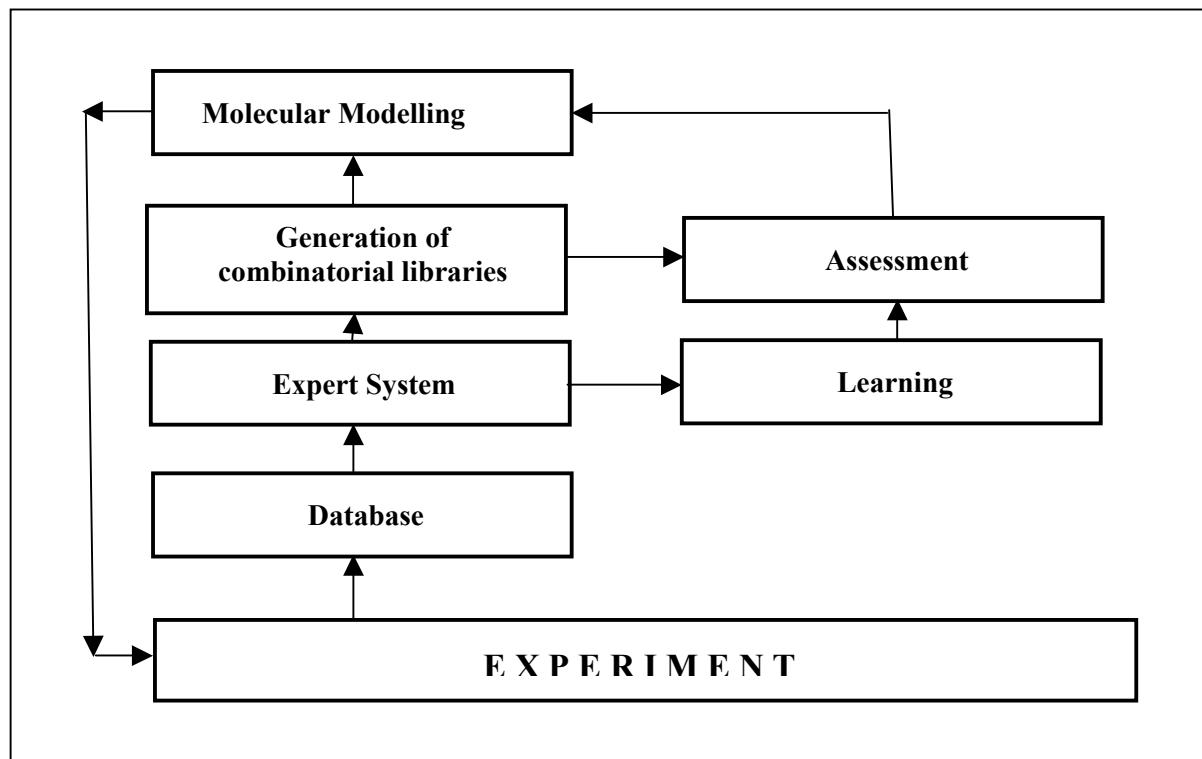

\* Institute of Physiologically Active Compounds, Chernogolovka, Russia

This article concerns the design of a prototype of information system for solvent extraction of metals including a comprehensive factual database, an expert system to analyse experimental extraction data and a generator of virtual libraries of extractants. A prototype of the solvent extraction database is developed. Each database record corresponds to one extraction reaction and contains three information parts (bibliographic, extraction system description and extraction properties) including chemical structural 2D and 3D information for extractants, as well as thermodynamic and kinetic data in textual, numerical and graphical forms. As expert system we use the Substructural Molecular Fragments method which models structure-property relationships using information retrieved from the database. Its performance is assessed on the distribution coefficients of Hg, In and Pt extracted by 26 phosphoryl-containing monopodands, and of uranium extracted by 32 mono- and tripodands or by 22 monoamides. The generation of virtual combinatorial libraries of potential metal binders using substructural molecular fragments is discussed.

### INTRODUCTION

A theoretical design of an extraction process with desired characteristics requires development of an information platform involving collection and generalization of available experimental data on extraction kinetics and thermodynamics (database), coupled with the chemical informatics methods that establish quantitative structure-extraction property relationships and generate potential metal binders. So far, such an ensemble of computational tools has not been developed.

This article concerns the development of an informational system for complexation/extraction of metals which involves three main elements: (i) a database, (ii) an expert system, and (iii) a combinatorial module. Figure 1 illustrates links between these modules. On the learning stage, a data set selected from the database is used by the expert system in order to establish relationships between structure of the molecules and their complexation/extraction properties. Then, the combinatorial module generates libraries of virtual compounds, from which the expert system selects "the best" potential metal binders using knowledge obtained on the learning stage. Tri-dimensional structures of selected candidates and explicit characteristics of host-guest interactions in solution could then be obtained using molecular modelling methods. New processes proposed on the basis of theoretical calculations can be experimentally tested, in turn providing the database with new information.

## SOLVENT EXTRACTION DATABASE AND RELATED COMPUTATIONAL TOOLS

### Sources of Extraction Data in the Literature

A bibliographic search performed from 1970-1999 on solvent extraction with PASCAL, Science Citation Index and Chemical Abstracts databases resulted in (together with SEPSYS database [1, 2]) about 12,000 references, some of them concerning several individual extraction systems. This information could probably be enriched by numerous publications in the Russian and Chinese scientific literature which are not covered by "western" bibliographic databases (see [3-5]). According to our estimates, about 20,000 papers on extraction chemistry (including Russian and Chinese bibliographic sources, industrial reports, etc.) reviewing 50,000 – 70,000 extraction systems have been published since 1970.

### Solvent Extraction Database: Graphical Interface and Related Programs

A graphical user-friendly interface for a Solvent eXtraction Database (**SXD**) [6] has been designed using DELPHI programming platform for WINDOWS 98/2000/NT. It allows the user to load, to store in the SDF format [7] and to retrieve bibliographic and structural 2D and 3D information as well as experimental data presented in numerical and graphical forms, and to compare data from different records. **SXD** uses its own editor of 2D structures whereas the WebLabViewer Lite program [8], freely available from the INTERNET, is used for visualization and manipulation of 3D structures.

### Record and Queries Fields

Each **SXD** record describes one extraction system and contains three main parts: 1) bibliographic part including title, source (journal, book, proceedings), date of publication, authors and their addresses, keywords, abstract; 2) description of extraction system, *i.e.*, extractant(s): compound name, CAS number, empirical formula, molecular weight, 2D and 3D structures, concentrations (Figure 2); extracted species: cation, anion and their concentrations in aqueous phase; aqueous phase: background compound(s), their

concentrations, pH, ionic strength; organic phase: diluent(s) and their concentrations, background compounds and their concentrations; experimental conditions: temperature, pressure, experimental and equilibration technique; 3) extraction properties, *i.e.*, extraction equilibrium: reaction, thermodynamic data (extraction constant, free energy, enthalpy and entropy of extraction), partition coefficient and separation coefficient; extraction kinetics: extraction process, kinetic data (rate constant, activation free energy, enthalpy and entropy); other parameters represented as tables or graphs. The graphical interface of **SXD** allows experimental data to be stored in 85 fields grouped in 6 sections, and permits data-treatment to be carried out.

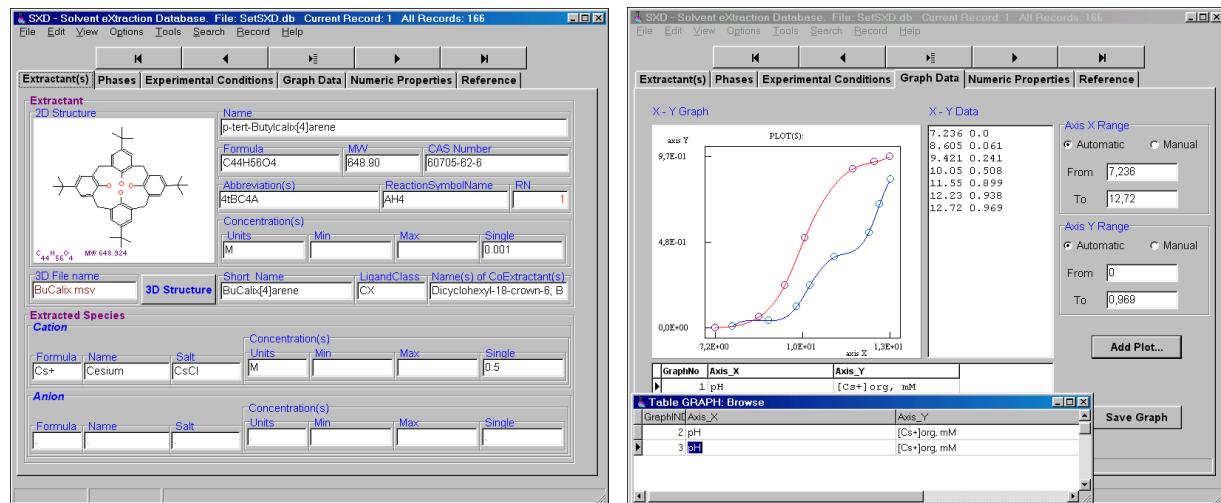

Figure 2. Two of six informational pages of Solvent Extraction Database.

### Retrieval of Data and Their Analysis

A search of information can be performed by any individual textual, numerical and 2D structure field or by their combinations using AND, OR and NOR Boolean operators. The search engine of **SXD** is based on the Borland Database Engine (BDE) for textual and numerical information, and tools developed here for 2D structural information. A CURVE option in the graphical interface of **SXD** performs a comparison of graphs from different records. It verifies if selected graphs have the same notation for "X" and "Y" axes, and superposes curves in a separate window using user-defined scale. If necessary, the program extrapolates or interpolates original curves. The program can also create the input files for commercial program packages for additional treatment of the curves. Data retrieved from the database can be used as an input for the TRAIL expert system discussed below.

## EXPERT SYSTEM

### Substructural Molecular Fragments Method and Related Computer Tools

An expert systems on solvent extraction has to be able (i) to classify and generalize the data from SXD, (ii) to establish relationships between the composition of extraction systems and their properties, and, (iii) to propose new extraction systems possessing desirable properties. Development of such an expert system represents a difficult task due to the large number of variables affecting the thermodynamic and kinetic parameters of solvent extraction. In this paper, we present its first version based on recently developed Substructural Molecular Fragments (SMF) method [6-9] which allows one to model structure-property relationships for the series of different molecules participating in similar processes. Currently, this method uses only one variable-molecular structure of extractant, assuming that other components of extraction systems (nature of cation, anions, pH, diluent(s), background compounds, etc.)

and experimental conditions are the same for a given series of processes. The SMF method is based on the representation of molecular graph by fragments (atom-bond “sequences” or “augmented atoms”) and on the calculation of their contributions to a given property.

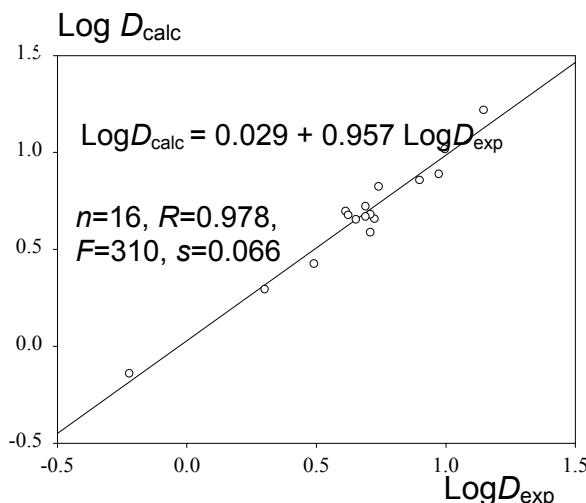

The TRAIL program [9] has been developed to calculate structure-property correlations based on the SMF partitioning. TRAIL generates all possible types of fragments coupled with one of three linear or non-linear fitting equations, which correspond to 147 fitting models involving 49 typical sets of fragments. Selection of the best models is based on statistical parameters such as correlation coefficient ( $R$ ), standard deviation ( $s$ ), Fischer's criterion ( $F$ ),  $R_H$ -factor of Hamilton, the fitness criterion of Kubinyi ( $F/T$ ) [10].

Earlier, we have shown that the SMF method represents an efficient tool to model the octanol/water partition coefficient, stability constants of host-guest complexes in water and in non-aqueous solution [6, 9].

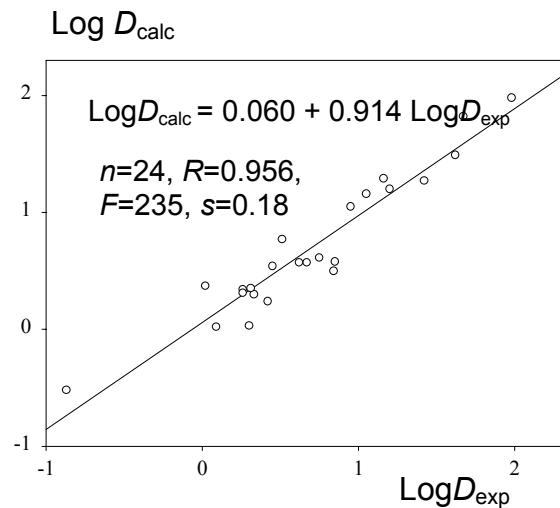

**Table 1.** Phosphoryl-containing podands and amides extraction properties of which were calculated by the SMF method.

*Figure 3. Extraction of uranyl nitrate by amides in toluene (left) and by phosphoryl-containing podands in dichloroethane (right). Experimental data are taken from [11] (for amides) and [12] (for podands). The graphs show the correlation between experimental and calculated distribution coefficients ( $\log D$ ) on the learning stage, tables report the experimental (exp) and "predicted" (calc)  $\log D$  values for the molecules from the validation set.  $R$  and  $s$  are correlation coefficient and standard deviation for the correlation between experimental and predicted  $\log D$  values.*

### Assessment of Thermodynamics Parameters for Solvent Extraction

The SMF method was used to assess the extraction constants for the complexes of uranyl cation by phosphine oxides, and on distribution coefficients of Hg, In and Pt extracted by phosphoryl-containing monopodands, and those of uranium extracted by podands or by amides [6, 9]. Figure 3 illustrates the performance of this method to model distribution coefficients ( $\log D$ ) for  $\text{UO}_2^{2+}$  extraction. On the learning stage TRAIL selects the best (of

147) computational models to establish structure-property relationships for the molecules from the learning set (Table 1), which then are used for prediction calculations for the compounds from the validation set. One may see, that "predicted" log D values are very close to the experimental ones. Thus, the SMF method is a reliable tool for structure - extraction property modelling.

## GENERATION OF COMBINATORIAL VIRTUAL LIBRARIES

To generate virtual combinatorial libraries of potential extractants we used an algorithm based on the *Markush* structures [13]. It allows the user to attach a certain number of fragments to a molecular "core". A set of the extractants cores has been prepared analyzing all ligands from SXD database by the SMF partitioning. The generation module allows the user to select interactively molecular "bricks" and to launch computer "synthesis" of their possible combinations. The generated set of virtual compounds is saved in the SDF format to be used as an input by TRAIL for selection the best potential extractants.

## CONCLUSION

Three main elements of Informational system for solvent extraction (a prototype of a comprehensive database, an expert system, and a combinatorial module) have been developed and tested. This opens a perspective for computational design of new efficient extractant molecules.

## ELECTRICAL TOMOGRAPHY AND OTHER MEASUREMENTS IN LIQUID-LIQUID SYSTEMS

W. J. Korchinsky and G. Bolton\*

Department of Chemical Engineering, UMIST, Manchester, UK

\*Industrial Tomography Systems, Manchester, UK

Successful application of electrical capacitance tomography (ECT) to a stirred tank and to a countercurrent flow column has demonstrated the usefulness of such a technique to monitoring performance of liquid-liquid contacting equipment. In addition, electrical resistance tomography (ERT) has been widely used for investigating the behaviour of stirred tanks. These techniques have the potential, matched by no other existing technique, to monitor dispersed phase distribution in a liquid-liquid contactor. The results to date obtained with an ECT system are summarised. The potential for this method and other tomographic measurements are discussed.

Beyond the tomographic measurements, there is a need for other measurements to provide the values for the many additional parameters that are required to make possible accurate predictions of liquid-liquid extraction equipment performance. Models are available to explain dispersion hydrodynamics, including breakup and coalescence, and mass transfer rates, for single component and multicomponent transfer. The number of parameters which must be available to use these models is daunting. Can sufficient measurements ever be made to provide accurate predictions of all parameter values?

### INTRODUCTION

The literature, and that includes the various Proceedings of ISECs over the years, contains numerous models of the liquid-liquid extraction process. Now successful modelling of a process implies that a check of the accuracy of the model can be made. Every model is represented by equations with defined variables and perhaps model parameters, which it is hoped can be measured and used in the checks of the model's accuracy. For instance, dispersed phase holdup may be predicted either directly, by correlations such as that of Kumar and Hartland [1], or through some model of dispersed phase behaviour such as the population balance equations [2] provide. In the former case one needs only to measure the holdup, and all the variables in the prediction equation, such as physical properties, operating conditions, etc. In the latter case one is presented with variables such as drop size distribution functions, breakage and coalescence frequencies, daughter drop size distributions and – how many more? Has the accuracy of the approach been adequately tested? How sensitive is performance to the change in value of each of the defined parameters – rarely mentioned! How many measurements would be required just to obtain a set of drop population balance equations which were accurate and reliable in predicting column hydrodynamic behaviour? On-line measurement of required variables may in some cases be attainable, but at what cost would attainment of all the desired measurements be achieved? Few have tackled the problem of prediction of performance for multicomponent systems.

Are pilot plants here to stay?

## HYDRODYNAMICS

On-line, non-invasive, measurement by Electrical Capacitance Tomography of dispersed phase hold-up fraction in a mixer and column extractor has been demonstrated successfully at UMIST [3]. Earlier attempts using other methods, such as the work on ultrasound techniques by Tavlarides and coworkers [4] looked promising, but the technique has not been applied widely. The use of electrical capacitance (ECT) and resistance (ERT) tomography techniques in process monitoring and control is a rapidly developing field, as expertly summarised by Williams and Beck in 1995 [5]. The techniques promise to give very useful on-line measurement of various processes in industrial plants. Most developed are ECT measurements in solid-gas systems, and ERT measurements in liquid-gas and miscible and immiscible liquid-liquid systems. The instantaneous, non-invasive, measurement of dispersed phase hold-up, this important parameter of extraction operation, would be of considerable interest to researchers and process operators.

At the last ISEC, the preliminary results of the application of ECT to liquid-liquid systems were announced [6]. Since, there has been further publication of results, which are now summarised. The typical capacitance sensor system employed is illustrated, for a mixer, in Figure 1. Eight to twelve capacitance electrodes, in this case of 50 mm height, are attached to the wall (in this case the outside of a Perspex wall). Except for a gap between electrodes, the electrodes cover the circumference of the vessel. To obtain accurate capacitance measurements between electrodes, grounded 'driven guards' are placed above and below the electrodes, and a screen to protect from outside interference is placed around the entire electrode system.

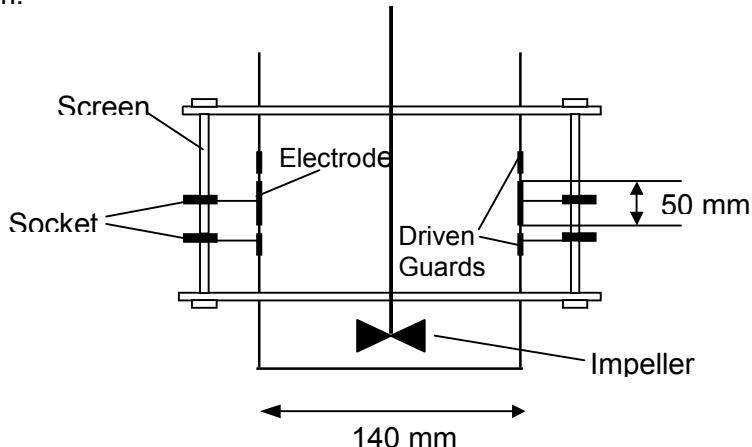

Figure 1. Detailed diagram of the stirred tank capacitance sensor.

The electrical signals from the capacitance sensors are transferred to a data acquisition system and then to a computer, where software is used to reconstruct images of electrical permittivity distribution which are translated into liquid phase distributions. Stirred tank dispersed phase content in a stirred tank can be averaged and illustrated on-line by colour projections of the capacitance data – see Figure 2. Accuracy of determination of the holdup is within 5%rel.

On-line visualisation of the unsteady state approach to steady state in a mixing tank has been demonstrated – over a 100 scans per second can be generated. Clear indications of phase mal-distribution in a counter-current flow column have been demonstrated. There was some difficulty applying the same system to a much larger (1 m) diameter vessel, but some progress was made. Multiple sets of sensors could be applied to give instant on-line-measurements of the change of hold-up with height. Multiple sets of sensors have been applied with an ERT system [7] to track variation with height. Images of vortex formation and

geometry, gas-liquid mixing, and brine tracer distribution were generated. Identification of non-standard conditions inside mixing vessels is a particularly important application of these measurement systems, aside from their potential use in providing quantitative information for model prediction methods. Other work at UMIST on tomographic techniques is in the area of two-phase and three-phase flows, fluidised beds, foams and froths.

- *Available* – On-line - dispersed phase hold-up measurement.

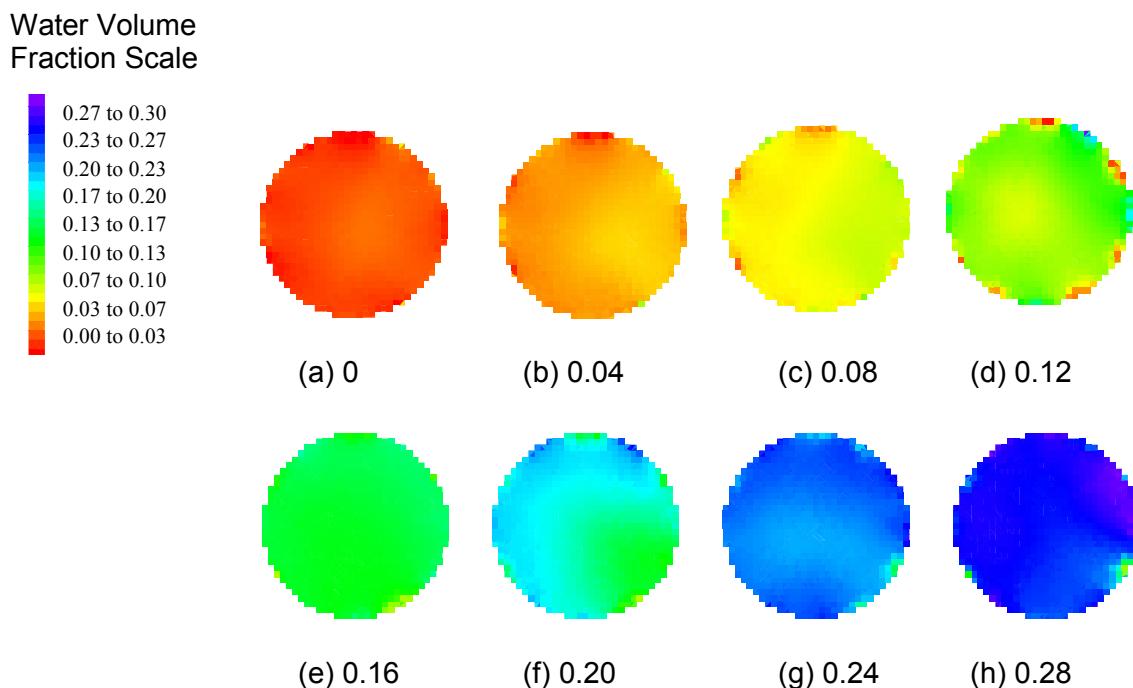

Figure 2. Colour-scale tomographic images of homogenous mixtures of water dispersed in kerosene for several water volume fractions.

### Drop Size and Population Balances

Measurement of drop sizes has largely been by photography, from outside the column, necessarily focussing on the drops near the column wall. Are they representative of all the drops in the column? There has been recent work reported on on-line drop size measurements by Ritter and Kraume [8], 2000 and by Wille *et al.* [9], 2001. The Kumar and Hartland [1] prediction equations, developed for the RDC, show the dependency on operating conditions and system physical properties, and a constant C, which depends on mass transfer direction.

But the Sauter-mean diameter does not in most cases accurately represent the performance of the entire dispersed phase, so one needs to develop prediction methods for the measured drop size distribution. The Mugele-Evans [10] distribution function has largely been employed. When drop size control at the inlet is maintained [11], values of the function parameters may be determined which give good predictions of drop size distribution and column performance. But the distribution function parameters have not been widely determined.

- *Available* - Sauter mean drop size, column averages
- *Required* - Drop size distribution function parameters

But the drop size distribution changes, in most cases, with column position – in particular with column vertical position. How do we model this change? Drop population balances have been developed by many researchers– see Kumar and Hartland [12], Ribeiro *et al.* [13], Hoting and Vogelpohl [14], Shen and Tavlarides [15] and Zamponi *et al.* [16]. The developed equations model the change in size distribution, and dispersed phase holdup, but require the values of a number of additional parameters. From a given drop size distribution, the birth and death rates of each size of drops determine the distribution changes with height. An example of the equations developed [13] is given below - the original may be consulted for an explanation of all the variables used. It is given here only to illustrate the complexity of the calculations required.

$$\begin{aligned} \frac{\partial}{\partial t} f(v, c, \tau, t) + \frac{\partial}{\partial c} [f(v, c, \tau, t) \dot{c}] + \frac{\partial}{\partial \tau} f(v, c, \tau, t) = \\ 2 \int_{v' > v} \int_{c'} \int_{\tau'} f(v', c', \tau', t) g(v') \beta(v|v') \delta(\tau) \delta(c' - c) dv' dc' d\tau' + \\ 2 \int_{v' > v} \int_{c'} \int_{\tau'} \int_{\tau''} f(v', c', \tau', t) f\left(v - v', \frac{vc - v'c'}{v - v'}, \tau'', t\right) h(v', v - v') \lambda(v', v - v') \delta(\tau) dv' dc' d\tau' d\tau'' + \\ \frac{1}{\theta} f_{\text{feed}}(v, t) \delta(\tau) \delta(c - c_{\text{feed}}) - f(v, c, \tau, t) \left[ g(v) + \int_{v'} \int_{c'} \int_{\tau'} f(v', c', \tau', t) h(v, v') \lambda(v, v') dv' dc' d\tau' + \frac{1}{\theta} \right] \end{aligned} \quad (1)$$

#### *Required*

- Drop breakage rate
- Number of daughter drops produced by breakup of a drop of given volume
- Drop probability density
- Drop collision frequency
- Coalescence frequency

Have they all been measured? Certainly not! These are still mostly empirically set and the theory tested by how well the measured change in drop size distribution is predicted with a particular set of these parameters. But widespread applicability is some way off. To quote Gourdon *et al.* [17], “If ...one considers the gap between the demand of the scientists and the impact on the economy of the sort of the results that could be obtained, it is questionable whether the endeavour is worth the trouble”!

## MASS TRANSFER

To develop models which predict accurate mass transfer rates, the hydrodynamic models need to be integrated into an appropriate mass transfer model. The model must then accurately predict mass transfer driving forces and rates. To determine driving forces, equilibrium concentrations and therefore chemical potentials in highly non-ideal liquid-liquid systems must first be determined.

### **Equilibrium Prediction**

To be able to design from first principles, it must be possible to predict driving forces, or departure from equilibrium conditions. Although measurements of equilibrium concentrations can be made for specific systems, a model of liquid phase behaviour which will accurately predict these is still not available. Additional data which can be used to develop a suitable model are needed.

*Required*

- “Chemical potential ” or activity coefficients for highly non-ideal liquid systems

### Mass Transfer Rate Prediction

#### Single-component mass transfer

A relatively simple model of mass transfer in a continuous contactor has been developed by Chartres and Korchinsky [18]. Differential equations representing solute balances in the dispersed phase droplets, and the continuous phase, were written. With measured drop size distributions, dispersed phase holdup, and concentration profiles, these equations, with appropriate boundary conditions, may be solved to generate values of the continuous phase axial dispersion coefficient, and drop size-dependent mass transfer coefficients [19]. These equations assume no change with height, no coalescence and break-up, and no interaction between species transferring in a multicomponent system.

*Required:*

- Drop size dependent mass transfer coefficients
- Continuous phase axial dispersion coefficients

#### Multicomponent mass transfer

To model multicomponent mass transfer the Maxwell-Stefan equations are recommended. The Maxwell-Stefan equations have been developed by Krishna *et al.* and are well explained in books written in 1993 [20] and 2000 [21]. The basic equation for diffusion in multicomponent systems is

$$F_i = - \frac{d\mu_i}{dz} = - RT \frac{d \ln a_i}{dz} = - RT \frac{d \ln \gamma_i x_i}{dz} = \sum_{j \neq i} \zeta_{i,j} x_j (u_i - u_j) \quad (2)$$

This can be rearranged to a form which can be used more readily,

$$f_i = F_i c x_i = - c R T x_i \frac{d \ln \gamma_i x_i}{dz} = R T \sum_{j \neq i} \frac{x_j N_i - x_i N_j}{\mathfrak{D}_{i,j}} \quad (3)$$

where the friction coefficient,  $\zeta$ , has been replaced by the Maxwell Stefan diffusion coefficient,  $\mathfrak{D}_{i,j}$ , ie  $\mathfrak{D}_{i,j} = RT / \zeta_{ij}$ . The net component fluxes,  $N_i$ , have replaced the products,  $c x_i u_i$ . It is not possible to measure the Maxwell-Stefan diffusivities directly, but for binary systems they can be calculated from measured Fick Diffusivities,  $D_{i,j}$  as follows

$$\Gamma = 1 + x_i \frac{d(\ln \gamma_i)}{dx_j} = \frac{D_{i,j}}{\mathfrak{D}_{i,j}} \quad (4)$$

where  $\Gamma$  is the “thermodynamic correction factor”. A matrix of mass transfer coefficients may also be defined in terms of the Stefan-Maxwell diffusivities.

*Required:*

- Multicomponent Maxwell-Stefan diffusivities (or the equivalent mass transfer coefficients)
- Activity coefficients and Fick diffusivities

Applications of the Maxwell-Stefan approach to multicomponent liquid-liquid systems have been reported, by Negri and Korchinsky [22], Taylor and Krishna [20], Brodkorb and Slater [23], Wesselingh and Krishna [21], and Uribe-Ramirez and Korchinsky [24], but this work has only scratched the surface. As stated by Wesselingh and Krishna [21], the prediction of rates in multicomponent systems is unreliable because there is a “lack of good data on multicomponent diffusivities” (or mass transfer coefficients).

## CONCLUDING REMARKS

There are a large number of variables which must be predicted to apply developed models successfully. There is still little confidence in applying these models widely. Furthermore, there are variables which may affect performance considerably and are not "modelled". To mention only a few - concentration of cruds, slimes, fines, surfactants, and colouring (black!) agents in the mixture, and the accumulated effect of equipment wall ageing, distributor clogging, etc! More models and measurements? Or pilot plant performance studies?

## ACKNOWLEDGEMENTS

The authors are grateful to the EPSRC and Separation Processes Service, AEA Technology for their financial support of the electrical capacitance studies.

## SOLVENT IMPREGNATED RESINS: PERFORMANCE AND ENVIRONMENTAL APPLICATIONS IN METAL EXTRACTION

The late Abraham Warshawsky and Jose L. Cortina\*

Department of Organic Chemistry, Weizmann Institute of Science, Rehovot, Israel

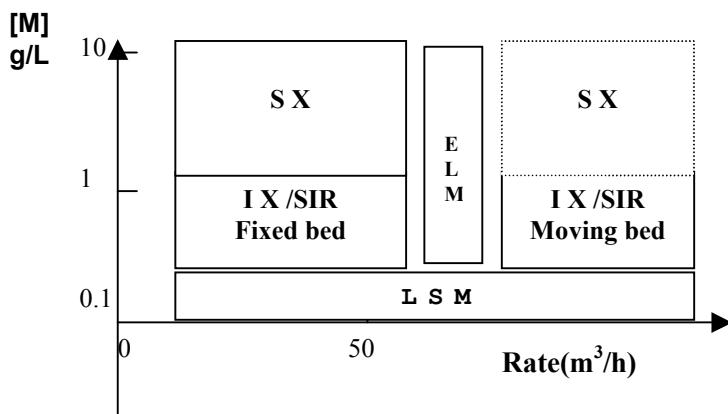

\*Universitat Politecnica de Catalunya, Barcelona, Spain

In this paper the extraction performance of solvent impregnated resins in heavy metal removal and separation in environmental applications is presented. Solvent impregnated resins were prepared by both direct adsorption of the active component onto macroporous polymeric supports and by co-polymerization of styrene and divinylbenzene in the presence of the active component. Resins based on two types of extractant functionalities (phosphoric and phosphinic acids) were evaluated. Separation of Zn, Cu and Cd was achieved using pH changes as parametric pumping and by modifying ligand metal extraction properties using mixtures of organophosphorous extractants.

### INTRODUCTION

Novel metal decontamination and water treatment technologies are required for a range of purposes in the European Union and with special needs in the metallurgical and mining sectors [1]. Both types of industries are characterised by using huge volumes of water streams with high contents of strong acids and bases, high content of electrolytes and moderate to low levels of metal ions. Many of the separation, transformation and destruction processes required already exist, such as ion exchange (IX), solvent extraction (SX) and membrane filtration processes. However, improvements are needed, notably in economic efficiency of the treatment and minimisation (volume reduction)/neutralisation/further processing and treatment of by products. This is reflected in the large number of scientific contributions during the last decades and the impetus is in the development of new separation chemistry techniques, particularly for treatment of liquid wastes and effluents [2-3]. These advances result from recent progress in the field of fundamental chemistry involving the synthesis of new classes of extractants, exchangers and absorbents capable of significantly improving the selectivity and the efficiency of a number of separation techniques (SX, supported liquid membranes, etc.). Despite the high selectivity of the chelating and IX resins, the application of these resins in separation processes on a technological scale seems to be limited by the complexity of their synthesis, the very often difficult and time-consuming procedures needed for covalently linking the functional group to the backbone of the resin, and their high cost.

Taking into account these limitations in the preparation of chelating and IX resins and the recent advances in the synthesis of new organic reagents for SX, which are bound to significantly improve both separation efficiency and selectivity for a wide range of chemical species, the development of solvent impregnated resins (SIR) as a link between SX and IX processes has become an important field of development in separation science. The place and limits of these materials in the domain of metal recovery methods covering the IX and SX sectors are shown in Figure 1 [4]. As can be seen the role of SIR materials will be closely related to that played by IX covering the low level range (below 1 g/l).

*Figure 1. Semiquantitative application limits for selected metal separation processes. (Ion Exchange(IX), Solvent Extraction (SX), Solvent Impregnated Resins (SIR), Supported Liquid Membranes (SLM) and Emulsified Liquid Membranes (ELM)).*

Since SIRs are posed in competition to IX materials and liquid-liquid metal extractants dissolved in organic diluents, SIR development efforts have been directed mainly to evaluation and performance studies. Preparative procedures remained simple and are mainly directed towards improvement in metal binding efficiencies and separation factors and are published elsewhere [5-6]. Reactive polymer (anion exchangers) supports have become important since they were shown to improve resin process kinetics and efficiency in removing metal ions from ppm or ppb range concentrations. Some of this work now in press [7-8] concerns mainly the newly discovered phenomena of extractant migration within SIR containing DEHPA, DEHTPA and DEHDTPA and comparison between SIR and their chemically-bound analogues. While important progress has been achieved in applications of SIR in analytical chemistry [6] maturation of such resins for hydrometallurgical applications are still to be achieved. More recently, new solutions to improve the separation of mixtures of dissolved heavy metals by means of parametric pumping with variation of pH have been presented for IX resins [12]. The most important property of this method is the fact that it is a regenerant-free separation or ion exchange process. Separation is possible if a parameter of substantial influence on the sorption equilibrium is varied.

In the present paper the application of SIRs in the removal and separation of toxic and heavy metal ions (Zn, Cu, Cd) present in many industrial streams at low levels is presented. Acidic organophosphorous derivatives (DEHPA, Cyanex 272) have been used as active component due to their high affinity and complexing properties with heavy and toxic metal ions and also for their suitable properties in the stripping step. The possibility of using parametric pumping with variation pH is presented.

## NON-FERROUS METAL REMOVAL FROM INDUSTRIAL LIQUORS

Many non-ferrous metal industries are generating basically two types of metal containing effluents: highly concentrated liquors from spent baths of electroplating or tanning operations and diluted streams typically generated by rinsing operations. While the first type are directed to recovery operations such as chemical precipitation, electrowinning or cementation, the second type of liquor needs a pre-concentration step in order to reduce volume and to achieve suitable concentrations to be treated like the spent baths. Additionally, as those diluted streams could contain mixtures of metal ions, a separation step is required to achieve suitable conditions for subsequent recovery. Metal ion mixtures are also found in acidic waters generated by dedusting off gases of many domestic and industrial waste incineration plants, thermal power stations and metallurgical plants. These solutions contain a wide range of non-ferrous metals such as Zn, Cd, Pb, Cu in the order of 0.5 to 0.01 g/L and non-metals such as As, Sb and Bi, typically of the order 0.01 to 0.001 g/L. The main components of such a stream are summarised in Table 1.

*Table 1. Typical composition of acidic metallurgical waste effluent.*

Metals (M): 0.1-0.5 g/l	Non metals (NM): < 0.01g/l	Common anions (A <sup>a-</sup> ) (150 to 0.1 g/l)	Common cations (C <sup>c+</sup> )(100 to 0.1 g/l)
Zn	As	Cl <sup>-</sup>	Ca <sup>+2</sup>
Cu	Sb	SO <sub>4</sub> <sup>-2</sup>	Na <sup>+</sup>
Cd	Bi	NO <sub>3</sub> <sup>-</sup>	Mg <sup>+2</sup>
Pb	Se		H <sup>+</sup> (pH (1-6))

\*Variation ranges are indication of typical values

Although traditionally these solutions are treated by the physico-chemical process of precipitation with lime, current efforts are directed to the selective recovery and separation of the metals Zn, Cd and Pb for subsequent treatment by electrolysis (for Zn, Pb, Cu) or cementation by powder metallic zinc (for Cd). Those effluents with relatively low levels of metal ions cannot be treated efficiently by SX but can be treated by transforming the SX system into the corresponding SIR system.

### Separation and Preconcentration of Heavy Metals

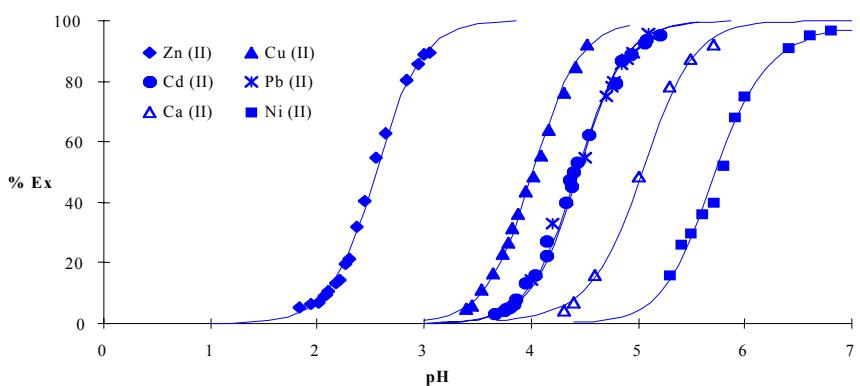

A great effort has been directed to the separation of Zn from Cu and Cd, and problems were encountered when applying strong cation exchange (bearing sulphonate acid groups) or chelating (bearing carboxylic, diiminoacetic or aminophosphinic groups) resins. Benefiting from the extensive extraction studies of Zn, Cu and Cd using organophosphorus extractants in SX applications [13] significant pioneering work was initiated on the homologues SIR systems [5-8]. Impregnated resins containing acidic organophosphorous derivatives (Cyanex 272 and DEHPA) impregnated onto Amberlite XAD2 or Levextrel type resins (Lewatit 1026 OC, Lewatit TP807) were made and tested. The behaviour of such materials (in terms of selectivity) was controlled modulating polymer properties or by modifying extraction properties or by using mixtures of extractants [6].

The extraction dependence of divalent metals on SIR containing acidic organophosphorous extractants on the acidity of the aqueous solutions is described by the following general reaction:

The pH<sub>50</sub> (pH for which a 50% extraction efficiency is achieved) has been used to measure the separation factors. A practical ΔpH<sub>50</sub> (M<sub>1</sub>/M<sub>2</sub>)≥1 allows an effective separation efficiency of M<sub>1</sub> (>95%) over M<sub>2</sub> (<5%). The pH<sub>50</sub> and ΔpH<sub>50</sub> values for the set of selected metals for SX, IX and SIR systems (Table 2) shows that sulphonate, phosphoric and carboxylic groups do not allow efficient separation factors, yet phosphinic acid extractants such as Cyanex 272 could offer an appropriate answer to solve this separation problem.

The pH dependence functions for the selected group of metals (Table 1) were determined by batch experiments. Results for Cyanex 272 impregnated resins with the highest separation factors are shown in Figure 2. The extraction function of Zn(II) in relation to Cu(II) and especially to Cd(II) makes this resin suitable for use in the separation of this metal couple.

*Figure 2. Extraction of Zn (II), Cu (II), Cd(II), Pb(II), Ca(II) and Ni(II) as a function of pH for Cyanex 272 impregnated resin.*

*Table 2. ΔpH<sub>50</sub> of Zn(II), Cu(II) and Cd(II) with solvent impregnated and Levextrel resins.*

\* Lewatit 207, chelating resin containing aminophosphinic groups.

NA\*\* no available data.

The extraction efficiency of SIR resins prepared by direct adsorption of Cyanex 272 onto a macroporous polymeric support of styrene-divinylbenzene (Amberlite XAD2) and those prepared by polymerisation of styrene-divinylbenzene in the presence of Cyanex 272 (Levextrel type) were evaluated in column operations. The breakthrough curves obtained for solutions containing Zn(II), Cu (II) and Cd(II) in the low concentration range 10-50 ppm are shown in Figure 3.

In column runs known amounts of swollen resins (10 g) were slurry-packed in an Omnifit borosilicate glass column fitted with porous 25-micron polyethylene frits and Teflon end pieces. A peristaltic pump at the column entrance delivered solution at constant flow rate of 0.5 to 1 mL/min. Metal ions were determined by following the change in concentration with throughput of the samples collected to follow the extraction histories. After each metal extraction experiment, the flow of the metal solution was stopped and the resin washed successively with water, stripping solution at flow rate of 1 mL/min through the resin bed in the column. Metal ion concentration was determined in all the samples.

As can be seen metal capacity of the SIR resins is highly dependent on operating pH and Cd(II) extracted at the higher pH values show lower resin loadings. Metal solutions were in sulphate media (1000 ppm) and pH was adjusted to 5.5 by adding sodium hydroxide. As the metal extraction process progresses the metal/proton exchange reaction takes places, the increased proton concentration causes decreased pH of the feed solution which in turns results in favoured extraction of Zn(II) and Cu(II) at lower pH values. Consequently, relative high metal loadings between 20 and 30 g metal/kg resin were obtained.

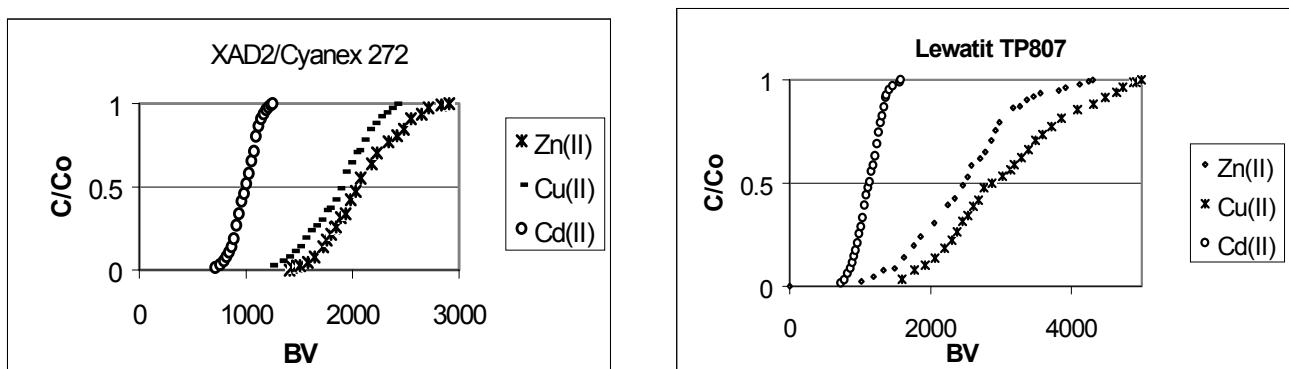

Figure 3. Breakthrough curves of XAD2/Cyanex 272 and Levextrel TP807'84 resins.

Elution runs for single systems were performed using 1 mol/L HCl solutions and results are shown in Figure 4. Concentrated solutions containing 4 g/L metals can be obtained.

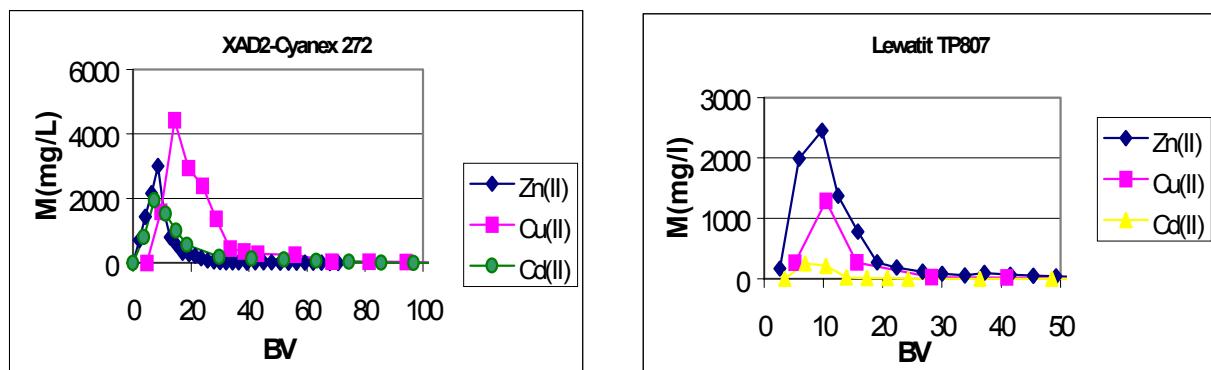

Figure 4. Breakthrough and elution curves of XAD2/Cyanex 272 and Levextrel TP807'84 resins.

Preconcentration factors (PF) achieved are shown in Table 3. Higher preconcentration factors obtained operating with lower flow rates allow the achievement of concentrated solutions (up to 10-20 g/L) suitable for subsequent cementation or electrowining steps.

Table 3. Preconcentration factors (PF) of Zn(II), Cu and Cd(II) with SIR.

Resin	PF (Zn(II))	PF(Cu(II))	PF(Cd(II))
Reagent: DEHPA: XAD2/DEHPA	40	45	45
Lewatit 1026 OC	60	70	60
Reagent: Cyanex 272: XAD2/Cyanex	65	70	50
Lewatit TP807	60	55	80

The strong acid dependency observed during the column operation was evaluated as a possible separation method to be efficiently applied using parametric pumping. Only few publications in the literature describe the variation of weak parameters (e.g., variation of ionic strength and the change of molecular sizes) as a factor in parametric pumping that will allow separation of heavy metals. The main current activity in this direction was only the use of pH as a controlling factor in parametric pumping. In this study parametric pumping assays were performed by dividing an original solution into two half volumes. Both half volumes were by turns contacted with a Cyanex 272 resins and an exchange reaction occurs during each contact. As favourable parameter values were adjusted, Cu and Cd were transported from one solution to the other whereas Zn was transported in the opposite direction.

Direct parametric pumping assays were performed by simply varying the pH of the solutions. Using more strongly acidic impregnated resins containing DEHPA, a significant effect was found when the hydrogen ion concentration of low pH solution exceeded the concentration of the heavy metals by some magnitude. On the other hand, the pH of the higher-pH solution is limited by the precipitation of heavy metal hydroxides, and additionally increases the DEHPA molecules distribution to the aqueous phases. Direct efficient mode separations were not possible using resins containing phosphoric groups (e.g., DEHPA) and effort was directed to resins containing a weaker acidic organophosphorous function such as phosphinic groups (Cyanex 272). Parametric pumping experiments were carried out at laboratory scale using 1-litre volume containers. The pH was controlled and automatically adjusted by means of a pH-controlling unit with two dosage pumps for adding acid or base if required. In each half-cycle, the stirrer with the resin material rotated for 120 minutes due to the kinetic behaviour of those resins, in each solution. Between the contacts with the two solutions, the liquid in the resin packing was centrifuged off.

Separation experiments of the couples Zn/Cu and Zn/Cd with Lewatit TP807 using the direct mode were carried out and results are shown in Figures 5 and 6.

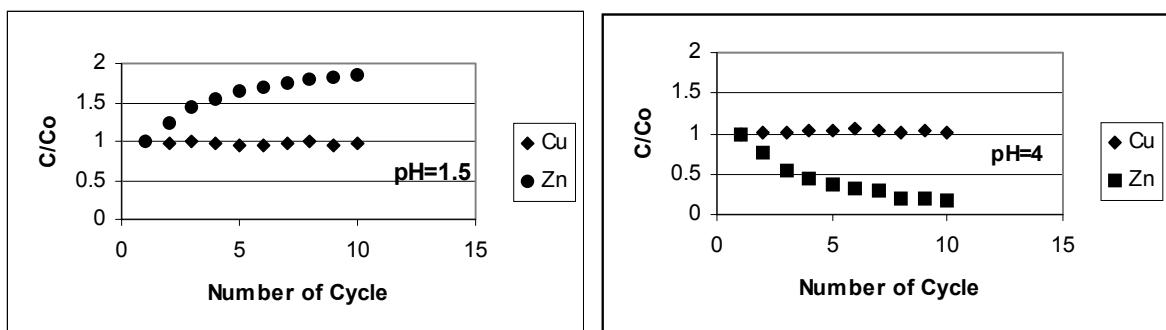

Figure 5. Parametric pumping assays for the system Zn/Cu Lewatit TP807 in the two half volumes system.  $C_o$  (Zn(II)) =  $C_o$  (Cu(II)) = 2 mmol/L.

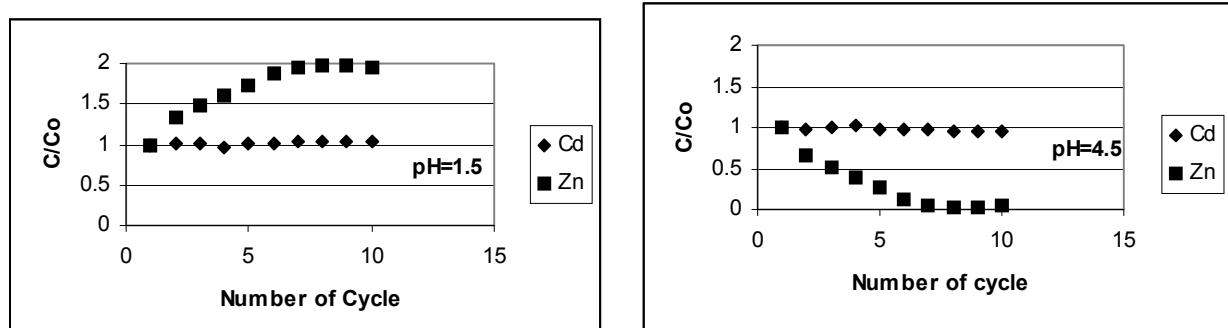

Figure 6. Parametric pumping assays for the system Zn /Cd and Lewatit TP807 in the two half volumes system.  $C_o$  (Zn(II)) =  $C_o$  (Cd(II)) = 2 mmol/L.

Separations in the direct mode were achieved. The pH values were adjusted according to the pH-dependency functions of Cyanex 272 resins given in Figure 2. Figure 5 shows the separation of Zn from Cu. Zn is extracted at pH 3 whereas the extraction of Cu commenced only after reaching pH 4 or higher. Zinc therefore was transported into the pH 1.5 vessel. After ten cycles, the pH 4 vessel contained a Cu(II) solution with 2% Zn(II). Similarly, Figure 6 shows the separation of Zn from Cd, using in this case, a vessel of pH 4.5 where Zn was transported into the pH 1.5 vessel. After ten cycles, the pH 4.5 vessel contained a Cd(II) solution with 1% Zn(II).

## CONCLUSIONS

Solvent impregnated resins and Levextrel-type resins containing phosphoric and phosphinic derivatives can be used to efficiently concentrate diluted solutions of Zn, Cu and Cd and when using phosphinic containing resins efficient separation factors of Cd over Zn could be achieved if acidity of the solution could be controlled. Parametric pumping experiments to achieve these objectives were assayed and preliminary results obtained open new ways to successfully achieve the needed pH control.

## ACKNOWLEDGEMENTS

We wish to acknowledge to Bayer AG, Rohm & Haas for resin supply and to Cytec for extractants supply. This work was supported by CICYT Project QUI99-1025-C03-02 (MEC, Spain) and by MOSA in Israel and MAE in Spain for grants allowing an exchange research collaboration program. A. Warshawsky was the holder of the Rebbecca and Israel Sieff professorial chair in organic chemistry. His colleagues and friends were saddened to learn of his death during publication of this manuscript.

## STUDY OF THE SORPTION OF Zn(II) WITH XAD-7 RESIN IMPREGNATED WITH IONQUEST 801

M. Benamor and M. T. Draa

Department of Chemical Engineering, University of Bejaia, Bejaia, Algeria

Studies have been conducted on the sorption characteristics of Zn(II) from nitrate media with XAD-7 macroporous resin containing Ionquest 801 (2-ethylhexylphosphonic acid mono-2-ethylhexyl ester, HEHEHP, HL). The evaluation of the impregnation procedure shows that the extractant retention on the polymer is better in the case of an excess of water in ethanol-water mixture. It reaches a plateau value of 2.85 mol HL/kg dry resin for an impregnation solution of 0.33 mol HL/L, and an ethanol-water ratio of 1:2.

The impregnated resin shows good affinity towards the extraction of Zn(II). The sorption of the metal increases with aqueous pH solution and extractant retention in the resin phase.

Experimental data were numerically analyzed, and the results show that sorption equilibrium on the impregnated resin can be satisfactorily explained by taking into account the formation of  $ZnL_2$  complexes in the resin phase and  $ZnL^+$  in the aqueous phase.

### INTRODUCTION

The recovery of metal ions from dilute solutions using solvent impregnated resins (SIR) has been proposed as a technological alternative to solvent extraction technique [1]. It has been shown that macromolecular resins containing an extractant within their lattice provide the best use of the advantages of both solvent extraction and ion exchange. A significant number of works dealing with sorption and separation of metal with SIR has been carried out [1, 2]. Numerous metal extractants were used in these studies. They include acidic organophosphorus extractant like DEHPA [3, 4], CYANEX 272 [5], PC-88A [6], neutral extractants like TBP [7] and also basic extractants like tri-*n*-octylamine (TOA) [8]. These extractants were impregnated on different supports [1, 2]. The stability of impregnated resins depends principally on the type of support used and the nature of the organic reagent retained. Generally these support are hydrophobic macroporous organic polymers with a high surface area and good mechanical stability. The amberlite resins XAD are among the most suitable [1, 2].

The objectives of these studies were mainly devoted to explaining the impregnation processes, to elucidate the equilibrium reactions involved as well as kinetics. The approaches used in studying chemical equilibrium are based on those developed for liquid-liquid extraction [4]. But, in spite of these efforts, discrepancies result still exist. In this paper, a sensitive method for sorption of Zn(II) with Ionquest 801 impregnated in polymeric support, amberlite XAD-7 resin, has been developed and the operating parameters have been evaluated.

## EXPERIMENTAL

### Apparatus and Reagents

The pH of the aqueous phase was measured with a 3420 electrochemistry analyzer (Jenway) with a combined glass-saturated calomel electrode. The concentration of metal ions was analyzed with a Shimadzu atomic absorption spectrophotometer (model AA 6501f.) with an air-acetylene flame.

Ionquest 801 (2-ethylhexylphosphonic acid mono-2-ethylhexyl ester, HEHEHP), denoted hereafter by HL, was supplied by Albright and Wilson and used as received. Zinc nitrate, and other inorganic chemicals were of analytical reagent grade and were used without purification.

Stock solutions of Zn(II) ( $1\text{g}/\text{dm}^3$ ) were prepared by dissolving the corresponding salts in a solution of nitric acid ( $10^{-2}\text{ M}$ ). The aqueous solution consisted of  $0.1\text{ M}(\text{Na}^+, \text{H}^+, \text{Zn}^{2+})\text{NO}_3^-$ . The total nitrate concentration was kept constant at  $0.1\text{ M}$ . The aqueous pH was adjusted by changing different fractions of  $\text{HNO}_3$  and  $\text{NaNO}_3$ .

Amberlite XAD-7 resin (Rohm and Hass, size 0.3-0.9 mm) was used as support. The resin was washed in 50% methanol-water solution containing  $4\text{ M HCl}$  in order to remove inorganic impurities.

### Impregnation Procedure

The impregnated resins were prepared according to a slightly modified version of the dry method [1]. Amounts of 5 g of fresh resin XAD-7 were placed for 12 h in an ethanol-water mixture containing Ionquest 801 at different concentrations. After filtration, the Ionquest 801 content of the impregnated resin was determined after washing a given amount of the resin with ethanol, and titration with NaOH.

### Zinc Extraction with XAD7-Ionquest 801

The extraction of Zn(II) was carried out with batch experiments at room temperature. Samples of 0.2 g of resin containing Ionquest 801 were put in contact with 50 ml of an aqueous solution and were magnetically mixed. Preliminary work showed that a 2 h mixing time is sufficient to reach equilibrium.

## RESULTS AND DISCUSSION

### Evaluation of the Impregnation Method

The impregnation procedure was evaluated as a function of both solvent and extractant concentration. The evaluation of the impregnation procedure shows that the extractant retention on the polymer is better in the case of an excess of water in ethanol-water mixture. This is probably the result of different solubility of the extractant in these solutions. The same result was observed by Cortina *et al.* [9] in the case of DEHPA-XAD-2.

Figure 1 shows the relation between the quantity of adsorbed extractant  $q_{\text{HL}}$  (mol HL/kg Res) and the extractant concentration in the impregnation solution  $C_{\text{HL}}$  (mol HL/L). It is evident that  $q_{\text{HL}}$  increases with increasing  $C_{\text{HL}}$  until it reaches a plateau value of approximately 2.85 mol HL/kg resin for an impregnation solution of 0.3 mol HL/L, and an ethanol-water ratio of 1:2.

The model of Langmuir was used to characterize the sorption isotherms by the following expression:

$$\frac{q}{q_m} = \frac{bC}{1+bC} \quad (1)$$

where:

$q$  = moles of the adsorbed solute per mass unit of adsorbent (mol/kg)

$q_m$  = maximum concentration of the adsorbed solute per mass unit of the adsorbent (mol/kg)

$C$  = concentration of the solute at equilibrium in the impregnation solution (mol/L).

The parameters of the model were obtained from experimental data by the non-linear least square method. The values of these parameter obtained are:  $q_m = 2.89$  mol/kg,  $b = 27.29$  (L/mol). The curve obtained is depicted in Figure 1 (solid line). Good agreement exists between experimental and calculated values.

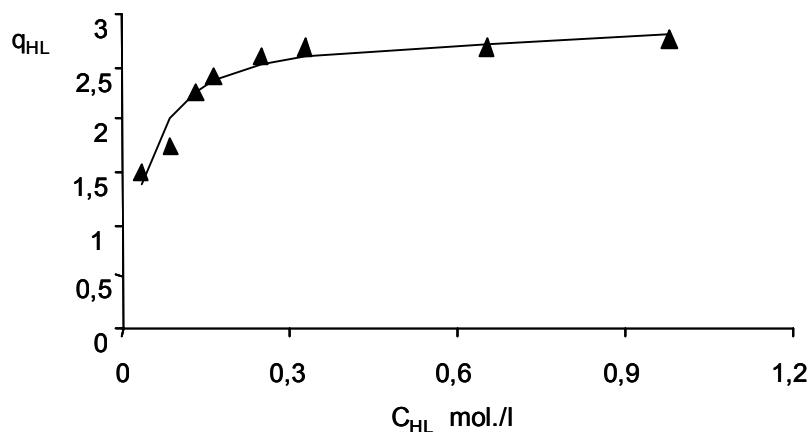

Figure 1. Influence of the extractant Concentration on the resin.  
Loading impregnation solution ethanol-water Mixture 1:2.  $q_{HL}$  : mol.HL / kg resin.

### Effect of pH and Extractant Concentration on Metal Sorption

The distribution of metal ions between the aqueous phase and the resin phase containing Ionquest 801 can be directly obtained as:

$$D = [M]_{R,T} / [M^{m+}]_T \quad (2)$$

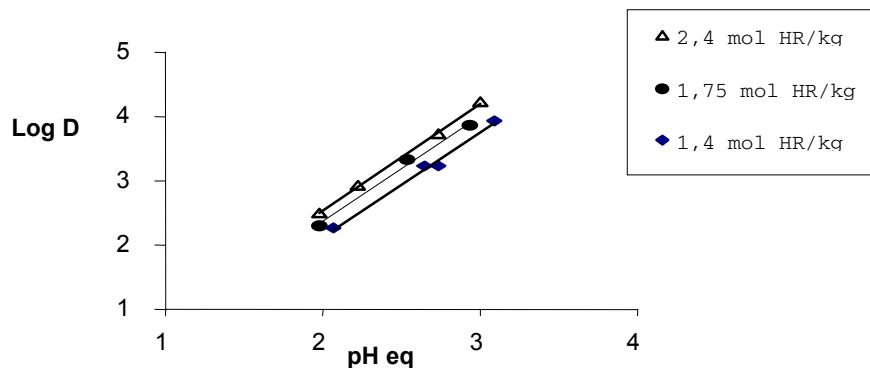

where  $[M]_{R,T}$  is the total concentration of metals in the resin phase in mol/kg dry impregnated resin and  $[M^{m+}]_T$  represents the concentration of the different species in the aqueous phase. The total concentration of metals in the resin phase can be expressed as:

$$[M]_{R,T} = \{ [M^{m+}]_0 - [M^{m+}]_T \} \times (V/m_R) \quad (3)$$

where  $[M^{m+}]_0$  is the initial total concentration of the metal in the aqueous phase,  $V$  denotes the volume of the aqueous phase, and  $m_R$  is the mass of dry impregnated resin.

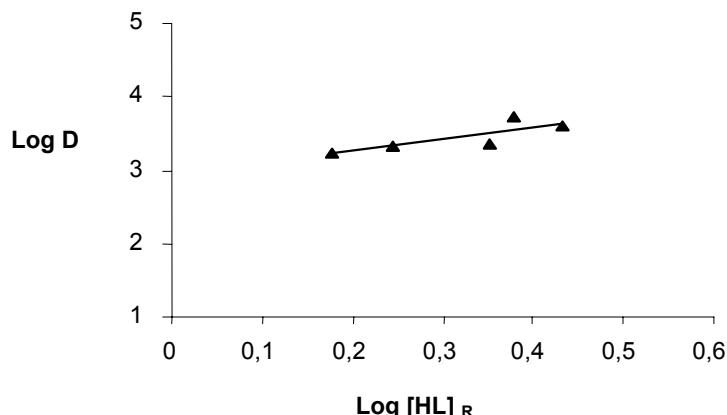

Figure 2 depicts the influence of the equilibrium pH on the distribution coefficient  $D$  at different resin loading  $[HL]_{R,T}$ . It is found that the distribution coefficient increases with aqueous pH; the slope of  $\log D$  versus  $pH_{eq}$  varying between 1.5 and 2 suggests that one or two protons are exchanged during the extraction sorption.

In order to investigate the influence of the extractant concentration, this latter was varied between 0.03 and 0.97 mol/L (Figure 3). The results obtained illustrate that for a constant pH,  $\log D$  increases with the free extractant concentration of the resin and the slope of  $\log D$  versus  $\log [HL]_R$  is close to 2 indicating that two molecules are associated with the extracted metal complex.

*Figure 2. Influence of the equilibrium pH on the sorption of Zn(II) in the XAD-7 impregnated resin with Ionquest 801 for three different resin loading 0.1M NaNO<sub>3</sub>.*

The influence of the metal concentration shows also that there is no polynuclear complex species formed during the sorption of the metal between the extractant and the metal in the resin phase.

*Figure 3. Influence of the extractant concentration of the resin on the distribution coefficient of Zn(II), pH<sub>eq.</sub> = 2.75.*

### Sorption Equilibrium

Divalent metal ion extraction using impregnated resins with organophosphorus extractants can be described by the general reaction [1, 2]:

where the subscript R designs the resin phase.

$$K_{mn} = \frac{[ML_2(HL)_n]_R [H^+]^2}{[M^{2+}] [HL]_R^{2+n}} \quad (5)$$

The corresponding equilibrium constant  $K_{mn}$  based on concentration is defined by taking into account that the extractant adsorbed in the resin phase is involved also in other equilibrium like distribution between the resin and aqueous phase, dissociation in the aqueous phase, and dimerization in the resin phase. We can derive the following mass balance for  $[HL]$  in the case of low metal concentration [2]:

$$[HL]_{o,R} = \{1 + (1/K_D) + (K_a/K_D[H^+])\}[HL]_R + 2K_2 [HL]_R^2 \quad (6)$$

where  $[HL]_{o,R}$ ,  $[HL]_R$  and  $[HL]$  are the initial, free and aqueous phase concentrations of extractant, respectively.

In order to model these extraction equilibrium, the equilibrium constant of the extractant ( $pK_A$ ,  $K_D$ ,  $K_2$ ) must be known. In the case of Ionquest 801, the value of  $pK_a$  of HL was taken from reference [11] and is equal to 3.

The best formulation of the complexes formed in the resin phase is obtained by minimization of the error squares sum defined by:

$$U = \sum (\log D_{exp} - \log D_{calc})^2 \quad (7)$$

where  $D_{exp}$  is the experimental distribution coefficient and  $D_{calc}$  is the one calculated assuming the formation of one set of species and the above mass balance equations. This is achieved by searching the best values of the equilibrium constants  $K_{mn}$  as well as the distribution and the dimerization constant  $K_D$ ,  $K_2$  for extractant, which minimize the error squares sum  $U$ . The Microsoft Excel 97 program was used for this purpose. The standard deviation  $\sigma(\log D)$  is calculated by:

$$\sigma(\log D) = (U/N_p)^{1/2} \quad (8)$$

where  $N_p$  is the difference between the total number of data points and the total number of equilibrium constants calculated.

In the first attempt, and following the slope analysis results, the value of  $n$  was varied between 0-2. Table 1 shows the best formulation for the metal-HL complexes, together with the calculated equilibrium constants obtained. This results show that only a single Zn(II)-HL complex is formed on the macroporous resin and the simultaneous formation of binary complex is rejected.

*Table 1. Results of the numerical calculation obtained in the Zn(II)/XAD-7 system for various model species: case where only free cationic metal in the aqueous phase.*

Specie	U	$\sigma(\log D)$	$\log K_{mn}$
ZnL <sub>2</sub>	0.277	0.13	-1.57

Another scheme consistent with the results of slope analysis was also considered. This latter takes into consideration the reaction between the metal and the ionized extractant in the aqueous phase [10] following the mechanism:

This second model gave a better value of  $U$  (0.19) than the first case. Table 2 depicts the principal result obtained together with the corresponding equilibrium constants.

*Table 2. Results of the numerical calculation obtained in the Zn(II)/XAD-7 system:  
case where the aqueous phase contains ionized complexes species.*

Specie	U	$\sigma(\log D)$	pK <sub>A</sub>	$\log K_D$	$\log K_2$	$\log K_{ex1}$	$\log K_{ex2}$
ZnL <sub>2</sub>	0.19	0.10	3	2.15	3.04	2.73	5

## CONCLUSION

The extraction of Zn(II) from nitrate solutions by impregnated resins containing Ionquest 801 on the amberlite XAD-7 polymeric support in a batch system has been investigated. The evaluation of the impregnation procedure shows that that the extractant retention on the polymer is favoured in the case of an excess of water in ethanol-water mixture. This retention reaches a constant value of 2.85 mol HL/kg dry resin for an impregnation solution of 0.33 mol HL/L, and an ethanol-water ratio of 1:2.

The impregnated resin shows good affinity towards the extraction of Zn(II). The sorption of the metal increases with aqueous pH solution and extractant retention in the resin phase. The data were analyzed numerically and the results show that by taking into account the formation of ZnL<sub>2</sub> in the resin phase, and ZnL<sup>+</sup> complexes between metal and ionized extractant in the aqueous phase, the experimental result could be satisfactorily explained.

## ACKNOWLEDGEMENT

We are grateful to Albright and Wilson (USA) for kindly donating Ionquest 801.

In this work a new family of solvent-impregnated resins based on alkylguanidine functionality (LIX 79) has been synthesised and chemically and physically characterised. Solvent-impregnated resins are prepared by both direct adsorption of the active component onto macroporous polymeric supports and by co-polymerisation of styrene and divinylbenzene in the presence of the active component. The extraction performance of these new materials on metalcyanides from mineral leaching solutions has been evaluated and separation factors and extraction efficiency for the materials are determined. It is shown that gold(I) is extracted into the organic phase by formation of the species  $\text{RH}^+\text{Au}(\text{CN})_2^-$ . Stripping of gold from loaded resin phases is carried out using NaOH, NaCN and NaOH/NaCN mixture solutions. Finally the application of those impregnated resins to extract gold from cyanide solutions is evaluated on different mineral leaching solutions derived from two auriferous Brazilian minerals.

### INTRODUCTION

The application of hydrometallurgy to the recovery of precious metals from dilute ore sources is increasing in use [1]. For example, dump, heap and vat leaching in cyanide media of selected ores are employed commercially in the gold mining industry. In the case of gold the circuit consisting of leaching, carbon adsorption and electrowinning is the most economical way to produce gold.

Although, in this process gold extraction is achieved using activated carbon, in recent years, research efforts have attempted its substitution by ion exchange (IX) or solvent extraction (SX) reagents. The main objective of the application of IX and SX is to solve existing problems associated with the use of activated carbon and thereby improve the selective recovery of goldcyanide, increase loading and stripping efficiencies, and develop an integrated process of leaching and extraction such as resin/solvent-in-leach (RIL/SIL) and resin/solvent-in-pulp (RIP/SIP).

Commercially available resins and extractants are unable to compete with activated carbon due to poor selectivity and the requirement for complex elution and regeneration processes. Since typical leach solutions contain gold as  $\text{Au}(\text{CN})_2^-$  at pH about 10, it was reasoned that these shortcomings might be overcome if an extractant or a resin containing a functional group (L), which would operate on the hydrogen ion cycle shown in the following reaction were used:

where the equilibrium lies far to the right at pH < 10 and far to the left at pH > 12.5. Gold cyanide extraction will be accomplished by the following reaction:

A new reagent that can accomplish the required type of pH cycle, has recently been commercialised by Cognis Co [2]. The reagent, known as LIX 79 contains a guanidine ion-pairing functionality. In previous studies [3,4] the extraction of gold(I) from aurocyanide aqueous solutions using LIX 79 was evaluated and showed that the aurocyanide complex is extracted preferentially over other metal cyano complexes at alkaline pH. This study has been extended to the evaluation of this extractant when immobilised onto polymeric macroporous supports.

Solid adsorbents prepared by immobilisation of liquid extractant onto polymeric materials has been proposed in the last decades as an alternative to solvent extraction by combining the mass transfer properties of solvent-extraction systems with the simplicity provided by polymeric adsorbents on plant design and operation. The impregnated adsorbents can be prepared by simple immobilisation of the extractant onto macroporous supports or by polymer synthesis in the presence of the extractant as has been used by Bayer [5] and Sorbent Center [6].

This paper deals with recent investigations in the application of impregnated resin adsorbents (TVEX-LIX 79) in the extraction, separation and recovery of gold cyanide from leaching solutions. The impregnated resins prepared were obtained by polymerisation of styrene and divinylbenzene in the presence of LIX 79. Solid-liquid studies of gold cyanide extraction using batch and column experiments were performed. The influence of both reagent and polymer functional structure on the extraction ability and the influence of the aqueous composition were studied.

## EXPERIMENTAL PROCEDURE

### Materials Preparation

The extractant LIX 79 was used as supplied by the manufacturer (Cognis Corp.); the active substance of the extractant is based on the guanidine functional group, the structure of which is shown in Figure 1.

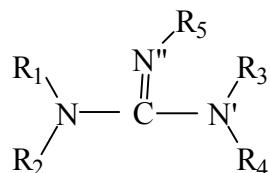

Figure 1. Basic structure of the guanidine functional group ( $R_1$  to  $R_4$  represent alkyl groups).

### Preparation of impregnated adsorbents

Synthesis of solid extractant (TVEX) containing 40–50 % LIX79 was carried out in a glass reactor fitted with a mixer, thermometer and backflow condenser [7]. Starch solution (1%), used as emulsion stabiliser, was first added to the reactor. Then reaction mixture containing styrene, divinylbenzene, LIX79 and benzoyl peroxide as initiator of radical co-polymerisation was fed into the reactor at 55 °C with agitation. Polymerisation was carried out for 5 h at 85–90 °C. The TVEX granules were washed with water and dried with nitrogen.

XAD2-LIX 79 resins were prepared according to a modified version of the wet impregnation method described previously [8]. The amount of LIX 79 impregnated in both types of resins was evaluated by washing a known amount of resin with ethanol, which completely elutes these extractants for subsequent determination by potentiometric titrations. Impregnates prepared achieved loadings of 0.33 g LIX 79/g resin for XAD2 impregnates and 0.20, 0.35 g LIX 79/g resin for TVEX impregnates.

### Aqueous solutions

Stock solutions of  $\text{Au}(\text{CN})_2^-$ ,  $\text{Zn}(\text{CN})_4^{2-}$ ,  $\text{Ag}(\text{CN})_2^-$ ,  $\text{Fe}(\text{CN})_6^{4-}$  and  $\text{Cu}(\text{CN})_3^{2-}$  ( $1\text{g} \cdot \text{dm}^{-3}$ ) were prepared by dissolving the corresponding salts (Johnson Mathey, A.R. grade) in sodium cyanide solution. Real cyanide leach liquors were obtained by leaching of a gold mineral ore from Brazil. The compositions of the solutions are shown in Table 1.

Table 1. Composition of the Metal Cyanide Solutions (mg/L.)

Metal	Leach Liquor 1	Leach Liquor 2	Synthetic Liquor
Gold	11.6	9.6	10.0
Silver	0.7	5.7	5.0
Copper	12.4	20.4	30.0
Iron	10.7	25.7	30.0
Zinc	3.1	6.1	4.0

### Experimental Procedures

Samples between 0.1-0.2 g of impregnates, were mixed mechanically in glass tubes with an aqueous solution (20 ml) until equilibrium was achieved. The composition of the aqueous solutions varied depending on the nature of the experiment. After phase separation the equilibrium pH was measured using a combined electrode. Metal content in both phases were determined using atomic absorption spectrophotometry or inductively coupled plasma spectrophotometry, depending on solution composition. Experiments were repeated on average three times and the accuracy of the estimation of the metal concentration in the loaded resin phase by mass balance was checked by experiments in which complete stripping of the loaded resin phase was carried out and the stripped solution was analysed. An average accuracy of 97%, between calculated and analytical results, was regularly obtained.

## RESULTS AND DISCUSSION

### Influence of the Extractant Concentration

Figure 2 shows the variation in gold extraction against pH for experiments carried out with aqueous phases of 10 mg/l gold(I) and resin impregnated phases which contained different LIX 79 loadings.

As expected, as the extractant concentration increased the corresponding gold extraction curve shifted to more alkaline pH values. The figure also compares the performance of prepared TVEX and XAD2 impregnated resins against a liquid LIX 79/Kerosene mixture. Gold loadings of 20 g/kg achieved with TVEX (0.35 g/g) in solutions at pH 10 are comparable with those published elsewhere with the resin analogue of LIX 79 extractant (AURIX) [9].

### Gold Extraction Mechanism

The expected general equilibrium from which the aurocyanide complex is extracted by LIX 79 can be represented by the reaction:

where R denotes the extractant molecule and the subscript res, a species in the resin phase.

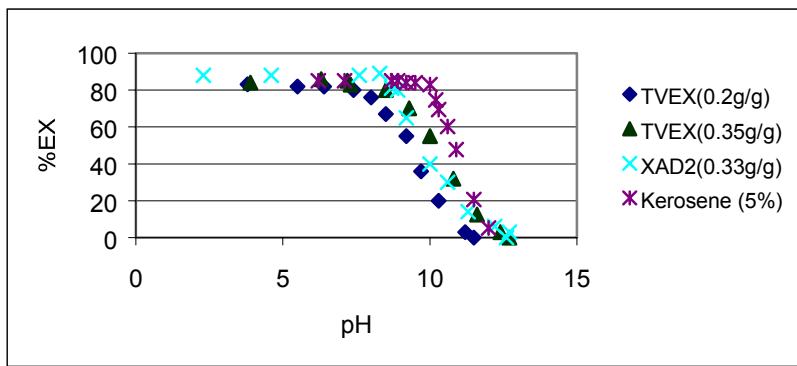

Figure 2. The influence of the LIX79 loadings of the impregnates on gold(I) extraction.

Assuming ideal behaviour for the reaction in eqn (3) in resin and aqueous phases, the stoichiometric equilibrium constant ( $K_{ex}$ ) can be written as:

$$K_{ex} = \frac{[RH^+Au(CN)_2^-]_{res}}{[R]_{res}[H^+][Au(CN)_2^-]} \quad (4)$$

and taking into account the distribution coefficient  $D_{Au}$

$$D_{Au} = \frac{[Au(I)]_{res, tot}}{[Au(I)]_{aq, tot}} \quad (5)$$

dependence of the distribution coefficient and operation parameters can be described by the following equation:

$$\log D_{Au} = \log K_{ex} - pH + \log[R]_{res} \quad (6)$$

The  $pH_{50}$ , pH where a 50% of extraction ( $D_{Au}=1$ ) is obtained, is defined by the following equation:

$$pH_{50} = \log K_{ex} + \log[R]_{res} \quad (7)$$

Figure 3 shows that the variation of  $pH_{50}$  as a function of LIX 79 loadings has a linear relation with a slope of 0.99 and an intercept of 12.9 as the  $\log K_{ex}$  value. This shows that gold cyanide extraction on LIX 79 impregnates occurs via formation of a  $RH^+Au(CN)_2^-$  complex onto the resin phase. This is similar to the described behaviour for this reagent when used in liquid-liquid extraction systems.

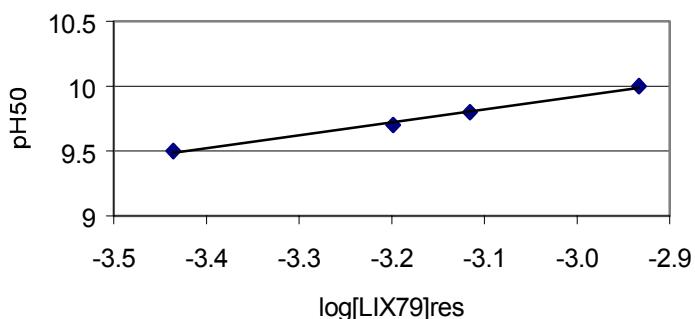

Figure 3. Dependence of  $pH_{50}$  on LIX79 loading on the resin impregnates.

### Selectivity of the TVEX/LIX79-Au(CN)<sub>2</sub>-Extraction System

The selectivity of TVEX/LIX 79 resin for various metal cyano complexes is illustrated in Figure 4, which represents the percentage of metal extraction against equilibrium pH. The aurocyanide complex is extracted at the most alkaline pH value and, consequently, gold loading can be increased relative to the other metal-cyano complexes present in the aqueous phase in this pH range.

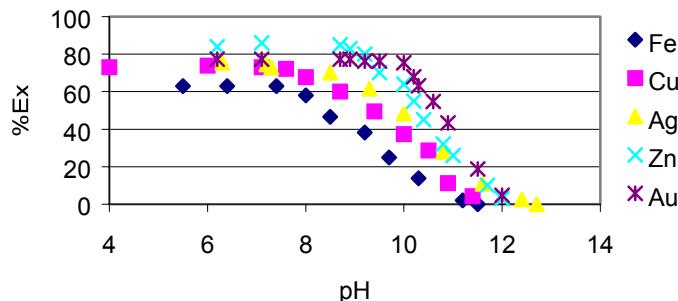

Figure 4. Extraction-pH dependence of  $\text{Au}(\text{CN})_2^-$ ,  $\text{Zn}(\text{CN})_4^{2-}$ ,  $\text{Ag}(\text{CN})_2^-$ ,  $\text{Fe}(\text{CN})_6^{4-}$  and  $\text{Cu}(\text{CN})_3^{2-}$  with TVEX/LIX79 (0.35 g/g) impregnates.

The following extraction sequence can be tentatively established for these metal-cyano complexes:  $\text{M}(\text{CN})_2 > \text{M}(\text{CN})_4^{n-} \sim \text{M}(\text{CN})_6^{n-}$ ; thus the extraction of these complexes depends on the metal co-ordination number. In general, the complexes with lower co-ordination numbers were extracted preferentially to those with higher numbers and the lower charge complexes were extracted preferentially to higher charge complexes.

Extraction experiments were performed with the real leach liquors (Table 1) and the results expressed in terms of the separation factors ( $K_{\text{Au/metal}}$ ), are compared with those for synthetic liquor in Table 2.

Table 2. Separation factors for synthetic and mineral leaching solutions.

Solution	pH <sub>eq</sub>	K <sub>Au/Ag</sub>	K <sub>Au/Zn</sub>	K <sub>Au/Fe</sub>	K <sub>Au/Cu</sub>
Synthetic	10,2	3	6	40	20
Synthetic	10,4	4	8	45	23
Leach 1	10,4	2	4	20	15
Leach 2	10,6	2	5	30	15

The results show that independent of the aqueous solution, the apparent order follows the series:

$$K_{\text{Au/Ag}} > K_{\text{Au/Zn}} > K_{\text{Au/Cu}} > K_{\text{Au/Fe}}$$

This selectivity is in agreement with the fact that the hydrophilicity of the polymer matrix and the ionic density (number of ionic groups per unit volume) play important roles in determining the selectivity characteristics of a resin. Ion-water interactions are stronger in the aqueous phase than in the resin phase, for the simple reason that more free water is available for solvation in the aqueous phase. Thus on this basis alone, the ions with the greatest ionic charge tend to have a lower extraction onto the resin phase. In the resin phase a low degree of hydrophilicity and a low ionic density increases the selectivity for gold and silver and favors those metals over the base metals, iron and copper.

### Stripping

The stripping of gold from loaded TVEX resins (0.2 g/g and 0.35 g/g) was studied using various stripping reagents. Table 3 shows the effect of both the stripping reagent and its concentration on stripping. Stripping efficiency follows the order NaOH > NaCN and tends to increase with increasing reagent concentration, although good gold recoveries were obtained using low NaOH or NaCN concentrations. When the stripping process is completed, the active component [R] of the extractant is deprotonated (eqn (3) shifts to the left), and no metal ions are present in the polymer phase.

Table 3. Stripping of  $\text{Au}(\text{CN})_2^-$  from TVEX/LIX 79 impregnated resins.

Eluant	Stripping %	
	LIX79 (0.2 g/g)	LIX79 (0.35 g/g)
NaOH 0.2 M	94±3	93±1
NaOH 0.5 M	95±2	96±2
NaOH 1.0 M	98±1	96±2
NaCN 0.1 M	90±2	92±3
NaCN 0.2 M	97±2	96±2

### CONCLUSIONS

The use of LIX 79 extractant supported onto polymeric substrate of styrene divinylbenzene allowed gold extraction from alkaline cyanide media. Gold extraction seems to be independent on the initial metal concentration, slightly dependent of the organic diluent and more dependent on the extractant concentration and aqueous pH values. The aurocyanide complex is extracted preferentially over other metal cyano complexes at alkaline pH values. Stripping is accomplished using NaOH or NaCN solutions, the efficiency of stripping slightly increases with the increase in the reagent concentration.

### ACKNOWLEDGEMENTS

This work has been supported by CICYT (QUI99-1025-C03-02) and CIRIT (SGR96-101) Cognis is thanked for providing LIX 79 used in this work.

## SOL-GEL SYNTHESIZED ADSORBENTS FOR NOBLE METAL SEPARATIONS

J. S. Lee and L. L. Tavlarides

Department of Chemical Engineering and Materials Science, Syracuse University, NY, USA

Sol-gel adsorbent materials are synthesized with imidazole and pyrazole chelation ligands which have advantages over conventional solvent extraction systems for selective separation of platinum, palladium, and gold in the presence of copper and iron from leach solutions. These adsorbents are effective for the hydrochloric acid concentration range of 0.1 M to 5.0 M. The sol-gel synthesis starting with precursor silanes and siloxanes results in gel particles of desired pore characteristics and high capacity and stability. Characterization studies, such as adsorption isotherms, breakthrough curves for fixed bed operation, and material stability show promising results for applications to noble metal extraction.

### INTRODUCTION

The technology of noble metal extraction from ores has been developed for a long period of time, but it is still an important research topic because the demand for noble metals continues to increase in various applications such as catalysts, electronics, and corrosion-resistant materials. In addition, the recovery of precious metals from industrial wastes, such as from spent electronic components and catalysts, receives great attention because significant amounts of noble metal-containing wastes are being generated from such industries [1].

Refining processes employing solvent extraction techniques for precious metal mining can achieve highly selective separations and effective enrichments [2], and many organic chelants have been developed to improve the efficiency of currently available extraction processes [3]. These organic chelants are used as solvent extractants or immobilized sorbents on solid supports such as polymer resins [4] and ceramics [5]. The use of immobilized chelating agents on solid supports is a favorable alternative for the recovery of noble metals from dilute leaching solutions.

Recently, our research group reported a sol-gel processing technique synthesizing organo-ceramic adsorbents for the extraction of heavy metal ions [6]. The developed adsorbent, SOL-AD-IV, has significantly improved metal uptake capacities for mercury and cadmium ions compared to those developed by covalent attachment or solvent impregnation on silica matrices. Similarly, two organo-ceramic adsorbents functionalized with imidazole (SOL-IPS) and pyrazole (SOL-PzPs) are developed for the extraction of palladium, platinum, and gold chlorides from hydrochloric acid solutions (0.1 M – 5.0 M).

In this paper, synthesis of adsorbents by sol-gel processing and adsorptive characteristics for the separation of palladium, platinum, and gold chlorides in HCl solutions are discussed.

## EXPERIMENTS

### Materials and Reagents

SOL-IPS and SOL-PzPs adsorbents are synthesized by the sol-gel processing technique as reported in our patent application [7]. N-(3-triethoxysilylpropyl)-4,5-dihydroimidazole (Gelest, Inc.) and N-(trimethoxysilylpropyl)-pyrazole are used as functional precursors for SOL-IPS and SOL-PzPs, respectively, and tetraethoxysilane is used as the cross-linking silane for both adsorbents. Results of pore characterization, elemental analysis, and maximum uptake capacity of palladium(II) chlorides are summarized in Table 1.

*Table 1. Ligand density, metal uptake capacity and pore characteristics of SOL-IPS and SOL-PzPs adsorbents.*

Adsorbent	Ligand density <sup>a</sup> , mmol/g	Metal uptake capacity <sup>b</sup> , mmol/g			Pore characteristics	
		Pd(II)	Pt(IV)	Au(III)	D, Å	SA, m <sup>2</sup> /g
SOL-IPS	2.98	1.54	1.41	2.43	ND <sup>c</sup>	ND <sup>c</sup>
SOL-PzPs	3.16	1.41	0.56	1.48	37	437

a: results of elemental analysis for carbon and nitrogen

b: SOL-IPS at [HCl] = 0.1 M and SOL-PzPs at [HCl] = 2.0 M

c: Not detectable in mesoporous range

Palladium, platinum, and gold chloride solutions are formulated by dissolving potassium tetrachloropalladate(II) (Alfa Aesar Co.), potassium hexachloroplatinate(IV) (Aldrich Chemical Co.), and potassium tetrachloroaurate(III) (Aldrich Chemical Co.) in hydrochloric acid solutions at appropriate concentrations. All other chemicals used in this study are reagent grade.

### Characterization

The metal concentrations are measured with an atomic absorption spectrophotometer (Perkin-Elmer Model 2380) and an ICP-OES (Perkin-Elmer OPTIMA 3300DV). Average pore sizes and surface areas of the adsorbents are measured by nitrogen adsorption at 77 K with Micromeritics ASAP 2000. Carbon and nitrogen contents of synthesized adsorbents are measured by the elemental analysis (Oneida Research Services Inc., Whitesboro, NY).

Maximum uptake capacities for Pd(II), Pt(IV), and Au(III) chlorides at various HCl concentrations are measured by equilibrating desired amounts of adsorbents (0.1 – 0.25 g) with 7–10 mmol/L of the metal chloride solutions at 25°C. For equilibrium adsorption isotherms, desired amounts of adsorbents are equilibrated with the metal chloride solutions at desired HCl concentrations (0.1 mol/L for SOL-IPS and 2.0 mol/L for SOL-PzPs). Multi-metal breakthrough experiments are performed for SOL-IPS and SOL-PzPs adsorbents by using 2.0 g-packed 0.8 cm ID columns and feed solutions containing 0.1 mmol/L each of Pd(II), Pt(IV), and Au(III) chlorides, and 2.5 mmol/L each of copper and iron at desired HCl concentrations (0.1 mol/L for SOL-IPS and 2.0 mol/L for SOL-PzPs). The feed solutions are passed through the columns at approximately 1.0 ml/min flow rate. The stability of SOL-IPS and SOL-PzPs are tested in each 0.5 g of adsorbent packed column (0.8 cm ID). The metal loading solutions are 200 ml of 4.75 mmol/L palladium chloride at 0.1 mol/L (SOL-IPS) and 2.0 mol/L (SOL-PzPs) HCl concentrations that are circulated through the columns for 24 hours at 1.0 ml/min flow rate. After the palladium loading, the columns are washed with 10 ml of water and then stripped with 50 – 75 ml of 0.5 mol/L thiourea in 0.1 mol/L HCl solution. The stripped columns are washed with 0.5 mol/L HCl solution before the next palladium loading. These loading, washing, stripping, and washing cycles are repeated until the desired criteria are satisfied.

## RESULTS AND DISCUSSION

### Maximum Uptake Capacity

Maximum uptake capacities of SOL-IPS and SOL-PzPs for Pd(II), Pt(IV), and Au(III) chlorides are determined at various HCl concentrations to determine appropriate operational conditions. As shown in Figure 1, the uptake capacity of SOL-IPS for Pd(II) is approximately 0.5 mmol/g larger than that for Pt(IV) within the studied HCl concentration range. The uptake capacity for Au(III) rapidly decreases as HCl concentration increases 0.1 M to 1.0 M, and it is even smaller than that for Pd(II) or Pt(IV) at 1.0 M HCl concentration. Hence, the capacity difference for these metal chlorides is insignificant when HCl concentration is higher than 1.0 M. On the other hand, the metal uptake capacities of SOL-PzPs are significantly different with those of SOL-IPS. Uptake capacities of SOL-PzPs for Pd(II) and Au(III) are much higher than that for Pt(IV) within the studied HCl concentration range (< 5.0 M). Hence, this adsorbent can be employed to extract Pd(II) and Au(III) from solutions at HCl concentration range of 0.1 M - 5.0 M.

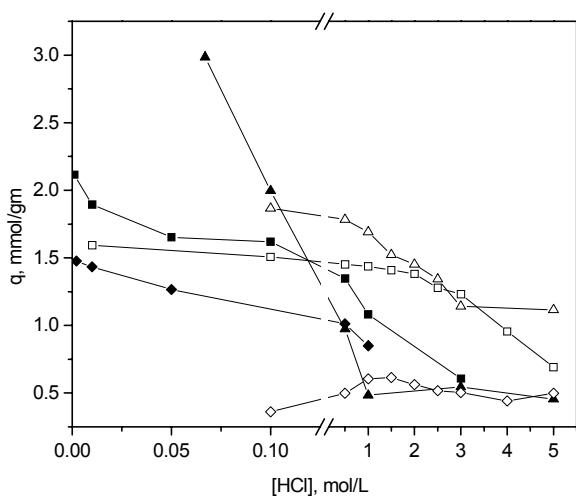

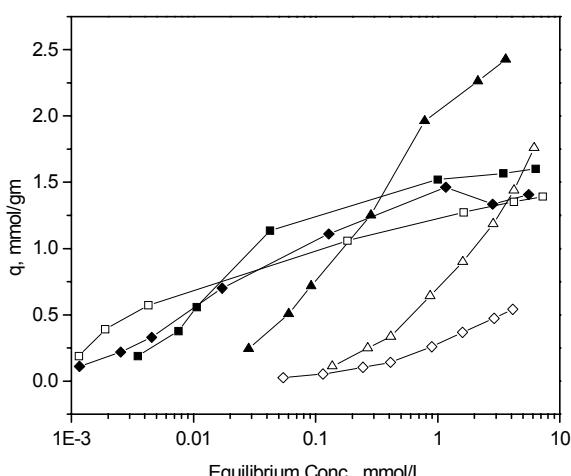

Figure 1. Maximum metal uptake capacities of SOL-IPS (solid symbols) and SOL-PzPs (open symbols) for palladium (■, □), platinum (◊, △), and gold (▲, Δ) chlorides at various HCl concentrations.

### Equilibrium Loading Capacity

The experimental results of equilibrium loading capacity at 0.1 mol/L HCl concentration show that SOL-IPS has a higher uptake capacity for palladium chloride over platinum and gold chlorides when the metal concentrations in the solutions are smaller than 0.2 mmol/L (Figure 2). On the other hand, the uptake capacity for gold chloride is higher than that for palladium and platinum chlorides when the metal concentrations are higher than 0.2 mmol/L. For SOL-PzPs, palladium uptake rapidly increases at low concentration while the uptake capacities for platinum and gold chlorides increase steadily as the solution concentrations increase. This implies that the adsorbent has stronger affinity for palladium chloride than for platinum and gold chlorides, thus an almost complete separation of palladium over platinum and gold is expected at low metal concentrations (< 0.2 mmol/L).

*Figure 2. Equilibrium adsorption isotherms of SOL-IPS at  $[HCl] = 0.1 \text{ mol/L}$  (solid symbols) and SOL-PzPs at  $[HCl] = 2.0 \text{ mol/L}$  (open symbols) for palladium ( $\blacksquare$ ,  $\square$ ), platinum ( $\diamond$ ,  $\square$ ), and gold ( $\blacktriangle$ ,  $\Delta$ ) chlorides.*

### Multi-metal Breakthrough Curves

For both adsorbent systems, multi-metal breakthrough experiments are performed to demonstrate the capability to extract noble metals from highly concentrated transition metal solutions (Figure 3). The breakthroughs of iron and copper from both adsorbent columns occur immediately after starting the experiments. From both columns, the breakthroughs of gold and platinum chlorides occur together, and these metals are exchanged by palladium chloride. The displacements of gold and platinum chlorides by palladium chlorides are approximately 55% and 33% from the maximum loadings (at  $C/C_0 = 1$ ), respectively, for SOL-IPS (within 2,800 and 6,500 bed volumes) and 44% and 100% for SOL-PzPs (within 300 and 6,000 bed volumes), respectively. The displacements of gold and platinum chlorides indicate that SOL-IPS and SOL-PzPs have higher affinity for palladium chloride than for gold and platinum chloride. However, no difference in affinity is observed between gold and platinum chlorides in both adsorbent systems. These experiments show that both adsorbent systems can be used to selectively extract noble metals from concentrated transition metal solutions. In addition, SOL-PzPs shows high possibility to separate palladium from mixture solutions with platinum and gold chlorides at relatively high HCl concentrations (~2.0 M). After complete loading, the loaded palladium, platinum, and gold are recovered with 92 - 100% efficiency by using only ten bed volumes of 0.5 M thiourea in 0.1 M HCl solution. In addition, only trace amounts of platinum is detected in the eluted solution from loaded SOL-PzPs column.

### Material Stability

Experimental results of operational stability of SOL-IPS and SOL-PzPs in packed columns show that the palladium uptake capacities of SOL-IPS and SOL-PzPs are maintained at approximately 100% of the original capacity for six cycles, and decreases to 85% after 17 cycles (Figure 4). The column fails after that due to increase in pressure drop in both columns. The decreasing trends of palladium uptake capacity of these two adsorbents virtually overlap even though the two adsorbents have different functional groups and are operated at different HCl concentrations. Hence, the major reason for pressure drop and the degradation of performance seems to be due to deposition of thiourea on adsorbents leading to column plugging. To avoid degradation of adsorbents and to minimize pressure buildup in packed columns, other stripping agents are recommended even though thiourea is the most powerful stripping agent for noble metals reported in the literature.

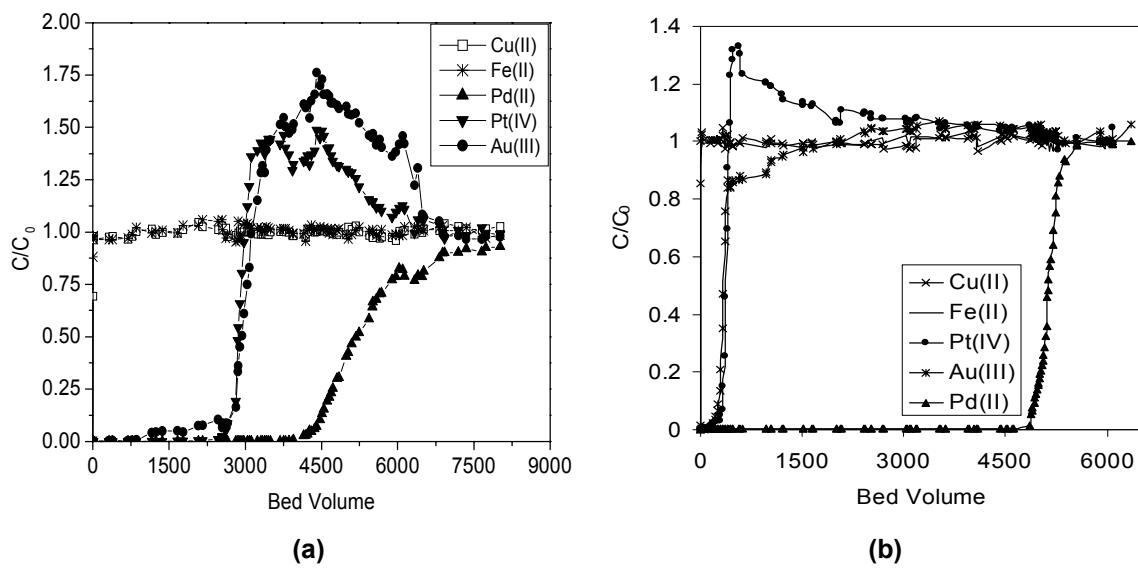

Figure 3. Multi-metal breakthrough curves in columns of SOL-IPS (bed volume = 3.36 ml) at  $[HCl] = 0.1\text{ M}$ , (a) and SOL-PzPs (bed volume = 2.98 ml) at  $[HCl] = 2.0\text{ M}$ , (b): flow rate = 1.0–1.1 ml/min; maximum loading of SOL-IPS = 0.88 mmol Pd/g, 0.50 mmol Pt/g, and 0.47 mmol Au/g; maximum loading of SOL-PzPs = 0.77 mmol Pd/g, 0.0 mmol Pt/g, and 0.03 mmol Au/g.

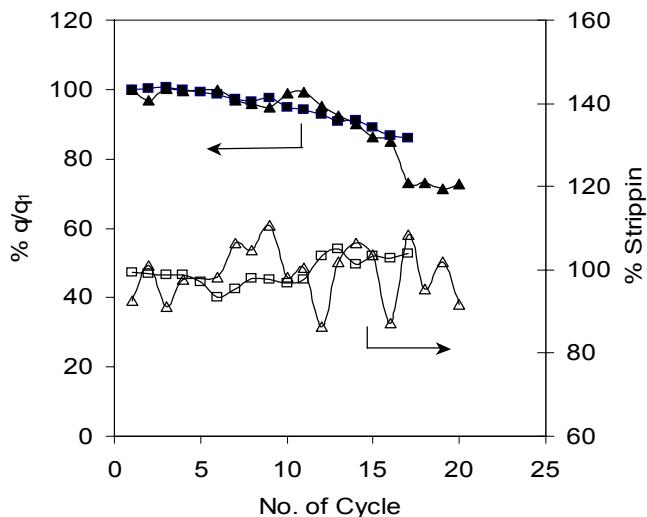

Figure 4. Results of stability tests of SOL-IPS ( $\blacktriangle$  and  $\square$ ) and SOL-PzPs ( $\blacksquare$  and  $\square$ ) by repeated Pd(II) loading and stripping cycles:  $q_i$  is palladium uptake capacity at  $i^{\text{th}}$  cycle;  $q_1$  is palladium uptake capacity at 1<sup>st</sup> cycle (1.42 mmol/g for SOL-IPS and 1.37 mmol/g for SOL-PzPs).

## COMPARISON OF ADSORBENTS FOR NOBLE METAL EXTRACTION

Most adsorbents for extracting noble metals reported in the literature are polymer resins developed through solvent impregnation, ligand coupling (covalent bonding), and copolymerization techniques. Of these approaches, the copolymerization technique generally produces higher ligand density than other techniques. However, the actual metal uptake capacities of these copolymers are usually lower than the predicted capacities obtained from metal-ligand stoichiometry due to the presence of ligands inaccessible to metal ions. The organo-ceramic adsorbents synthesized in this study, however, show high metal uptake capacities as well as high ligand densities. These imply that most of the ligands incorporated

into these silica structures can be accessed by metal ions. Also, these organo-ceramic adsorbents normally have faster equilibration time than chelating resins. In addition to these desirable properties, SOL-PzPs, in particular, has stronger selectivity for Pd(II) than polymer resins functionalized with similar functional groups (3(5)-methylpyrazole and 3,5-dimethylpyrazole) [8, 9]. Hence, this adsorbent is an attractive alternative for selective extraction of Pd(II) as compared to polymer resins at high HCl concentrations.

## CONCLUSIONS

Organic-ceramic adsorbents functionalized with imidazole (SOL-IPS) and pyrazole (SOL-PzPs) are synthesized by sol-gel processing technology for the separation of noble metals at low and high HCl concentrations, respectively. From multi-metal breakthrough experiments, both adsorbents show no adsorption of copper and iron, which exist in excessive quantities in noble metal leaching solutions. More importantly, the pyrazole functionalized adsorbent shows strong selectivity for palladium chloride over platinum and gold chlorides. Hence, this adsorbent has a high potential for application in the separation and recovery of noble metals from leaching solutions of ores, spent catalysts, and disposed microelectronic components. Further investigation is on going to selectively recover platinum and gold in copper and iron enriched HCl solutions. Accordingly, complete extraction and separation of palladium, platinum, and gold can be achieved with sequential fixed beds using these adsorbents.

In an ongoing research program dedicated to the improvement of solvent extraction methodology for the separation of metal ions, we have developed a new extraction system called Triple Phase Extraction Systems that can significantly improve both the extractability and selectivity of such separations. Triple phase extraction is a method involving the introduction of a hydrophobic silica gel separation agent, having an alkyl chain, into a solvent extraction system, thereby improving extractability and selectivity. This is a phenomenon unique to triple phase extraction systems and is not achieved in a synergic extraction systems. We describe extraction of copper(II) ions with TTA and extraction of rare earth with H<sub>2</sub>Clbbpen. We think that the triple phase extraction method is adaptable to macro-scale separations.

## INTRODUCTION

Solvent extraction is a useful method for the separation and reservation of precious metals. The improvement of selectivity and extractability has been extensively examined [1,2]. Many synergic extraction systems, which use a synergic effect to improve the extractability, have been investigated [3]. In many synergistic extraction systems, selectivity decreases. A further disadvantage arises from the use of halogenated hydrocarbons as carrier solvents (or diluents) because of the adverse environmental effects of their use. We found that, by modifying the characteristic behavior of a typical solvent extraction system by the addition of a hydrophobic silica gel, we could achieve the desired increase in selectivity. For obvious reasons, we call this new technique Triple Phase Extraction System (TPES) [4-6]. It is a method of adding the hydrophobic silica gel separation agent, which has an alkyl chain, into a general solvent extraction system. In this method, metal complexes are extracted into organic solvent. After that, metal complex distributed to silica gel separation materials. Therefore, high extraction ability is shown. In this case, the selectivity improves because the distribution constant is different according to metal complex. The extraction of a transition metal ion and lanthanide ion is described in this paper.

## EXPERIMENTAL

### Reagents and Apparatus

The synthesis of hydrophobic silica gels were performed according to previously described methods [7]. Hydrophobic silica gel materials in which octadecyl group, dodecyl group and phenyl group are introduced are abbreviated as C18g, C12g and C6g, respectively. Carbon content of synthesized C18g was 22%. The synthesis of H<sub>2</sub>Clbbpen in Figure 1 was performed according to the method of Neves *et al.* [8]. TTA (4,4,4-trifluoro-1-(2-thienyl)-1,3-butanedione) was made by Dojindo Laboratories. All other chemicals were reagent-grade materials and deionized water was used throughout. The pH and the metal concentration in the aqueous phase were determined with a Hitachi-Horiba F-13 pH meter equipped with glass electrode and a Seiko SPS-1200R inductively coupled argon plasma spectrometer was used to determine metal concentrations. For metal concentrations in the organic phase the solution was first back extracted into 1 M sulfuric acid and then analysed by ICP. Gel separation agent were separated using centrifugation or filtration.

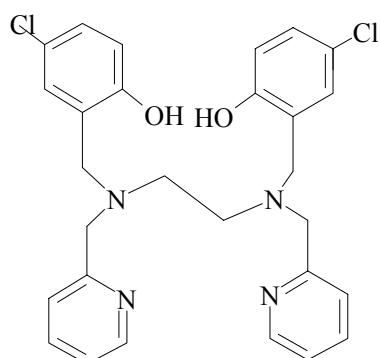

Figure 1. *N,N'-bis(5-chloro-2-hydroxybenzyl)-N,N'-bis(2-methylpyridyl)ethanediamine (H<sub>2</sub>Clbbpen).*

### Extraction of Metal Ion

#### Extraction of copper(II) ion with TTA

In a 30 cm<sup>3</sup> centrifuge tube, an aliquot of toluene (10 cm<sup>3</sup>) containing 0.01 M TTA was equilibrated with an equal volume of an aqueous phase containing 0.1 M sodium nitrate and 0.02 M buffer (chloroacetic acid and acetic acid) containing 1.0 × 10<sup>-4</sup> M Cu<sup>2+</sup>. After the two phases were separated by centrifugation, the pH and Cu(II) concentration of the aqueous phase were measured. In the TPES experiment, 5 g of the gel per 100 cm<sup>3</sup> solvent was added.

#### Extraction of lanthanide ions with H<sub>2</sub>Clbbpen and picrate ion

Lanthanide ions were extracted in a manner similar to that of copper(II) extraction. In a 30 cm<sup>3</sup> centrifuge tube, an aliquot of toluene (10 cm<sup>3</sup>) containing 0.02 M H<sub>2</sub>Clbbpen and an equal volume of an aqueous phase containing 1.0 × 10<sup>-4</sup> M Ln<sup>3+</sup>, 0.01 M sodium picrate and the 0.02 M buffer (acetic acid, 2-(N-morpholino)ethanesulfonic acid (MES), 3-(N-morpholino)-propanesulfonic acid (MOPS) and N-tris(hydroxymethyl)methyl-3-aminopropanesulfonic acid). After aqueous and other phase were separates by centrifugation, the pH and lanthanide concentration of aqueous phase were determined.

## RESULTS AND DISCUSSION

#### Extraction Mechanism and Equilibrium Analysis

Figure 2 shows the extraction scheme of triple phase extraction system in the case of extraction of transition metal ions. First, metal ion was complexed with extractant in aqueous phase. The metal complex is distributed to an organic phase. Second, extracted metal

complexes in the organic phase are distributed to the gel phase. Each distribution constant is assumed to be P and P'. The extraction constant and extraction equilibrium of a general solvent extraction system can be shown as follows.

$$K_{ex} = [ML_2]_o [H^+]^2 / [M^{2+}] [HL]_o^2 \quad (2)$$

$$D = [ML_2]_o / [M^{2+}] \quad (3)$$

where subscript o denote the species in the organic phase.

First, in the absence of hydrophobic silica gel,  $[ML_2]_{(o+s)}$  equals  $[ML]_o$ . Therefore, the extraction constant reduces to that of the general extraction.

In the presence of the gel, we have the following formulation.

$$[ML_2]_o + [ML_2]_g = C - [M] \quad (4)$$

where subscript s denote the species in the solid phase (gel phase) and C represents the initial concentration of metal ions. Therefore, the metal concentration except for aqueous phase  $[ML_2]_{(o+s)}$  can be calculated in equation (5) and there are following relation on  $[ML_2]_o$  and  $[ML_2]_g$ .

$$[ML_2]_{(o+s)} = [ML_2]_o + [ML_2]_g \quad (5)$$

$$P' = [ML_2]_g / [ML_2]_o \quad (6)$$

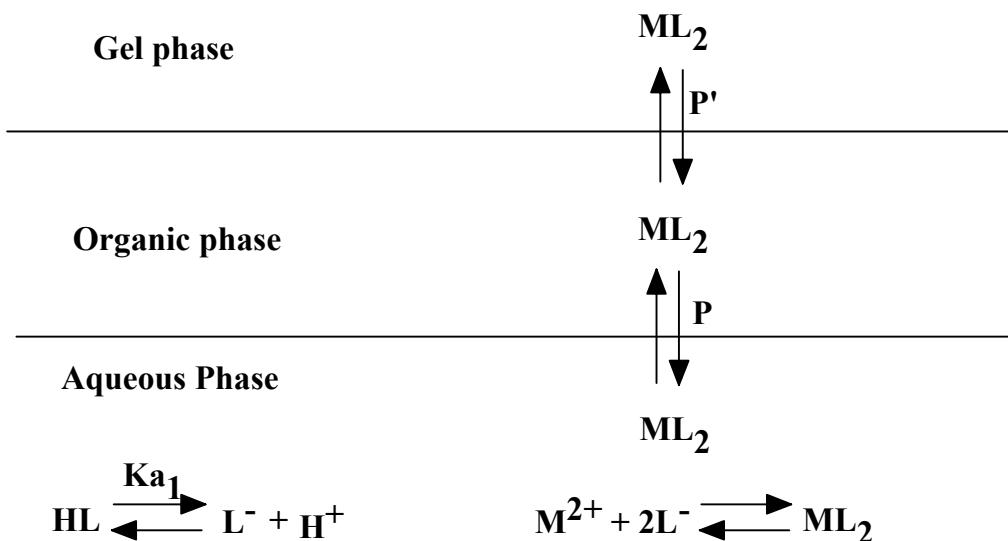

By using these equations, the metal concentration except for aqueous phase  $[ML_2]_{(o+s)}$  can be described as follows.

$$[ML_2]_{(o+s)} = \{1 + P'\}[ML_2]_o \quad (7)$$

This equation was substituted for expression (2), the extraction constant of triple phase extraction system( $K_{ex}'$ ) was described as follows.

$$\begin{aligned} K_{ex}' &= [ML_2]_o \{1 + P'\} [H^+]^2 / [M^{2+}] [HL]_o^2 \\ &= \{1 + P'\} K_{ex} \end{aligned} \quad (8)$$

The effect of addition of hydrophobic silica gel can be quantitatively discussed by using partition constant (P'). The extraction curve was analyzed based on such a formulation.

*Figure 2. Extraction mechanism of triple phase separation system.*

HL : Extractant; P: Distribution constant of metal complexes between organic and aqueous phase;  
P': Distribution constant of metal complexes between organic and gel phase;  
 $K_{a1}$  and  $K_{a2}$  : dissociation constants of ligand.

### Extraction of Transition Metal Ion using TTA

Log D vs. pH plot when the copper ion is extracted by using various separation materials and TTA is shown in Figure 3, and a half extraction pH is shown in Table 1. The overall extraction equilibrium, constant ( $K_{ex}$ ) and extraction constant of triple phase extraction system ( $K_{ex}'$ ) of copper(II) ion can be described as:

$$K_{ex} = [CuL_2]_o [H^+]^2 / [Cu^{2+}] [HL]_o^2 \quad (10)$$

$$\begin{aligned} K_{ex}' &= [CuL_2]_o \{1 + P'\} [H^+]^2 / [Cu^{2+}] [HL]_o^2 \\ &= \{1 + P'\} K_{ex} \end{aligned} \quad (11)$$

As can be seen from Figure 3, the results conform to a linear relationship between the log Cu extracted and the pH as predicted from Eqn. (11) both in the presence and absence of the gel. The added distribution occurring with the gel increases the extractability at each pH, as seen in the lower values of  $pH_{1/2}$  corresponding to a higher value of the distribution constant. Table 2 shows the relation of extraction solvent and distribution constant ( $P'$ ) when the copper ion is extracted by using TTA with C18g. When using a small organic solvent of the permittivity and the dipole moment is used the magnitude of the distribution constant is large. It is thought that the ratio which extracted complex distributes into the gel phase is large because the solubility of complex is small. Extractability increases when the introduced alkyl chain becomes long. Moreover, when the solvent with small solubility of complex is used, the distribution constant is large and an increase in the extractability is large.

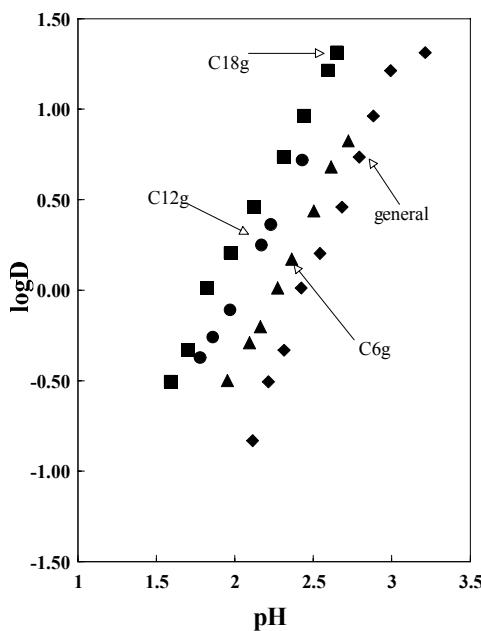

Figure 3.  $\log D$  vs.  $pH$  of TTA- $Cu^{2+}$  extraction system.

$Cu^{2+} : 1.0 \times 10^{-4} M$ ; TTA :  $0.01 M$ ; Buffer :  $0.02 M$ ; Sodium Nitrate :  $0.01 M$ ; Organic solvent : Toluene; Hydrophobic gel separation agent  $5 g/100 cm^3$  solvent.

Table 1.  $pH_{1/2}$  of triple phase extraction systems.

Extraction system	C18g	C12g	C6g	general
$pH_{1/2}$	1.82	2.08	2.24	2.38

$Cu^{2+} : 1.0 \times 10^{-4} M$ ; TTA :  $0.01 M$ ; Buffer :  $0.02 M$ ; Sodium nitrate :  $0.1 M$ .  
Organic solvent : Toluene ; Hydrophobic gel separation agent  $5 g/100 cm^3$  solvent.

### **Ion Pair Extraction of Rare Earth Metal Ion using H<sub>2</sub>Clbbpen**

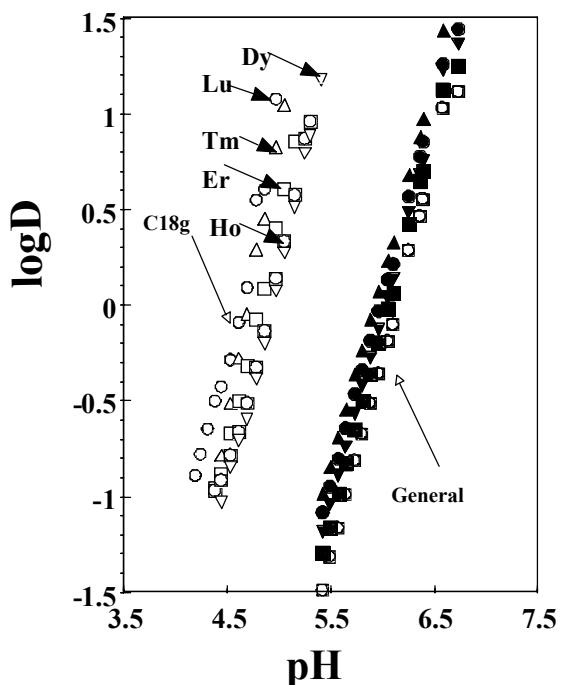

Lanthanide ions can be extracted with H<sub>2</sub>Clbbpen and picrate ion into toluene and dichloroethane as an ion pair species. Extractability of system decreases when the toluene was used. The solubility of the extracted ion pair species was small because the permittivity of the toluene is smaller than that of dichloroethane, and the extractability is also small. The overall ion pair extraction equilibrium, extraction constant ( $K_{ex}$ ) and extraction constant of triple phase extraction system ( $K_{ex}'$ ) of lanthanide ion can be described as:

$$K_{ex} = [LnL^+ \cdot pic^-_o][H^+]^2 / [Ln^{3+}][H_2L_o][pic^-] \quad (13)$$

$$\begin{aligned} K_{ex}' &= [LnL^+ \cdot pic^-_o]\{1 + P'\}[H^+]^2 / [Ln^{3+}][H_2L_o][pic^-] \\ &= \{1 + P'\}K_{ex} \end{aligned} \quad (14)$$

From Figure 4 may be seen that the log D vs. pH plot is in accord with the scheme developed in Eqns. (12)-(14). In each of the systems the data exhibit a linear relationship of slope 2, with the pH<sub>1/2</sub> moving to lower values as the length of the alkyl chain is increased. It is also seen that differences in pH<sub>1/2</sub> from neighboring Ln ions also increases, signifying an increase of selectivity (see Table 2).

*Figure 4. log D vs. pH of ion pair extraction of lanthanide metal.*  
 Ln<sup>3+</sup> : 1.0 × 10<sup>-4</sup> M ; H<sub>2</sub>Clbbpen:0.01 M ; Buffer : 0.02M ; Sodium picrate : 0.01 M ;  
 Organic solvent : Toluene; Hydrophobic gel separation agent 5 g/100 cm<sup>3</sup> solvent.

When the extraction constants of the same metal are compared, it is seen that the extraction constant of triple phase extraction system is large. Separation factors of triple phase extraction systems are larger than that of a general extraction system. Therefore, it is understood that extractability and selectivity improved by adding the hydrophobic gel separation agent. The selectivity of lanthanide metal ion improves for the difference of the distribution constant. The distribution constant was increasing with decreasing ionic radii of lanthanide metal ions. The selection improves because the distribution constant of heavy lanthanide metal ion with a high extraction constant is large. This phenomenon is unique to triplephase extraction system and is not seen in a synergic extraction system. This method should be broadly applicable to many metal ion separation processes.

## COALESCENCE EXTRACTION - FROM MOLECULAR DYNAMICS TO CHEMICAL ENGINEERING APPLICATION

Achim Schaad and Hans-Jörg Bart

Institute of Thermal Process Engineering  
University of Kaiserslautern, Kaiserslautern, Germany

Coalescence Extraction is an effective solvent extraction method which uses single phase extraction followed by spinodal phase decomposition. After a rapid temperature or composition quench the phases separate within seconds even in the presence of emulsifying agents. Phase separation kinetics are studied using crystal violet as surfactant. The formation of phase boundary during coalescence extraction is analysed by a microscopy set-up. Furthermore, coalescence extraction is carried out using a reactive solvent extraction mixture. Iodine, which is used as transfer component, is quantitatively transferred into the organic phase. In order to investigate the structure and dynamics from the very beginning of phase separation, molecular dynamics techniques are applied. The resulting diffusion coefficients are in good accordance with the literature.

### INTRODUCTION

An efficient solvent extraction method has been investigated which is called either 'Coalescence Extraction' [1] or 'Phase Transition Extraction' [2]. It is based on the use of a primary solvent which, in combination with the feed, forms a homogeneous solution. This homogeneous phase has enormous extraction potential for the treatment of cell fragments and other highly viscous materials. In the next step, a secondary solvent (Composition-Induced Phase Separation, CIPS) or a significant temperature change (Temperature-Induced Phase Separation, TIPS) is used to enter the spinodal two-phase region in which an extract and a raffinate are formed. The phases separate within seconds, even in the presence of emulsifying agents [3]. Furthermore, the interfacial surface area, which is one of the most relevant determinants of extraction rates, reaches its theoretical limit.

Stable emulsions may frequently develop in solvent extraction (e.g., with fermentation broths) which make the separation of the desired product difficult. Furthermore, the shear stress induced by vigorous stirring can in many cases damage high molecular weight compounds [4]. In addition, the product yield may be reduced through partially adsorbed solute molecules adhering to solid surfaces due to wetting and leaching problems of an organic solvent. This paper describes a strategy to solve these problems.

Although many experimental and theoretical studies have been carried out, which were summarised by [5], a fundamental understanding of the phase separation process does not yet exist.

## EXPERIMENTAL

The non-reactive system investigated contains a solvent mixture of 4-methyl-2-pentanone (MIBK), acetonitrile and an aqueous solution of crystal violet dye [6]. Crystal violet acts both as a surfactant and as a transfer component. Several functional groups cause its intensive colour. The surface-active properties of crystal violet are verified by measuring the interfacial tension. The second solvent system used is a binary mixture of 2,6-dimethylpyridine and water. Iodine is used as a model transfer component. A reaction takes place between 2,6-dimethylpyridine and iodine, forming charge-transfer complexes and ionic species [7]. Both selected solution systems have very low critical solution temperatures (CST).

An experimental set-up has been designed to study the dynamic behaviour of the phase separation process (Figure 1). It consists of a temperature-controlled cell (volume: 0.7 ml) and a CCD-camera which is mounted on an optical microscope. This allows an on-line observation of the phase separation process. Structures are resolved up to a size of 2  $\mu\text{m}$ . Two temperature baths are used for rapid temperature quenching. The solution is stirred in order to achieve fast heat transfer. The resulting frames are grabbed by a computer and analysed with commercially available software.

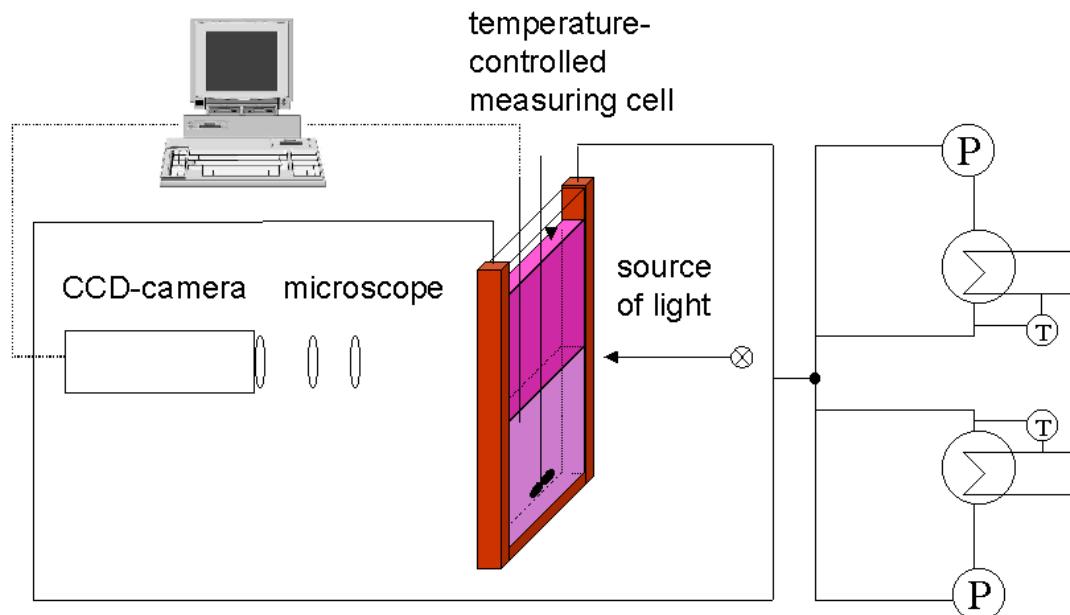

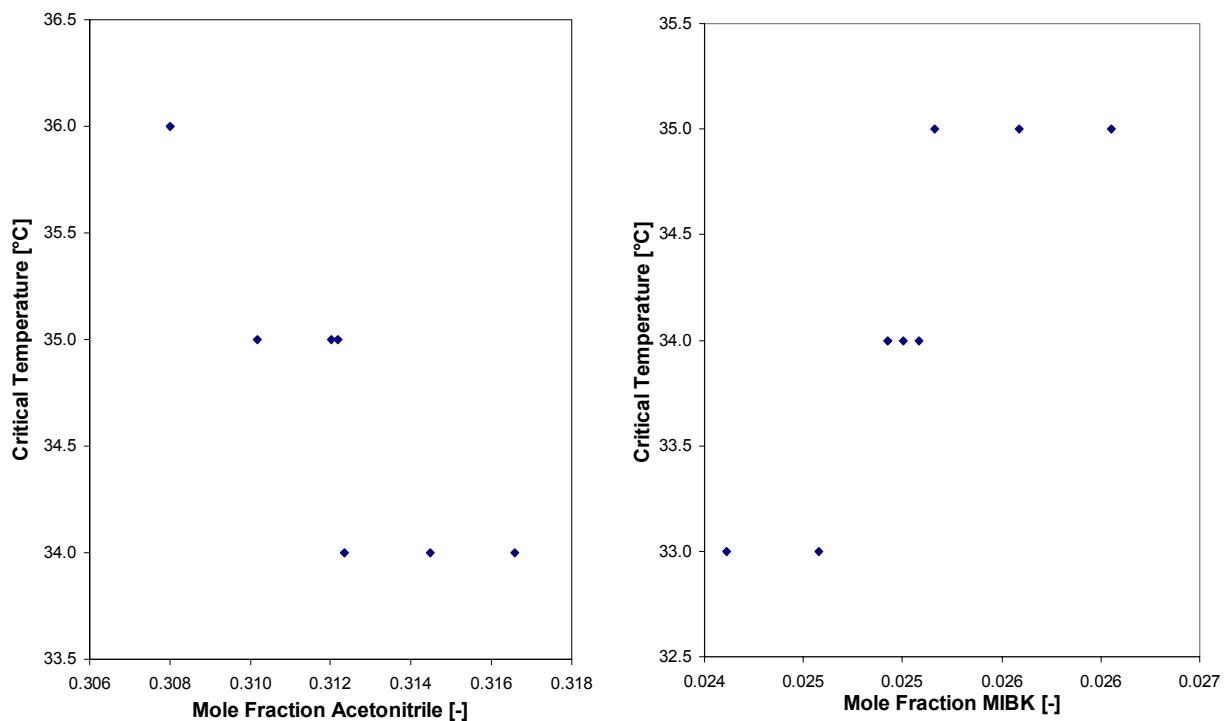

Figure 1. Experimental set-up.

## RESULTS AND DISCUSSION

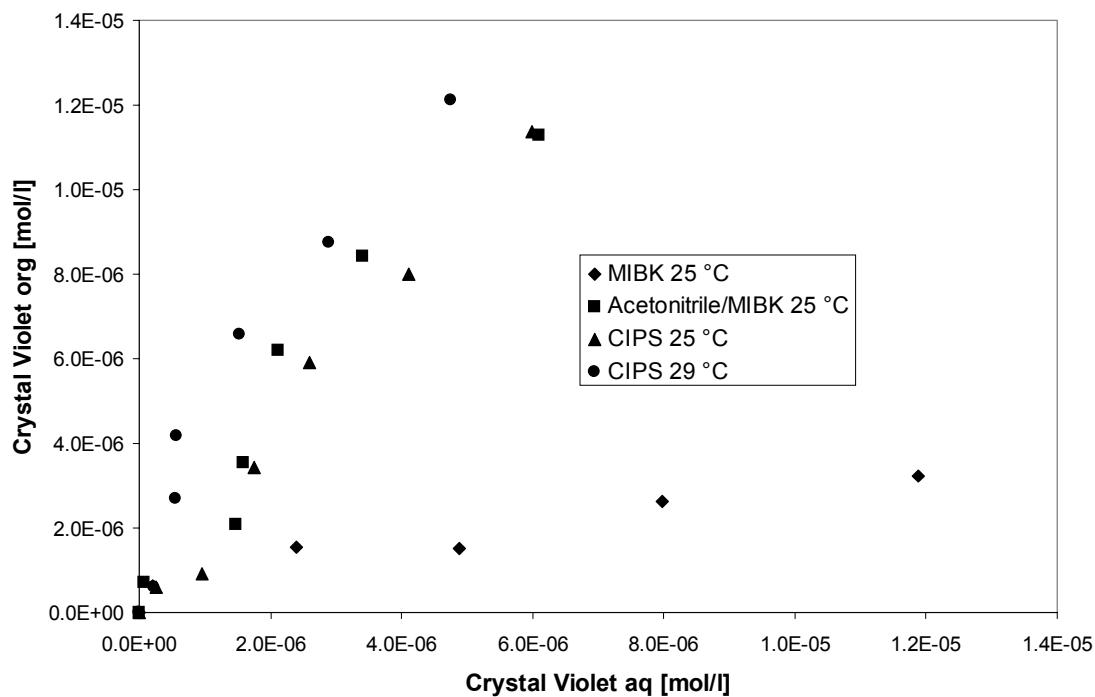

### Non-Reactive Coalescence Extraction

The non-reactive solvent mixture is investigated with regard to critical temperature, equilibria, kinetics of phase separation and microscopic structure of the phase boundary during phase disengagement. The correlation of critical temperature and composition of the solvent mixture is investigated using a crystal violet concentration of 5 mg/l in the aqueous phase (Figure 2). The upper critical solution temperature (UCST) of the mixture increases with increasing amount of MIBK. The opposite effect is observed when the mole fraction of acetonitrile increases, as it is known from the literature [8]. Even very small changes in composition cause significant changes in critical temperature. This is useful with respect to a technical application.

*Figure 2. Critical solution temperature.*

The equilibrium concentrations of crystal violet are measured by UV-spectroscopy. When only MIBK is used as organic solvent in a conventional extraction process, the efficiency of extraction is very poor compared with a mixture of acetonitrile/MIBK or with coalescence extraction, that is CIPS (Figure 3).

*Figure 3. Equilibria.*

Furthermore, Figure 3 shows that equilibria of conventional extraction and coalescence extraction are identical within tolerance as expected. In addition, equilibria are investigated at different temperatures. Significantly higher distributions of dye in the organic phase are observed at higher temperatures.

The phase separation kinetics are measured by several visualisation techniques. A series of macroscopic photos are taken by a stirring cell during the phase separation process using a digital camera. These images show that the solvent extraction method used influences the separation kinetics heavily. When the same amount of surfactant is dissolved both in conventional extraction and coalescence extraction, the kinetics of phase separation are found to be faster in orders of magnitude in the latter. In conventional extraction, intensive mixing of the phases yields a stable (30 minutes) emulsion zone. Since a single extraction phase is obtained in the case of coalescence extraction, moderate stirring is sufficient here. Moreover, the phases separate within seconds even in the presence of emulsifying agents. Since the coalescence process is very fast there are no well-defined phase boundaries to which surface-active compounds can adsorb [5].

Microscopic photos are taken during the phase separation process. A typical morphology of a emulsion-zone formed in conventional extraction processes consists of polydisperse droplets in the order of magnitude of 90  $\mu\text{m}$  (Figure 4 A). This almost rigid emulsion zone between the organic and the aqueous phase decreases during the phase separation process until a sharp phase boundary is obtained. The duration of this process ( $> 30 \text{ min}$ ) depends on the energy input which is brought into the system.

During the coalescence process, the situation is completely different, not only with respect to the dynamics, but also to the structure of the phase boundary. At the beginning of phase separation a interface between the phases appears which is initially very diffuse. At the same time dynamic domains on both sides of the phase boundary start to grow during the phase separation process. These domains spread out from the phase boundary. Figure 4 B shows the interconnectivity of phases which is characteristic of spinodal decomposition [5].

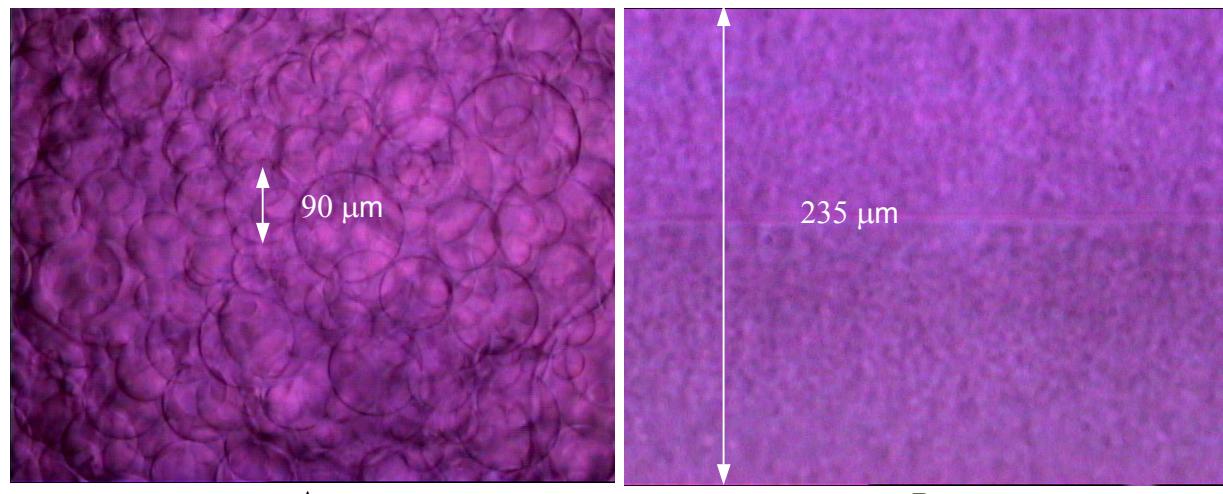

Figure 4. Microscope photos (A: Conventional Extraction, B: CIPS),

### Reactive Coalescence Extraction

The binary mixture of 2,6-dimethylpyridine and water has a lower consolute point at a temperature of 33.9 °C and a 2,6-dimethylpyridine concentration of 2.78 M [10]. Iodine, which is used as model transfer component, is bound through 2,6-dimethylpyridine by complexation. Equilibria measurements of different iodine concentrations (up to 100 mg/l) show a quantitative mass transfer in the organic phase. Using a 2.2 M 2,6-dimethylpyridine solution (critical

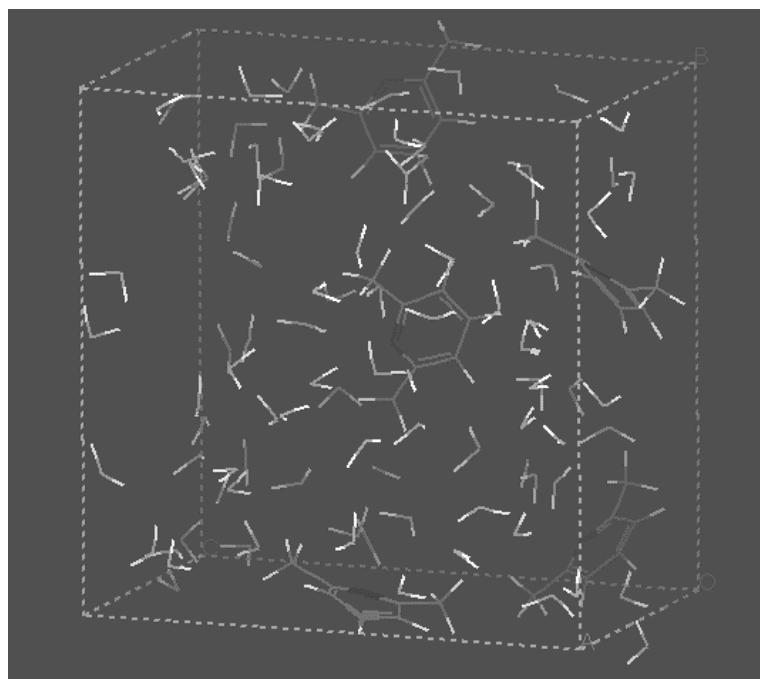

temperature: 34.3 °C [10]) the interfacial tension is measured at different temperatures as close as possible to the consolute point, resulting in a linear correlation. The interfacial tension decreases with decreasing temperature. If the regression curve is extrapolated to a interfacial tension of zero a critical temperature of 35.7 °C is obtained which is very close to published data.

### Molecular Dynamics Simulations

Since the phase separation kinetics in coalescence extraction are very fast, experiments will fail to study the first stages of this process. In order to investigate the structure and dynamics from the very beginning of phase separation, molecular dynamics techniques are applied. Molecular dynamics simulations involve numerical solution to Newton's equations of motion for a set of molecules [9]. Commercially available software is used to determine the diffusion coefficient of a 5 mole % solution of 2,6-dimethylpyridine in water. A periodic three-dimensional box (box-length: 16.8 Å) is built consisting of 5 molecules of 2,6-dimethylpyridine and 95 molecules of water (Figure 5). Afterwards, a minimisation is performed to optimise the conformation of the model so that such conformation corresponds to one at 0 K. Finally, a molecular dynamics simulation is carried out at a temperature of 298 K. From the resulting trajectories a mean-square displacement (MSD) is calculated as a function of the position of each diffusing molecule. As a result, the interdiffusion constant D is obtained using the Einstein relation (1) where N is the number of the atoms, r the position of the particle and t corresponds to the simulation-time in fs.

$$D = \frac{1}{6Nt} \langle |r(t) - r|^2 \rangle \quad (1)$$

D is obtained by calculating the slope of MSD vs. time. The result of this non-ideal solvent system,  $0.99 \cdot 10^{-10} \text{ m}^2 \text{ s}^{-1}$ , is in accordance with the literature value of  $1.03 \cdot 10^{-10} \text{ m}^2 \text{ s}^{-1}$  [10].

*Figure 5. Periodic three-dimensional 2,6-dimethylpyridine/water-box.*

## CONCLUSIONS

This work investigated coalescence extraction which is a benign extraction tool using partially immiscible solvents. When significant concentrations of surfactant are present, phase separation is found to be much faster than in conventional solvent extraction. The phase separation process is studied using microscopic measurements, yielding detailed information on the dynamics of phase separation. Molecular dynamics simulations are applied to investigate this process from the very beginning. The resulting diffusion coefficients are in accordance with the literature. Further work will deal with a detailed study of the binary system discussed last. The aim of such work is to investigate the structure and dynamics of the phase separation process. Conventional molecular dynamics simulations are useful to obtain diffusion coefficients and to analyse the structure of the phase boundary. Since the simulation time of conventional molecular dynamics is limited to a few nanoseconds, molecular dynamics can analyse only one part of the separation process. The molecular model used has to be simplified in order to obtain a complete theoretical description by using Dissipative Particle Dynamics (DPD) simulations. On the one hand, microscopic processes are investigated; on the other hand, molecular dynamics simulations are used. DPD will bridge the gap between the different time- and length-scales.

## LIQUID-LIQUID EXTRACTION IN AQUEOUS BIPHASE SYSTEMS: PARTITIONING BEHAVIOR OF SILICA AND HEMATITE IN THE DEXTRAN/TRITON X-100/WATER SYSTEM

**Xi Zeng and Kwadwo Osseo-Asare**

Department of Materials Science & Engineering, Pennsylvania State University,  
University Park, PA, USA

A two-phase system may be produced when a water-soluble polymer is added to another water-soluble polymer, an inorganic salt, or a surfactant in aqueous solution. Compared to conventional solvent extraction media, aqueous biphasic systems are potentially more environmental friendly since they can be formulated with non-toxic and degradable polymers. The feasibility of employing aqueous biphasic systems for fine particle separations was investigated by using dextran/Triton X-100/water mixtures as separation media, with hematite and silica as model materials. For the entire pH range investigated (pH 2-12), hematite preferred the bottom dextran-rich phase. In contrast silica exhibited a pH-dependent partitioning behavior. It was found that the partitioning behavior of both silica and hematite could be modified significantly in the presence of ionic surfactants. The physicochemical origins of these effects are discussed.

### INTRODUCTION

A two-phase system often forms when two different water-soluble polymers are mixed in water. This kind of aqueous biphasic system has been used as an extraction medium for bioseparations after the pioneering work of Albersson in the mid-1950s. Other aqueous biphasic systems of biotechnological interest are also known, such as those composed of a polymer and a surfactant or a polymer and an inorganic salt [1-3]. Recently, the application of aqueous biphasic extraction has broadened to include processing of ultrafine particles [4-6] and separation of metal ions [7].

In our laboratory, work is in progress to apply aqueous biphasic systems as the extraction media for ultrafine particle processing [8-10]. The partitioning behavior of several inorganic particles, e.g., pyrite, hematite, silica, alumina, and titania, has been studied in polyethylene glycol (PEG)/Na<sub>2</sub>SO<sub>4</sub> systems. As in conventional liquid-liquid extraction [11], the partitioning behavior relies on the surface properties of the solids and the interfacial interactions between the particles and the surrounding liquid solution. The distribution of particles is dependent upon many factors, such as the surface hydrophilic/hydrophobic balance, solution pH, the nature and concentration of collectors (surfactants), and specific interaction between the polymer and the oxides.

Previous work in the literature has mainly focused on the partition of solids in polymer/salt aqueous biphasic systems; little work has been reported for other systems. The only available result of solid partition in polymer/polymer biphasic systems concerns the work of Baxter *et al.* [6] who studied the partition of dispersed TiO<sub>2</sub> pigment and latex particles in the PEG/poly(N-vinylpyrrolidone) (PVP) system. In the available published literature, no research has been reported yet about the partition of inorganic particles in the polymer/surfactant system, although this system has been used in bioseparation [12-14]. This paper presents the results of an investigation into the partitioning behavior of particles (hematite and silica) in polymer/surfactant systems (dextran (Dex)/Triton X-100 (TX100)). First, the partitioning behavior at different pH values is presented; then, the feasibility of applying electrostatic force to modify particle partition is exploited. In polymer/nonionic surfactant systems, electrostatic interaction can have a significant effect on the distribution of biological materials [12-14]. In these systems, a weakly charged environment develops if an ionic surfactant is added, which is concentrated in the top surfactant-rich phase. Thus, Coulombic attraction or repulsion is produced between the surfactant-rich phase and charged proteins; therefore, the partitioning of proteins is affected by this electrostatic interaction [12-14].

## EXPERIMENTAL

Dextran (average molecular weight 24,500), Triton X-100, ferric oxide (< 5 μm size), were purchased from Sigma-Aldrich Co. Dodecyltrimethylammonium bromide (DTAB), sodium dodecyl sulfate (SDS), sodium hydroxide, and nitric acid were all of reagent grade (Aldrich). Distilled water was used in all experiments. The composition of the Dex/TX100 system was 9.0 wt% polymer, 11.0 wt% surfactant, and 80.0 wt% water. In this system, the bottom phase was enriched in dextran, the other component was concentrated in the top phase [12-14]. The experimental procedures used in this study were as previously described [8-10].

## RESULTS AND DISCUSSION

### Partitioning Behavior of Silica in the Dextran/Triton X-100 System

#### *Effect of pH on the silica partition*

Figure 2 shows the partitioning behavior of silica in the Dex/TX100/H<sub>2</sub>O system. Below pH 3.5, almost all the silica particles go into the top surfactant-rich phase. When the pH increases from 4.0 to 8.0, the particles begin to concentrate at the interface, and the yields in the top phase decrease with increase in pH. Between pH 9.0 and 11.3, the solids prefer the bottom polymer-rich phase. At pH 11.5 and 11.7, the oxide particles mainly stay at the

interface. With further increase in pH from 11.8 to 12.5, the solids transfer to the top phase again. For the cases when the solids accumulated at the interface, for purposes of mass balance, the particles were combined with the silica in the bottom polymer-rich phase.

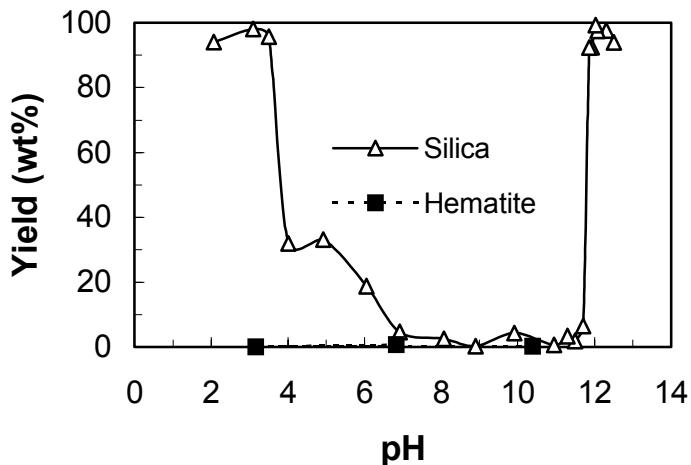

Figure 2. Effect of pH on the partitioning behavior of silica and hematite in the top phase of Dex/TX100 system. (Dex: 9 wt%, TX100, 11 wt%, solid: 2 g/L).

It is known that nonionic surfactants, such as Triton X-100, can adsorb on silica surface in aqueous solution [15-17]. The adsorption happens through the hydrogen bonding between the oxyethylene groups of TX100 molecules and the neutral silanol groups on solid surfaces [15-17]. On the other hand, dextran can also adsorb on silica, a result of hydrogen bonding between the surface silanol groups, and the glycosidic and hydroxylic acceptor sites in the repeating glucose units of the polysaccharide [18, 19]. However, this polymer only shows poor affinity to the solid surface [19].

According to the results available in the literature, in aqueous solution both dextran and Triton X-100 can adsorb on silica through hydrogen bonding [15-19]. Therefore, when silica particles are dispersed in the Dex/TX100 system, a competitive adsorption process occurs at the solid/liquid interface between the polymer and surfactant molecules. Therefore, the partition behavior of silicon dioxide is determined by the relative strength of the Dex/SiO<sub>2</sub> and TX100/SiO<sub>2</sub> interactions. At acidic pH values (< 3.5), most of silanol groups on the surface remain neutral since the pH<sub>PZC</sub> of silica is around pH 2 [20]. The interaction of TX100/SiO<sub>2</sub> may be stronger than Dex/SiO<sub>2</sub>, because dextran only shows poor affinity to the solid surface [19]. Therefore, the particles prefer to stay in the top surfactant-rich phase. With increase of pH, the surface acquires negative charges through deprotonation of silanol groups. Since the oxygen atom in the oxyethylene unit of Triton X-100 is partially negatively charged, which introduces certain level of electrostatic repulsion between the surfactant and the oxide. This repulsion force is demonstrated by the adsorption experiments in the literature which show that the uptake of TX100 by silica decreases with increase in pH [15, 16]. Thus, it follows that like increase in pH, the TX100/SiO<sub>2</sub> interaction becomes weak, even maybe less than that the Dex/SiO<sub>2</sub> interaction. The particles then begin to transfer from the surfactant-rich phase to the interface, then to the polymer-rich phase. This may explain the experimental trend in the pH range of 3.5 to 11.3.

The result at pH above 11.5 is very interesting; the particles preferred the top phase again. This behavior is difficult to explain from current literature about adsorption of dextran and TX100 on silica. From this experimental result, it can be deduced that the interaction of dextran/silica is less than that between TX100 and silica. Since the adsorption amount of TX100 on silica decrease with increase of pH [15, 16], it looks like that the adsorption of dextran on silica is suppressed by high pH environment. However, this needs to be demonstrated with other experiments at high pH, like adsorption study.

### Effects of surfactants on the silica partition

Figure 3 show the partition of silica in the dextran/Triton X-100 system in the presence of SDS and DTAB. With  $1.4 \times 10^{-3} M$  SDS, silica particles stay in the top phase at pH 2; at the interface from pH 3 to 5, and at pH 12; and in the bottom phase at pH 7 and 10. At higher SDS concentration ( $3.5 \times 10^{-3} M$ ), silica particles stay in the bottom dextran-rich phase from pH 8 to 12. However, below pH 7, this amount of SDS causes the whole system to form only one phase. From Figure e, it can be seen that with addition of  $1.3 \times 10^{-3} M$  DTAB, silica always stays in the top phase from pH 4 to 11.

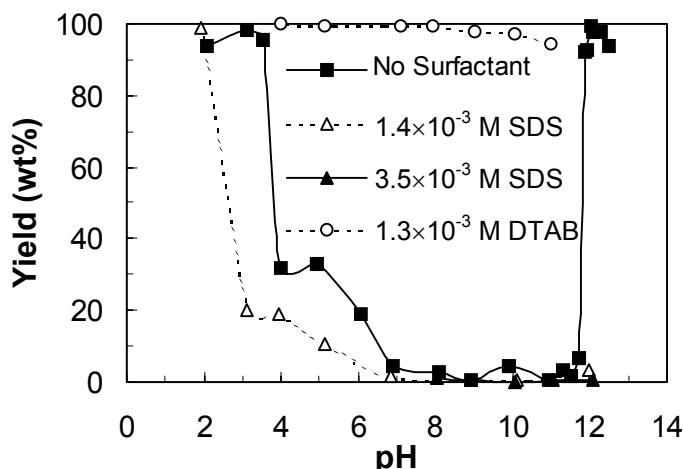

Figure 3. Effect of pH on the partitioning behavior of silica in the top phase of Dex/TX100 system in the presence of SDS and DTAB.  
(Dex: 9 wt%, TX100, 11 wt%, silica: 2 g/L; SDS & DTAB: as indicated in the figure).

In the polymer/nonionic surfactant aqueous biphasic system, ionic surfactants mainly concentrate in the top surfactant-rich phase. They form mixed micelles with the nonionic surfactant. Therefore, a weak charged environment is introduced into this kind of aqueous biphasic system [12-14]. In the Dex/TX100 system, the partition of silica in the top phase at certain pH values is due to hydrogen bonding between the oxyethylene groups of the nonionic surfactant and silanol groups on the solid surface. Addition of SDS makes the micelles in the top phase negatively charged [12-14]. Since silica is negatively charged above its pH<sub>PZC</sub> (about pH 2), it is expected that there is electrostatic repulsion between the mixed micelles and solid particles. Adsorption experiments show that TX100 adsorption on silica is suppressed from the mixed solution of TX100 and SDS [21]. Therefore, the particles are expected to move out from the top phase to the interface or bottom phase. The results show this really happens.

In this system, as with SDS, DTAB prefers the top surfactant-rich phase and forms mixed micelles with TX100 [12-14]. Thus, a weakly positively charged environment is formed in the top phase. Electrostatic attraction is then developed between the micelles in the top phase and silica surface. Therefore, silica particles are expected to prefer the top phase in the presence of DTAB. The experimental results demonstrate this expectation. From pH 4 to 11, silica particles stay in the top surfactant-rich phase with  $3.5 \times 10^{-3} M$  DTAB, irrespective of whether they are at the interface or in the bottom phase before addition of cationic surfactant.

## Partitioning Behavior of Hematite in the Dextran/Triton X-100 System

### Effects of pH on hematite partition

Figure 2 shows the partitioning behavior of hematite in the Dex/TX100 system at pH 3, 7, and 11. Under all the pH conditions, hematite stayed in the bottom polymer-rich phase. Like other metal oxides, hematite surface is covered by metal hydroxyl groups (Fe-OH), which make the surface hydrophilic. According to Albertsson's relative hydrophilic/hydrophobic scale, PEG is more hydrophobic than dextran [1]. Triton X-100 is a surfactant composed of a hydrocarbon chain and a chain of about 10 oxyethylene units which is the repeating unit of PEG, as shown in Figure 1. Therefore, it is reasonable to deduce that the solution of Triton X-100 is more hydrophobic than that of PEG. Hence, in the Dex/TX100 system, the bottom dextran-rich phase is more hydrophilic than the top surfactant-rich layer. Therefore, if one only considers the hydrophilic/hydrophobic properties, then hematite particles prefer the more hydrophilic bottom phase, not the more hydrophobic top one.

It is known that dextran interacts strongly with ferric oxide in aqueous solution and can even solubilize the oxide to form iron-dextran complexes [22, 23]. At the same time, the adsorption of nonionic surfactants on metal oxides is believed to be a physical process through hydrogen bonding and van der Waals attraction [15]. Thus, it is reasonable to conclude that dextran has stronger interaction with hematite than TX100; hence, the particles prefer to stay in the bottom dextran-rich phase. From the above discussion, it can be seen that both hydrophilic/hydrophobic properties and specific polymer-solid interaction favor the distribution of hematite into the dextran-rich phase.

### Effects of surfactants on hematite partition

Figure 4 shows the partitioning behavior of ferric oxide from pH 2 to 12 in the presence of DTAB and SDS. At all the pH values,  $3.5 \times 10^{-3}$  M SDS has no effect on the hematite partition. Addition of  $3.2 \times 10^{-3}$  M DTAB could modify the distribution of hematite particles. At high pH (pH 5, 8-11), the solids mainly stay in the top TX100-rich phase, although there are some particles at the interface. At pH 4, most of the oxide particles concentrate at the interface. In acidic solution (pH 2 and 3), the particles reside in the bottom phase, similar to the DTAB-free system. It needs to be noticed that at pH 6, 7, and 12, the system forms only one phase, not two phases. At these three pH values, no partition results are available.

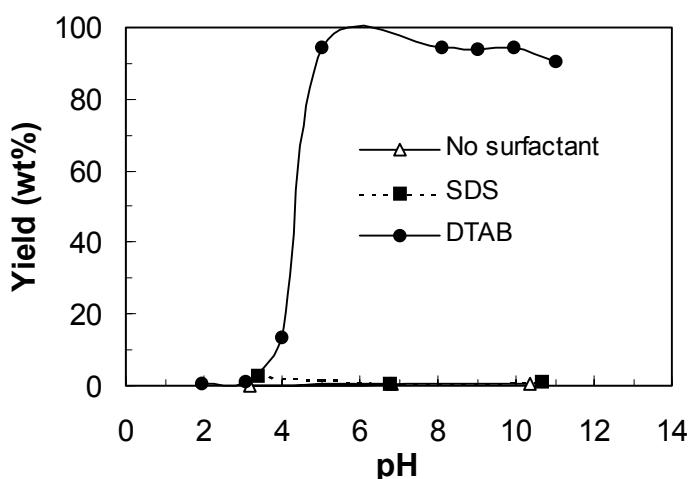

Figure 4. Effect of pH on the partitioning behavior of hematite in the top phase of Dex/TX100 system in the presence of DTAB and SDS.

(Dex: 9.0 wt%, TX100, 11.0 wt%, silica: 2.0 g/L, SDS:  $3.5 \times 10^{-3}$  M, DTAB:  $3.2 \times 10^{-3}$  M).

The pH<sub>PZC</sub> of ferric oxides is known to occur in the pH range from 5 to 8.6 [20]. Below this pH, the hematite surface is positively charged; the surface acquires negative charges above this pH. It is known that cationic surfactants can adsorb on the oxide surfaces above the pzc through electrostatic attraction [24]. Since in this system, DTAB concentrates in the top phase and forms mixed micelles with TX100 [12-14]. Therefore, at high pH values, DTAB adsorbs on hematite surface through electrostatic attraction and transfers the particles from the bottom to the top phase. In acidic solution, DTAB cannot adsorb on the surface of ferric oxide due to Coulombic repulsion, because both surfactant and solid surface are positively charged. Thus, the oxide surface is still covered with dextran layer. Hence, the oxide remains in the bottom phase. Although SDS can modify the surface chemistry of ferric oxide at certain pH values in conventional aqueous solution, it has no effect on the partitioning behavior of hematite in this system. Since dextran strongly interacts with ferric oxide in solution [22, 23], it appears that SDS is not able to replace the strongly adsorbed dextran layer on the hematite surface so that the particles continue to stay in the bottom phase.

## CONCLUSIONS

The principle behind the partition of inorganic particles in aqueous biphasic systems is the physicochemical interaction between the solid surface and the surrounding liquid solution. This study demonstrates that many factors, such as hydrophilic/hydrophobic properties, polymer-solid specific interaction, adsorption of surfactant on the solid surface, may influence the partition of metal oxides in aqueous biphasic systems. The experimental results show that in the dextran/Triton X-100 system, hematite stays in the bottom dextran-rich phase at all the pH values, while the partitioning behavior of silica is pH-dependent. Presence of ionic surfactants may modify the solid partition in this system. For silica particles, addition of SDS moves the solid from top phase to the interface or bottom phase; DTAB attracts the particles to the top phase from the interface or the bottom phase in the pH range of 4 to 11. However, only DTAB can transfer the hematite particles from bottom phase to the top phase or interface at high pH values; SDS has no effect on the partition.

## THE PARTITIONING OF SOME DYES AND THE EFFECT OF KSCN IN POLYETHYLENE GLYCOL/SALTS AQUEOUS TWO-PHASE SYSTEMS

Y. Xu, J. Lu \* and D.Q. Li \*

Department of Chemical Engineering, Hebei Institute of Technology, Tangshan, P.R. China

\*Laboratory of Rare Earth Chemistry and Physics, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun, P.R. China

The partitioning behaviors of three dyes in three oil/water biphasic systems were compared with that in three polyethylene glycol (PEG)/salt aqueous two-phase systems. It was found that the partitioning behaviors in PEG2000/salt aqueous two-phase systems are strongly correlated with that in the ethyl ether/water biphasic system. Potassium thiocyanate could alter the pH difference between the two phases, and thus affect the distribution ratios of the charged dye molecules. And the pH difference between two phases can be employed as the measurement of electrostatic driving force for the partitioning of small charged dye molecules in the PEG 2000/salt aqueous two-phase system.

### INTRODUCTION

Aqueous two-phase systems (ATPSs) have been studied extensively as gentle, non-denaturing systems for the separation of proteins, cell matter, and other biomolecules [1,2]. Although a considerable amount of research has gone into studying partitioning in ATPS, many of the phenomena concerning these complex systems are not yet completely understood. It had been observed that some salts can alter the partition coefficients of charged proteins in aqueous two-phase systems [3,4]. A combination of the proper salt and the proper pH, which affect the net charge of the protein, can steer the preferential partitioning to either phase. Previous studies of the salt effect have focused on the changes in potential difference between the two phases, and the investigations were mostly confined to the biomaterials in polymer/polymer ATPS [5,6].

Dyes have been used as affinity ligands in the partitioning of biomolecules. The dyes have either been bound directly to PEG [7,8] or simply allowed to selectively partition to one phase, thus influencing the direction of biomolecule partitioning [9,10]. Some dyes have also been used to extract metal ions from the salt-rich to PEG-rich phase [11,12]. Although there have been some studies on the nature of the dye characteristics responsible for the partitioning behavior in polymer/salt ATPS [13,14], more investigations are still needed. Most of the dyes are small charged molecules, the salt effect on their partitioning behavior in ATPS is not understood, and their electrochemical partitioning in ATPS has not been extensively investigated.

In this paper, the partitioning of Arsenazo III (AZ), Xylenol Orange (XO) and Cresol Red (CR) in three different organic solvent/water biphasic systems and three polyethylene glycol 2000 (PEG2000)/salt ATPSs was studied. The relationship between the distribution ratio in the oil/water biphasic systems ( $\text{InD}_o$ ) and that in PEG2000/salt ATPSs ( $\text{InD}$ ) was discussed. Then the effect of potassium thiocyanate on the partitioning of the dyes in the three PEG2000/salts (ammonium sulfate, dipotassium hydrogen phosphate and trisodium citrate) aqueous two-phase systems was investigated.

## EXPERIMENTAL

### Materials

PEG2000 was of reagent grade and all the chemicals were of analytical grade. The stock solutions of PEG2000 (32% w/v), ammonium sulfate (35% w/v), trisodium citrate (36% w/v), dipotassium hydrogen phosphate, (35% w/v) and potassium thiocyanate (6.0 mol/L) were prepared with distilled water. 0.01 mol/L arsenazolIII, xylenol orange water solution, and cresol red alcohol solution was used.

### Methods

For the measurements of distribution ratio for the dyes, 3 ml PEG2000 and 2 ml relevant salt stock solutions were mixed in graduated tubes, then 0.1 ml of dye solution and different amounts of potassium thiocyanate solution were added to the final volume of 5.5 ml. The systems were vortex mixed for 3 min (established by primary experiments), then disengaged by centrifugation. After determining the phase ratio, a 0.5 ml aliquot of each phase was taken for analysis. The concentrations of dyes were determined with spectrophotometry. pH values of the two phases were determined with a Model pHs-3C pH meter (Shanghai China). The  $\Delta\text{pH}$  is the pH of the top phase ( $\text{pH}_t$ ) minus that of bottom phase ( $\text{pH}_b$ ). All measurements were made in duplicate at room temperature. The method to estimate the partitioning behavior of the dyes in the three oil/water biphasic systems was same as described above.

## RESULTS AND DISCUSSION

The work from Rogers' group had indicated a preference for molecules with sulfonated aromatic rings to partition to the PEG-rich phase in PEG/salt ATPS [12,13]. For the substituted benzenes, partitioning behavior in PEG-salt ATPS was found to be strongly correlated with their partitioning in 1-octanol/water biphasic systems [15,16]. Here, the partitioning behavior of three dyes that contain the sulfonated aromatic rings in the molecules in three different oil (1-octanol, ethyl ether and hexane)/water biphasic systems was investigated (Figure 1). In the non-polar hexane system, the distribution ratios of all three dyes are low. In the 1-octanol system, the distribution ratio of CR alone reached very high, and that of AZ and XO increased slightly. We compared the distribution ratios of the dyes in the three oil/water biphasic systems with that in the three PEG2000/salt ATPSs and good linear relationships (the correlation coefficient  $R^2 = 0.9754$ ) were observed for the ethyl ether system (Figure 2 for ATPS with trisodium citrate). It is shown that the partitioning behavior of the dyes with sulfonated aromatic rings in PEG2000/salt ATPSs is strongly correlated with their partitioning in ethyl ether/water biphasic system. So, it is believed that the partition data in ethyl ether/water biphasic system can be used to estimate the partitioning behavior in the PEG/salt ATPSs for the small charged dye molecules with sulfonated aromatic rings.

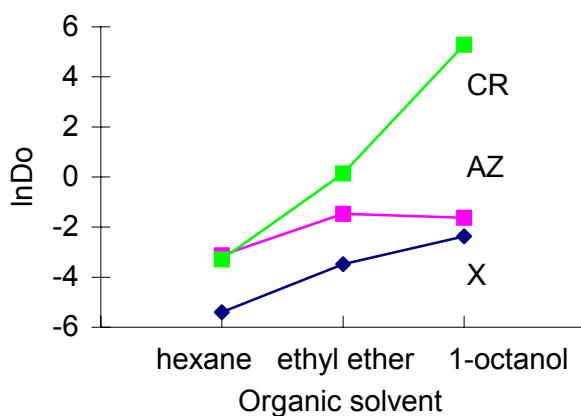

Figure 1. Distribution of dyes in oil/water biphasic systems.

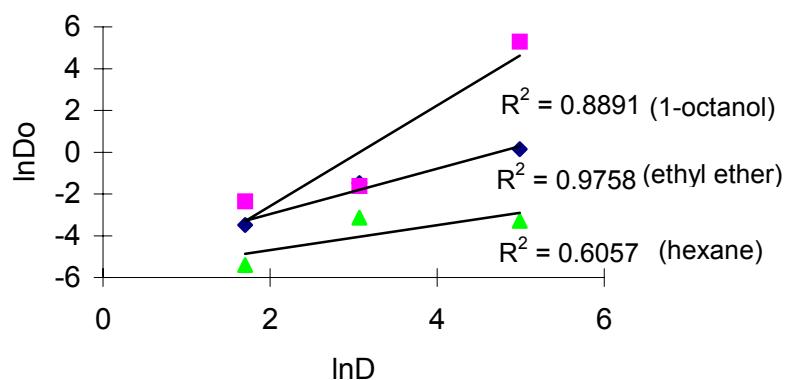

Figure 2. Relationship between the distribution ratio of dyes in oil/water systems and PEG2000 (18% w/v)/trisodium citrate (13% w/v) ATPS.

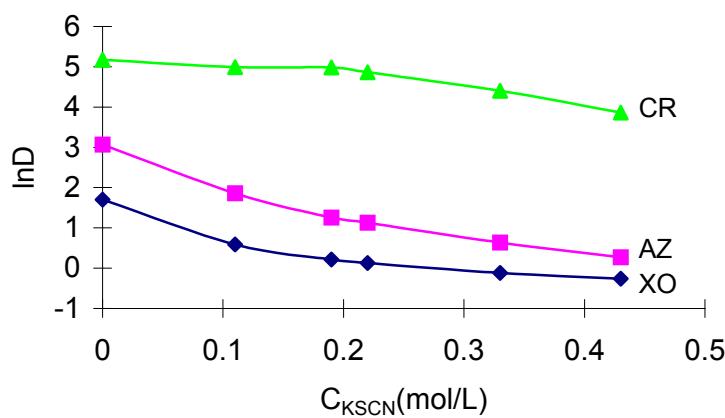

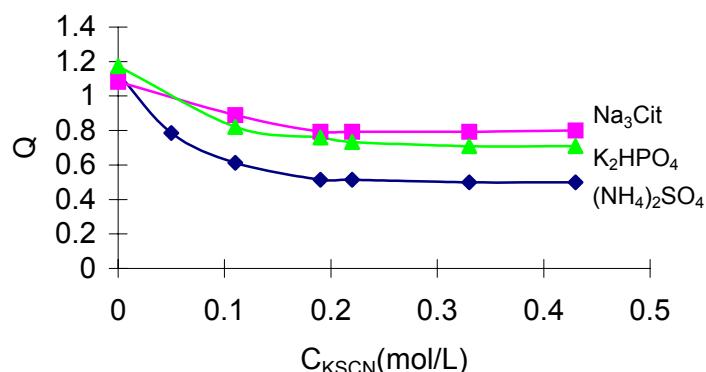

Figure 3. Effect of potassium thiocyanate on the distribution ratio of the dyes in PEG2000 (18% w/v)/trisodium citrate (13% w/v) ATPS, pH, 8.0.

In the presence of thiocyanate, the partition coefficients of positively charged proteins increase and those of negatively charged decrease in the PEG/dextran ATPS [4]. The effect of potassium thiocyanate was also observed in the PEG/ammonium sulfate ATPS for the charged proteins [17]. The effect of potassium thiocyanate on the distribution ratio of these

three small charged dyes in the three PEG2000/salt ATPSs has been examined. For these three negatively charged dye molecules, the distribution ratios decrease with the increase of potassium thiocyanate concentration in the all three PEG2000/salt ATPSs (shown in Figure 3 for ATPS with trisodium citrate), that is similar to the partitioning behavior of charged proteins in the ATPS. The more the dye molecules negatively charged, the greater the distribution ratio decreased.

In the PEG/dextran ATPS, the thiocyanates favor the PEG-rich (top) phase while the sulfates and phosphates favor the dextran-rich (bottom) phase [18]. Here, the effect of potassium thiocyanate on the phase ratio ( $Q$ ), which is defined as the ratio of the volume of PEG-rich phase to that of salt-rich phase, of the three PEG2000/salt ATPSs is studied (Figure 4). The adding of potassium thiocyanate causes the PEG-rich phase shrinking and the salt-rich phase expending. It had been pointed out that the thiocyanates have no ability to form two-phase systems in aqueous mixtures with PEG [19,20]. In the presence of phase-forming salt trisodium citrate, dipotassium hydrogen phosphate or ammonium sulfate, the thiocyanate also shows ability to salt out PEG, and so it is believed that the new polymer/mixed salts ATPSs are formed.

*Figure 4. Effect of KSCN on the phase ratio of the PEG2000 (18% w/v)/salt (13% w/v) ATPSs.*

Previous studies of salt effects on protein partitioning have focused on changes in the potential difference measured by two Ag/AgCl electrodes [5,6]. In our experiments, it is found that the addition of potassium thiocyanate can alter the pH difference between the top and bottom phase in the three PEG2000/salt ATPSs. The pH difference between two phases is believed to represent the distribution of proton in the aqueous two-phase system. The pH can be determined by glass electrode, and the electrode potential is expressed as ( $\varphi_g$ ):

$$\varphi_g = A - (2.303 RT/F)pH$$

$$\Delta pH = pH_t - pH_b$$

$$\Delta\varphi_g = \varphi_{gt} - \varphi_{gb}$$

$$\text{Then } \Delta\varphi_g = -(2.303 RT/F)\Delta pH \quad (1)$$

$A$  is a constant.  $\varphi_{gt}$  and  $\varphi_{gb}$  denote the glass electrode potential of top and bottom phases, respectively.  $\Delta\varphi_g$  can be thought to be the measurement of the driving force of proton distribution and employed to represent the electrostatic driving force for partitioning of the charged molecules.

$$\text{Suppose } \Delta\varphi = B\Delta\varphi_g \quad (2)$$

where B is a constant related to the systems. For the small charged dye molecules, the partitioning coefficient in the classical equation presented by Albertsson [1] should be substituted by the distribution ratio:

$$\ln D = \ln D_i + (z_p F/RT) \Delta\varphi \quad (3)$$

$D_i$  includes all the other factors affecting the dye partitioning,  $z_p$  denotes the average charge number of the dye molecules. Combining Eq. (3) with Eq. (2):

$$\ln D = \ln D_i - 2.303 B z_p \Delta pH \quad (4)$$

We correlated the natural logarithm of distribution ratio ( $\ln D$ ) of the dyes with the  $\Delta pH$ s in the three PEG2000/salt ATPS, the linear relationships were obtained and the parameters are listed in Table 1. The pH difference between the two phases of the PEG2000/salt ATPS can be taken as the measurement of electrostatic driving force for partitioning of the small charged dye molecules.

*Table 1. The regression parameters of  $\ln D$  to  $\Delta pH$  for the dyes in PEG2000/salt ATPS.*

## CONCLUSIONS

For small charged dye molecules that contain the sulfonated aromatic rings, their partitioning behavior in the PEG2000/salt ATPSs is strongly correlated with that in the ethyl ether/water biphasic system. The partition data in the ethyl ether/water biphasic system can be used to predict the partitioning behavior in the PEG/salt ATPSs for the small charged dye molecules. In the three PEG2000/salt ATPSs, the distribution ratios of Arsenazo III, Xylenol Orange and Cresol Red are all affected by the potassium thiocyanate. As potassium thiocyanate is added to the three PEG2000/salt ATPSs, the respective PEG2000/mixed salts ATPSs are believed to be formed. It is through its effect on the pH difference between the two phases, that the potassium thiocyanate can alter the distribution ratio of the charged dyes in the PEG2000/salt ATPSs. There is a linear relationship between the  $\ln D$  and  $\Delta pH$ , and the  $\Delta pH$  can be employed as the measurement of the electrostatic driving force for the partitioning of small charged molecules in PEG2000/salt ATPS.

## APPLICATION OF SOLVENT EXTRACTION TO PRODUCTION OF MULTICOMPONENT COMPOSITE POWDERS

Junji Shibata and Hideki Yamamoto

Department of Chemical Engineering, Kansai University, Osaka, Japan

Fundamental studies were carried out using liquid-liquid extraction to produce composite powders comprising two or three metal oxalates and to develop control of the particle size. The combination of samarium and cobalt was selected as the two-component composite powders. Stripping and crystallization occurred at the same time by contacting diluted Versatic Acid 10 loaded with the two metals and the aqueous solution containing oxalic acid. The effect of aqueous pH, oxalic acid concentration and agitation speed on the physical and the chemical properties such as crystallization percent, particle size and shape of each metal oxalate powder obtained in this process was examined. Analysis by using EDX showed that the two metal oxalates were distributed uniformly in the composite powders.

### INTRODUCTION

Composite metal and metal oxide powders of high purity are indispensable as industrial materials in the fields of electrical engineering, electronics and metallurgy. It is difficult to mechanically mix metal or metal oxide powders uniformly for the production of alloy or composite oxide powders. If insoluble metal salts are allowed to collect as crystallization products in a crystallization-stripping process, the conventional melting and crushing process can be avoided [1-4].

After mixing the organic phase containing metals at the fixed composition, fine metal oxalate powders are produced using a crystallization-stripping method [5-7]. The composite metal oxalates are converted to composite metal or metal oxide powders by roasting in H<sub>2</sub> or air. Versatic Acid 10 and D2EHPA, both acidic extractants, were chosen in the experiments, and the metal oxalate powders were produced using oxalic acid as a crystallization reagent. The mixed metal oxalates containing samarium and cobalt were precipitated from the organic phase containing these metals. The physical properties of the powders, such as particle size, shape and thermal decomposition, were measured in order to evaluate them for industrial purposes.

### SOLVENT EXTRACTION-CRYSTALLIZATION STRIPPING PROCESS

Solvent extraction usually comprises three processes, namely extraction, scrubbing and stripping. Extraction is the operation in which an objective component is separated from the aqueous phase into the organic phase using an extraction reagent; scrubbing is the operation in which undesirable components in the organic phase are removed to the aqueous phase; stripping is the operation where the objective component is returned from the organic phase to the aqueous phase again. Our process is a modification of conventional solvent extraction by adding a crystallization operation, in which the metal salts of low solubility are precipitated in the aqueous phase. The crystallization operation means the collection of stripped metal ions as insoluble salts in the aqueous phase. The reaction mechanism of this process is shown by the following equations.

The overall crystallization-stripping reaction is shown as:

where subscripts, aq, org, and s mean aqueous, organic and solid phases, respectively.

## EXPERIMENTAL METHOD

Versatic acid 10 and D2EHPA diluted in kerosene were used in the concentration range of 0.5 ~ 1.0 mol/dm<sup>3</sup>. Aqueous solutions containing Sm(III) and Co(II) were prepared at a fixed concentration as an aqueous feed. Crystallization-stripping experiments were carried out as follows. Fifty cm<sup>3</sup> of the organic phase containing metals and the same volume of oxalic acid solution were placed in a 4-necked flask and agitated with an impeller. One hundred cm<sup>3</sup> of the solvent mixture was separated in the separation funnel into organic-aqueous-solid phases. Metals in the organic phase were stripped using 2 mol/dm<sup>3</sup> HCl. Metal concentrations were determined by using an atomic absorption spectrometer (Z-6000 Hitachi Ltd.). The crystallization products were washed several times with acetone, and the composition was identified by X-ray diffraction analysis (JDX-3530 JOEL Ltd.). The size and shape of crystallization products were observed by SEM (JSM-5410 JOEL Ltd.). Thermal decomposition analysis of the crystallization products was carried out in order to confirm the temperatures at which metal oxalates were converted to oxides.

## RESULTS AND DISCUSSION

The aim of this study is to clarify the phenomena and mechanisms of the crystallization-stripping of metals from the organic phase containing Sm(III) and Co(II). Extraction curves of Sm(III) and Co(II) with Versatic Acid 10 and D2EHPA are shown in Figure 1. The figure shows that the metal ions can be extracted at different pH values with Versatic Acid 10 and D2EHPA. Sm(III) is extracted in the lowest pH range (pH 0-1) with D2EHPA, while Co(II) is extracted at pH 2-3.5 with D2EHPA. It is found that the separation of Sm(III) from Co(II) is carried out easily by the extraction with D2EHPA. On the other hand, Sm(III) and Co(II) are extracted at a higher pH with Versatic Acid 10 than they are extracted with D2EHPA. The difference in extraction behavior is based on the value of dissociation constants of the two extractants.

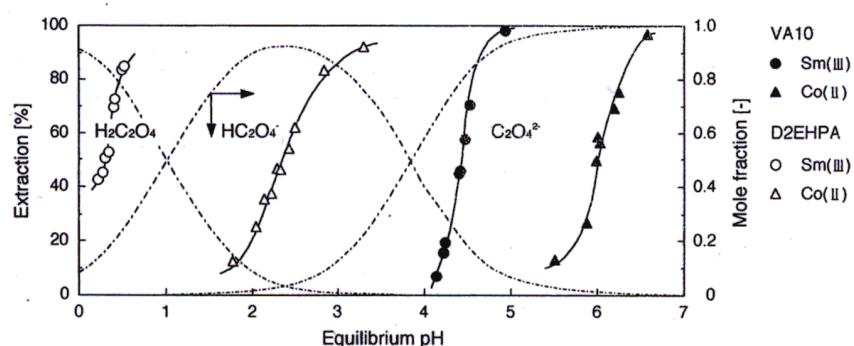

Figure 1: Mole fraction of oxalic acid in aqueous solution and extraction curves with various extractants

Figure 1 also shows a distribution diagram for oxalic acid in an aqueous solution. Oxalate ion ( $C_2O_4^{2-}$ ), which contributes to the formation of insoluble metal oxalates, exists in the condition of  $pH > 4.0$ . As the extraction is a reversible reaction, an aqueous solution of a lower pH than equilibrium pH of the extraction is required in order to strip the metals from Versatic acid 10. The extraction curves of Sm and Co with Versatic acid 10 locate in the pH region, 4-5 and 5.5-6.5, respectively, while the extractions of Sm and Co with D2EHPA take place in the pH region, 0-1 and 1.5-3, respectively. It is considered that the Versatic acid 10 is favorable for crystallization- stripping from the viewpoint of the distribution of oxalate ion ( $C_2O_4^{2-}$ ) and the position of the extraction curve.

The crystallization-stripping was carried out in a concentration of  $0.1\text{mol}/\text{dm}^3$  oxalic acid. The  $0.1\text{ mol}/\text{dm}^3$  Versatic Acid 10 containing  $0.01\text{mol}/\text{dm}^3$  Sm(III) or  $0.085\text{mol}/\text{dm}^3$  Co(II) was stripped by oxalic acid solution. Stripping and crystallization approach almost 100% within 300 s for Sm(III) and 1200s for Co(II). Figure 2 shows the relationship between pH and stripping, and pH and crystallization. The crystallization of Sm(III) takes place in aqueous solution prior to Co(II) crystallization because of the low solubility of Sm(III) oxalate. The crystallization of Sm(III) oxalate takes place in the wide pH range of 0.5 to 6, while Co(II) oxalate is quantitatively crystallized in the pH range of 2 to 6. The decrease in crystallization of Sm(III) in the higher pH is explained by the fact that the stripping does not proceed in the pH region, whereas the decrease in Co(II) crystallization in the lower pH is due to the high solubility of Co(II) oxalate in the pH region. The crystallization product was separated by filtration and washed with acetone several times. Then, undesirable components were removed from the surface of the crystallization products. The products were dried in a vacuum dryer at room temperature.

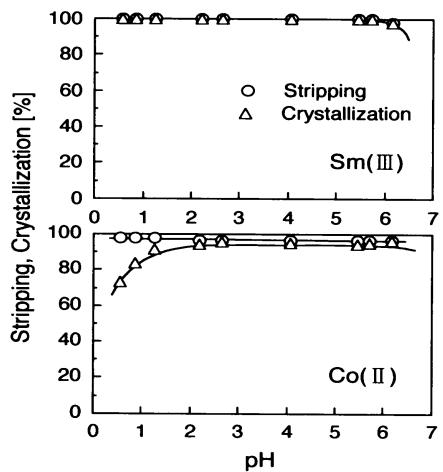

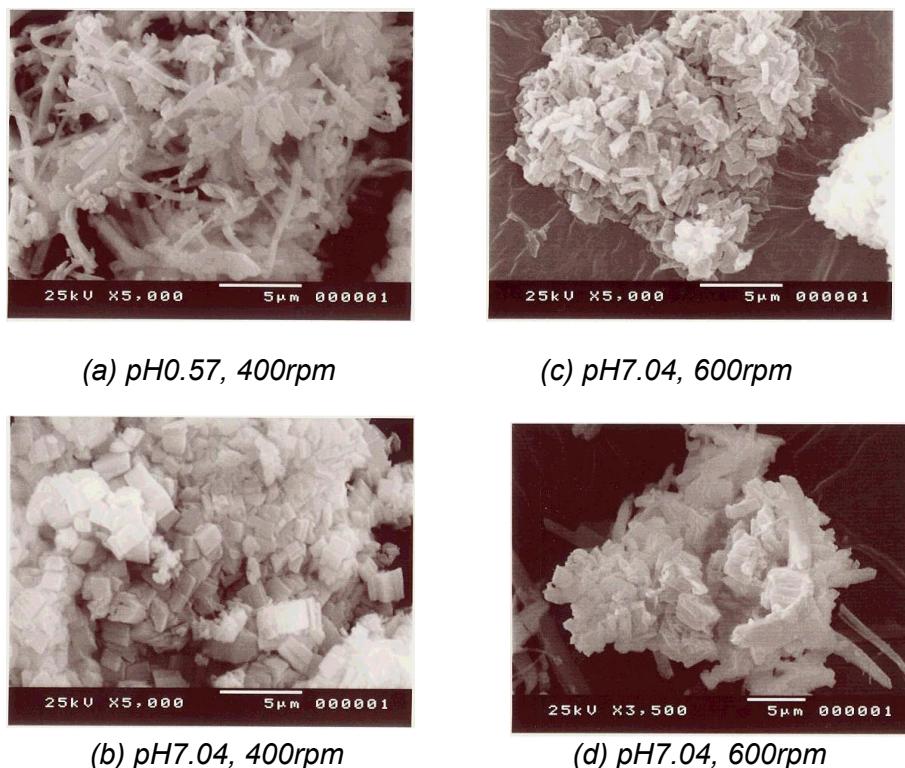

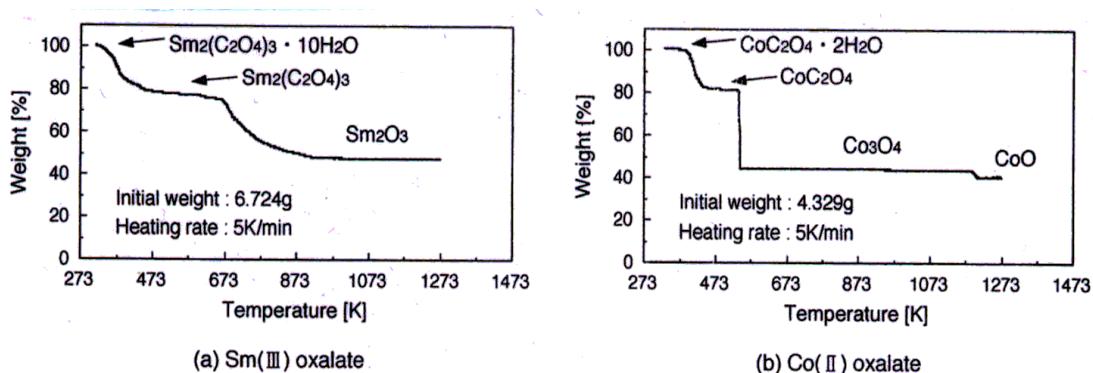

Figure 2 : Stripping, and crystallization of Sm(III) and Co(II) as a function of pH

Photos 1(a)-(d) show the complex oxalates of Sm(III) and Co(II). The size and shape of crystallization products for Sm(III) and Co(II) depend on the conditions, such as pH and mixing speed where the crystallization are carried out. The mixed organic phase was prepared by mixing each organic phase containing Sm(III) and Co(II) for the production of composite metal oxalates with the interest composition. The composition ratio of Sm(III):Co(II) =2:17 is required in the magnet industry field. Though the size and shape of the crystallization products depend on the conditions such as pH and mixing speed, Sm(III) and Co(II) oxalates in the crystallization product are both angular crystal as small as  $1\text{ }\mu\text{m}$  in the condition of pH 7 and 600 rpm. It is found from the EDX analysis that Sm(III) and Co(II) are uniformly distributed in the product crystallized in the above condition. For the condition of pH 0.6 and 400 rpm, Sm(III) and Co(II) oxalates in the crystallization products are the angular crystal of  $1\text{ }\mu\text{m}$  and the needle-like crystal of  $1\times 7\text{ }\mu\text{m}$ , respectively.

X-ray analysis showed the crystallization products to be  $\text{Sm}_2(\text{C}_2\text{O}_4)_3 \cdot 10\text{H}_2\text{O}$  and  $\text{CoC}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ . The temperature at which metal oxalates are converted to metal oxides should be lower for a practical use. The results of thermal decomposition analysis for each metal oxalate are shown in Figure 3. Sm(III) oxalate is decomposed to become the oxide in air at temperature of 913K, while the decomposition of Co(II) oxalate to the oxide takes place in air at temperature of 553K.

*Photo 1. SEM analysis of Sm(III)-Co(II) oxalate powders prepared under different conditions.*

*Figure 3: Thermogravimetric analysis of metal oxalates*

## CONCLUSIONS

The studies of a production process for metal oxide and metal powders were carried out using a solvent extraction method. Crystallization-stripping is a suitable method to produce composite powders comprising two or three metal salts. Though the size and shape of crystallization products depend on the conditions such as pH and mixing speed, Sm(III) and Co(II) oxalates in the crystallization product are both angular particle as small as 1  $\mu\text{m}$  at conditions of pH 7 and 600 rpm. Sm(III) and Co(II) are uniformly distributed in the products crystallized in the above condition.

## DETERMINATION OF PROTONATION CONSTANTS OF 2,2':6',2"-TERPYRIDINE FROM LIQUID-LIQUID DISTRIBUTION DATA

S. Andersson, C. Ekberg, J-O. Liljenzin and G. Skarnemark

Department of Nuclear Chemistry, Chalmers University of Technology, Gothenburg, Sweden

Spent nuclear fuel is a problem that has to be dealt with in the future. Transmutation of the most dangerous long-lived radionuclides into other less harmful ones can be considered a complement to direct disposal in a repository. Separation of the interesting nuclides is an important issue and liquid-liquid extraction is a suitable technique to achieve the necessary separation yields.

One group of extractants that can be used is oligopyridines and in this work basic research to determine the protonation constants of 2,2':6',2"-terpyridine has been performed. Results show that complexes with up to three hydrogen atoms, bound to the terpyridine molecule, exist. Terpyridine forms a strong complex with Cu(II)-ions, which facilitate spectrophotometric determination of the distribution of terpyridine between the two phases. This distribution, measured at different pH-values in the aqueous phase, makes it possible to determine the protonation constants.

### INTRODUCTION

Transmutation of the long-lived radionuclides in the nuclear waste into short-lived or stable nuclides can be considered a complement to disposal in a deep geological repository. The process requires a partitioning step where the material that has been converted is separated from the rest, which must be recirculated back for further neutron irradiation in the transmuter unit. The recirculated material consists mainly of actinides that have been selectively separated from the fuel fission products.

It is difficult to separate, for example, Am and Cm from trivalent lanthanides because of their similar chemical properties in aqueous solutions. The use of extractants containing soft donor ligands (e.g., N or S) facilitates the separation, probably because they form complexes with actinides that have more covalency in the bonds than lanthanides [1]. They also make it possible to get a sufficient yield of separation, both quantitatively and qualitatively. Knowledge of basic thermodynamic properties is important to be able to understand the separation process in more complex systems.

In this work a method to determine the protonation constants of 2,2':6',2"-terpyridine has been developed. The concentration of terpyridine in both phases are evaluated spectrophotometrically, facilitated by the fact that Cu(II)-ions form strong complexes with terpyridine. If the distribution of terpyridine is known at different pH-values, the protonation constants can be derived through modelling. This method to derive protonation constants, through a combination of solvent extraction and spectrophotometry, has not been used in this system before.

## THEORY

### Background

To understand the extraction behaviour of different extractants, it is important to be familiar with their basic thermodynamic properties, among them the protonation constants (often called the basicity of the reagent). The most common way to examine these parameters is to perform a potentiometric titration [2], but the method used in this work has, in comparison, some major advantages. With potentiometric titrations it is difficult to derive all three protonation constants, both from experimental difficulties, e.g., precipitation, and the fact that the solubility of terpyridine in water is very low.

### Simulations

A computer program, Spartan [3, 4], has been used to calculate the spatial positions and electrostatic charges of the different elements of the molecules, the density of the electrostatic and polarisation potential, the molecular orbitals, the dipole momentum, the heat of formation among other parameters. By addition of hydrogen atoms it is possible to predict where the first hydrogen ion will attach to the molecule through studying the heat of formation of the different possible complexes. It is also possible to see the difference in spatial constellation of the molecules, when protonation has occurred. When the stability constants have been determined, it is possible to compare them with the heat of formation of the complexes.

### Calculations

The reactions between terpyridine (Tp) and hydrogen ions can be expressed as

The number of hydrogen ions attached to the terpyridine molecule depends on the concentration of hydrogen ions in the aqueous phase. By varying this concentration it is possible to obtain the protonation constants.

The concentrations of the protonated complexes can be expressed with the protonation constants  $\beta_1$ - $\beta_3$  as

$$\{TpH^+\} = \beta_1 \{Tp\} \{H^+\} \quad (4)$$

$$\{TpH_2^{2+}\} = \beta_2 \{Tp\} \{H^+\}^2 \quad (5)$$

$$\{TpH_3^{3+}\} = \beta_3 \{Tp\} \{H^+\}^3 \quad (6)$$

At this stage the assumption that the activity coefficient of each species is constant is reasonable, since constant ion strength in the aqueous phase has been used throughout the experiments and the concentration of terpyridine always has been kept low in comparison with the total ionic strength. The activity coefficients are from this point included in the protonation constants themselves [5].

The distribution coefficient, *i.e.*, the ratio between the total concentration of terpyridine in the organic and aqueous phases can be written as (equal volumes of the two phases assumed)

$$D = \frac{\lambda}{1 + \beta_1[H^+] + \beta_2[H^+]^2 + \beta_3[H^+]^3} \quad (7)$$

where

$$\lambda = \frac{\text{Total concentration of } Tp \text{ in organic phase}}{\text{Total concentration of } Tp \text{ in aqueous phase}} \quad (8)$$

The value of  $H^+$  that should be used is the free hydrogen concentration in the aqueous phase. A total mass balance over the system concerning hydrogen makes it possible to express this concentration as

$$[H^+] = \frac{[H_{tot}]}{1 + \beta_1[Tp] + 2\beta_2[Tp][H^+] + 3\beta_3[Tp][H^+]^2} \quad (9)$$

Everything but the free terpyridine concentration in the aqueous phase is known in this expression. A balance over the system dealing with terpyridine makes it possible to calculate this concentration as

$$[Tp] = \frac{[Tptot]}{\lambda + 1 + \beta_1[H^+] + \beta_2[H^+]^2 + \beta_3[H^+]^3} \quad (10)$$

Guessing the free hydrogen ion concentration in equation (10) gives a value of the terpyridine concentration. These together are used in equation (9) to calculate a new hydrogen ion concentration. The procedure is repeated until the guessed and calculated values agree. This iterative calculation method makes it possible to get a theoretical value of the distribution of terpyridine between the two phases. By varying the values of  $\beta_1$  to  $\beta_3$  and comparing the theoretical distribution coefficient with the experimental one, it is possible to determine the protonation constants. The experimental distribution coefficient is given from the concentration of terpy in the two phases, spectrophotometrically determined. These are according to earlier assumptions, specific for 1 M ionic strength.

## EXPERIMENTAL

### Materials

2,2':6',2''-terpyridine (98% purity) as well as the organic solvent, *tert*-butylbenzene (99% purity), were obtained from Aldrich. Concentrated nitric acid (min. 65%) to produce the aqueous phases with different hydrogen ion concentrations came from Riedel-de Haën, as did the NaOH (0.1 M and 0.01 M) used for the titrations. The copper(II)-sulphate-5-hydrate (min 99%) and the sodium nitrate (>99%) used for keeping the ion strength constant in the aqueous phases was obtained from Merck. Ethanol used, both in the ordinary method (95% purity) and in the spectrophotometric measurements (min 99.5%), came from Kemetyl.

### Procedure and Apparatus

Liquid-liquid extraction experiments were performed to determine the distribution of terpyridine in a system with *tert*-butylbenzene as the organic phase and with varying hydrogen ion concentrations in the aqueous phase. 1 ml of each phase were added to a glass test tube and after 5 minutes of vigorous shaking the phases were allowed to settle. The temperature was held at 298 K to avoid temperature dependent changes in the protonation constants [6, 7]. The aqueous phases were prepared in advance and titrated with

sodium hydroxide to determine the true hydrogen ion concentrations. The hydrogen concentration was varied between 0.0001 M and 0.4 M, and the ionic strength was kept constant at 1 M with sodium nitrate. Experiments have also been performed at higher pH values. The composition of the organic phase before contact with the aqueous phase consisted of 0.01 M or 0.1 M terpyridine in *tert*-butylbenzene (the higher concentration at higher pH values).

The same method to obtain the concentration of terpyridine in both phases was used. 0.4 ml 0.08 M Cu<sup>2+</sup> solution (a mixture of 20% ethanol and 80% distilled water, which enables the same method to be used for concentration evaluation in both organic and aqueous phase) was added to a 10 ml volumetric flask. 1 ml 2 M hydrochloric acid was added to assure that the hydrogen ion concentration, in the method for concentration evaluation, was held constant. Some 95% ethanol was added and followed by 10 to 1000 µl of the sample from one of the phases in the shaking tube. Triple samples from each phase were always taken to minimise the statistical fluctuations and facilitate the spectrum evaluation. Ethanol was then added to a total volume of 10 ml and the solution was analysed in a spectrophotometer Perkin Elmer Lambda 19 UV/VIS/NIR. The wavelengths used were in the interval 320-345 nm, where *tert*-butylbenzene itself has no absorption peaks. Through shaking a test tube with only *tert*-butylbenzene and an aqueous phase of known hydrogen ion concentration it was seen that the hydrogen ion concentration in the aqueous phase did not change. All titrations were performed with an ABU91 autoburette from Radiometer Copenhagen.

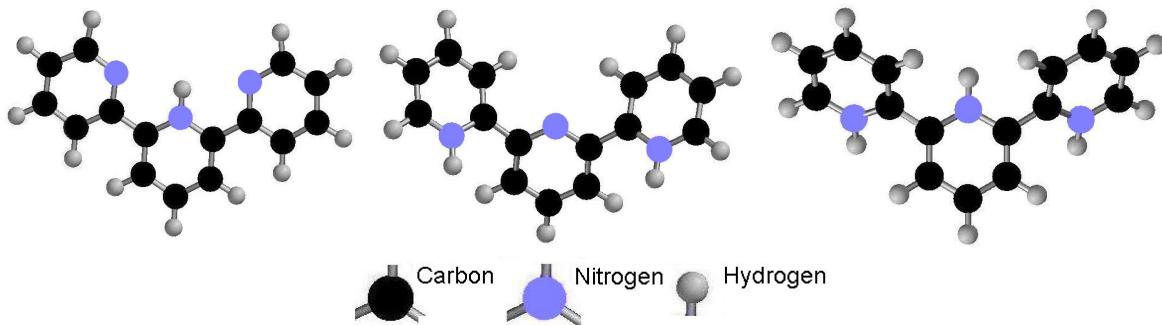

Other metal ions than copper have also been tested. Preparatory experiments to determine the, in this case, most suitable metal ion that forms a complex with terpyridine have been performed. Iron, nickel, cobalt, iron and magnesium were all tested, but copper was selected because of the shape of its spectrum with terpyridine. Some other metal ions also forms complexes with terpyridine [6, 8-11].

A calibration to determine the concentration of terpyridine in a sample has been performed. A linear relation between absorption and concentration (regardless of which phase the sample were taken from) was found to exist. In most cases the spectra of the organic and aqueous phases have been superimposed and the factor that has to be multiplied to one of the curves to fit the other gives the distribution coefficient of terpyridine. In some cases, though, the shape of the spectrum and the detection limit of the spectrophotometer prevent this method and the calibration line has to be used instead. Good agreement between both methods has been found.

## RESULT AND DISCUSSION

Spartan simulation of where the hydrogen ions will attach to the terpyridine molecule makes it possible to predict what the complexes will look like. The first hydrogen is attached to the central nitrogen atom, but is transferred to one of the outer nitrogen atoms as a second hydrogen is added. Previous work on stability constants has not proven that a third complex exists, but according to the results given in this paper the terpyridine molecule is able to add a third hydrogen, *i.e.*, all of the nitrogen may have hydrogen ions attached to themselves. Figure 1 shows the spatial constellation of the protonated complexes. The results are consistent with earlier published in this area [12], although only the energy aspect has been included in this paper.

The calculations have been performed in a semi-empirical manner and no surrounding media has been regarded. The heat of formation of the complexes can be found in Table 1.

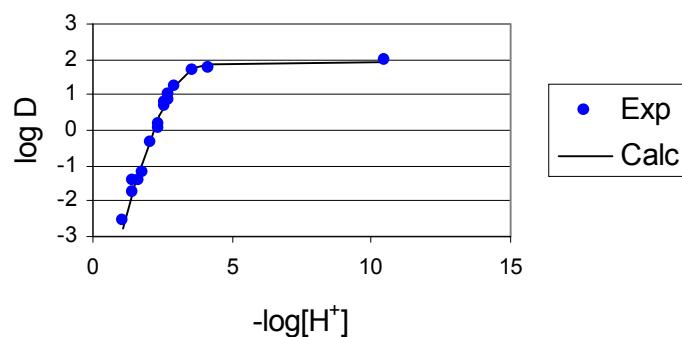

*Figure 1. Terpyridine with the hydrogen ions attached at the energetically most favourable sites.*

*Table 1. Heat of formation of protonated terpyridine.*

Tp, no H	398.1 kJ/mol
Tp, H on the central nitrogen	894.1 kJ/mol
Tp, H on the outer nitrogen	944.6 kJ/mol
Tp, 2H on the outer nitrogen atoms	1798.6 kJ/mol
Tp, 2H on the central and outer nitrogen atoms	1860 kJ/mol
Tp, 3H on all three nitrogen atoms	3068.9 kJ/mol

In Figure 2 the result of the experiments are shown. Both the experimental and calculated values of the distribution ratio are included, and good agreement between the two series can be found. It is not possible to explain the shape of the curve without taking the third protonated complex into account.

*Figure 2. Calculated and experimental distribution coefficients (298K, 1M NaNO<sub>3</sub>).*

A slope analysis in the lower pH region has been performed. In this part the existence of the three-protonated complex should dominate and taking the logarithm of equation (7) and neglecting the concentration of the first two complexes, a theoretical slope of 3 is found. The slope of the calculated curve in Figure 2 is ~2.8, which shows that a third complex really exists.

The stability constants can be found in Table 2. The statistical uncertainties in the stability constants have been estimated by the chi-square method [13] and are found in Table 2. It is difficult to compare the values of the stability constant with others earlier presented [6, 7, 14-18] because of a wide variety in temperature, ion strength and evaluation method, together with the fact that a third complex has been used to explain the shape of the extraction curve in this paper.

*Table 2. The acidity stability constants of terpyridine, 298K, 1M NaNO<sub>3</sub>.*

$\log \beta_1$	$3.21 \pm 0.2$
$\log \beta_2$	$2.84 \pm 0.2$
$\log \beta_3$	$1.81 \pm 0.5$

One conclusion that can be made from this work is that it is possible to determine the protonation constants of terpy with the above-described method. The complex of terpyridine with three hydrogen ions bound to it has been found to exist.

### ACKNOWLEDGEMENTS

The authors wish to thank the Swedish Nuclear Fuel and Waste Management Co., SKB, and the European Union (PARTNEW FIKW-CT2000-00087) for the financial support.

# SEPARATION OF PRECIOUS METALS WITH CROWN ETHERS AS THEIR ION-PAIR COMPLEXES BY MEANS OF SOLVENT EXTRACTION

T. Honjo, K. Z. Hossain and C. T. Camagong

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Japan

This article is a summary of the new data revealed by the present authors on extraction and back-extraction of precious metals (Pt, Pd, Rh, Ir, Au and Ag, etc.) as their ion-pair complexes with or without crown ethers in organic solvents, along with the papers reported previously.

## INTRODUCTION

The growing demands of precious metals attract great attention to their separation and purification, however, it is always a difficult task to achieve their mutual separation. The behaviour of precious metals (platinum, palladium, rhodium, iridium, gold and silver, etc.) traces in solvent extraction has been examined in detail with or without crown ethers in organic solvents. The effect of various factors on the extraction and back-extraction of precious metals at ppm to ppb levels has been investigated. On the basis of these results, several new analytical methods have been developed by combining with atomic absorption spectrometry (AAS) and inductively coupled plasma atomic emission spectrometry (ICP-AES).

## EXPERIMENTAL

The experimental procedures were almost the same as have been described in the previous papers [1-5]. Crown ethers and organic solvents used were 12-crown-4(12C4), 15-crown-5(15C5), 18-crown-6(18C6), dibenzo-18-crown-6(DB18C6), dicyclohexyl-18-crown-6(DC18C6) and dibenzo-24-crown-8(DB24C8) in organic solvents such as benzene, toluene, nitrobenzene, o-dichlorobenzene, cyclohexane, dichloromethane, chloroform, 1,2-dichloroethane and 1-octanol. The effect of various factors (acid concentration, pH, solvent, crown ether, potassium thiocyanate, hydrochloric acid, reagent concentration, shaking time, phase volume ratio, composition of the extracted species, separation and foreign ions, etc.) on the extraction and back-extraction of precious metals at ppm to ppb levels has been investigated in detail.

## RESULTS AND DISCUSSION

### Extraction Behaviour of Platinum(IV) in Chloroform with Crown Ether from Acidic Media [1]

A new method for the extraction of platinum(IV) from hydrochloric acid media has been established based on the formation of ion-pair complex of platinum hexachloro anion,  $\text{PtCl}_6^{2-}$ , with DC18C6 oxonium cation,  $(\text{H}_3\text{ODC18C6})_2^{2+}$ , in chloroform by means of extraction and back-extraction combined with ICP-AES.

Platinum(IV) in the presence of palladium(II) and rhodium(III) can be extracted quantitatively with 0.05 mol/L DC18C6 in chloroform at 8 mol/L hydrochloric acid within 5 min, where palladium(II) and rhodium(III) can not be extracted at all. Stripping of the extracted platinum(IV) was achieved with 0.1 mol/L hydrochloric acid within 5 min. The content of platinum in palladium chloride and rhodium chloride of guaranteed reagent grade was determined after its separation by DC18C6 extraction at 8 mol/L hydrochloric acid, and it was found to be 16.39 g/g and 8.94g/g, respectively.

#### **Separation of Trace Amounts of Palladium(II) with Crown Ether from Hydrochloric acid and Potassium Thiocyanate Media [2]**

A new method for the separation of trace amounts of palladium(II) from hydrochloric acid and potassium thiocyanate media has been established based on the formation of an ion-pair complex of palladium thiocyanate anion,  $\text{Pd}(\text{SCN})_4^{2-}$ , and the cationic potassium complex of DC18C6,  $(\text{KDC18C6})_2^{2+}$ , in chloroform.

Palladium(II) in the presence of rhodium(III) can be extracted completely with 0.05 mol/L DC18C6 in chloroform at 1 mol/L hydrochloric acid in the presence of 0.05 mol/L potassium thiocyanate within 4 min where rhodium(III) can not be extracted at all. Stripping of the extracted palladium was achieved with 0.1 mol/L ammonia buffer within 4 min.

The method can be combined with subsequent FAAS determination of palladium. The procedure was applied to determine palladium traces in chloroplatinic acid and rhodium chloride. The content of palladium traces in chloroplatinic acid and rhodium chloride of guaranteed reagent grade was found to be 31.66 g/g and 11.98 g/g, respectively.

#### **Separation of Trace Amounts of Rhodium(III) with Tri-*n*-butylphosphate from Nitric Acid and Sodium Trichloroacetate media [3]**

A new method for the quantitative extraction and separation of trace amounts of rhodium(III)from nitric acid and sodium trichloroacetate media has been established based on the formation of an ion-pair complex of hexahydrated rhodium cation,  $\text{Rh}(\text{H}_2\text{O})_6^{3+}$ , and the trichloroacetate (TCA) anion in tri-*n*-butyl phosphate (TBP). The effect of various factors (solvent, pH, sodium trichloroacetate, shaking time, phase volume ratio, composition of the extracted species, foreign ions, transformation of rhodium chlorocomplexes into hexahydrated cation, etc.) on the extraction and back-extraction of rhodium has been investigated.

The matrix of platinum(IV) and palladium(II) in rhodium(III) is previously removed by extraction with DC18C6 in chloroform, and then rhodium(III) can be extracted completely with TBP from nitric acid and sodium trichloroacetate media at pH 3 within 5 min. Stripping of the extracted rhodium was achieved with 8 mol/L perchloric acid within 20 min.

The method can be combined with subsequent FAAS determination of rhodium. The procedure was applied to determine rhodium traces in chloroplatinic acid and palladium chloride. The content of rhodium traces in chloroplatinic acid and palladium chloride of guaranteed reagent grade was found to be 24.09 g/g and 18.07 g/g, respectively.

#### **Extraction of Iridium(IV) from Hydrochloric Acid Media with Crown Ether in Chloroform and its Determination by ICP-AES [4]**

A new method for the quantitative extraction and determination of trace amounts of iridium(IV) from hydrochloric acid media has been established based on the formation of an ion-association complex of iridium hexachloro anion,  $\text{IrCl}_6^{2-}$ , with DC18C6 oxonium cation,  $(\text{H}_3\text{ODC18C6})_2^{2+}$ , in chloroform, then determination by ICP-AES.

Iridium(IV) can be extracted completely with 0.05 mol/L DC18C6 in chloroform at 8 mol/L hydrochloric acid within 5 min along with Pt(IV). Stripping of the extracted iridium(IV) was achieved with 1 mol/L hydrochloric acid within 5 min. The separation of platinum(IV) and iridium(IV) was conducted with 0.1 mol/L tri-*n*-octylamine (TOA) in benzene at 5 mol/L hydrochloric acid within 5 min, where platinum(IV) can be extracted completely, while iridium(IV) can not be extracted at all.

The procedure was used to determine traces of iridium in palladium chloride and rhodium chloride. The iridium content of palladium and rhodium chloride of guaranteed reagent grade was found to be 15.73 g/mL and 13.24 g /mL, respectively.

#### **Separation of Gold(III)with 18-Crown-6 from Hydrochloric Acid Media by means of Solvent Extraction [5]**

A new method for the separation of gold(III) at trace amounts from hydrochloric acid media was developed based on the formation of an ion-pair complex of gold tetrachloro anion,  $\text{AuCl}_4^-$ , with 18C6 oxonium cation,  $(\text{H}_3\text{O}18\text{C}6)^+$ , in 1,2-dichloroethane.

Gold(III) in the presence of silver(I) can be quantitatively extracted with 0.05 mol/L 18C6 in 1,2-dichloroethane from 4 mol/L hydrochloric acid within 5 min. A back-washing step was necessary for the complete separation of gold(III) and silver(I), otherwise, 2 to 6% of silver can be found in the gold extract. Stripping of the extracted gold(III) was achieved with 0.2 mol/L ammonia in the presence of 0.1 mol/L  $\text{Na}_2\text{S}_2\text{O}_3$  media within 5 min.

The method can be combined with subsequent FAAS determination of gold(III). The procedure was applied to determine gold(III) traces in first-class silver reagents such as silver nitrate and silver sulfate, where their content was under 0.25 ng/g (detection limit) after 20 times preconcentration.

#### **Separation of Silver(I) with dicyclohexyl-18-CROWN-6 from Hydrochloric Acid Media by means of Solvent Extraction**

A new method for the separation of silver(I) at trace amounts from hydrochloric acid media was developed based on the formation of an ion-pair complex of silver thiocyanate anion,  $\text{Ag}(\text{SCN})_4^{3-}$ , with cationic potassium complex of DC18C6,  $(\text{KDC}18\text{C}6)_3^{3+}$ , in 1,2-dichloroethane.

Silver(I) can be quantitatively extracted with 0.05 mol/L DC18C6 in 1, 2-dichloroethane from 1.0 mol/L hydrochloric acid in the presence of 0.05 mol/L potassium thiocyanate within 5 min. Stripping of the extracted silver was achieved with 3.0 mol/L potassium thiocyanate within 5 min.

## THE BINDING CONSTANTS OF METAL FULVATE AND HUMATE COMPLEXES

A.A. Helal, Gh. A. Mourad and S.M. Khalifa

Hot Labs. Center, Atomic Energy Authority, Cairo, Egypt

The solvent-extraction technique was used to measure the binding constants for Eu and Th fulvate complexes. For comparison, the binding constant for the Eu humate complex was also measured. The investigations were carried out radiometrically using  $(^{152,154})\text{Eu}$  and  $^{234}\text{Th}$ . The results indicated that in case of fulvic acid, one parameter,  $\beta_1$ , was required to fit the binding as a function of carboxylate concentration. In case of humic acid, two parameters,  $\beta_1$  and  $\beta_2$ , were required where  $\text{Eu}^{3+}$  bound forming 1:1 and 1:2 complexes. In both cases, the strength of binding increased with  $\text{pK}_a$  and degree of ionization of the ligands and with valency of the metal ions.

### INTRODUCTION

Naturally occurring fulvic acid (FA) and humic acid (HA) are known to be strong complexing agents to metal ions in the environment. As natural polyelectrolytes, humic compounds are heterogeneous mixtures possessing many types of acidic functional groups that can bind with cations in aqueous media. There are two types of metal fulvate and humate complexations: electrostatic binding due to the polyelectrolyte effect and inner sphere complexation including chelation. As pointed out by Rashid [1], FAs are low molecular weight humic compounds. They are weakly aromatized, poorly condensed compounds with a preponderance of aliphatic side chains. As compared with HAs, FAs are less polymerized. They are generally enriched in oxygen-containing functional groups. Therefore, they are soluble both in acids and bases. FAs are believed to form more readily than the corresponding HAs [2]. Once formed, FAs probably undergo condensation reactions to form more complex HAs.

An important characteristic of a metal fulvate or humate complex is its binding constant (BC), the value of which provides an index of the affinity of the cation for the ligand. Numerical values of BCs for metal fulvate and humate complexes would be of considerable value in predicting the behavior of radionuclides, trace elements, and toxic heavy metals in soils and sediments. As reviewed by Monsallier *et al.* [3], many experimental procedures have been used for the measurements of BCs such as solvent extraction (SX) [4], gel permeation chromatography [5], UV spectroscopy [6], ion exchange [7], laser-induced photoacoustic spectroscopy [8], time-resolved laser fluorescence spectroscopy [9], ultrafiltration [8,10] and dialysis [7,11]. Depending on the method, the results vary considerably.

According to Takamatsu and Yoshida [12], there are two difficulties in determining the BCs of metal fulvate and humate complexes, one related to determining concentrations of humic compound as complexant, and the other related to procedures for measuring the actual BCs. The average molecular weight, the maximum complexing ability and the number of titratable functional groups have been used to represent the concentration of humic compound as complexant. Because of variations in the physico-chemical characteristics of the humic compounds and the different methods used to measure the BC, the reported constants have no consistency [1]. SX is a suitable method for radionuclide investigation since it allows measurements at tracer level concentrations. Although extensive use has been made of the SX (and other methods) for determining BCs of metal humate complexes, little application has been made in studies of metal complexes of FAs. In particular, data on lanthanides and actinides are limited. In this work, the BCs of  $^{(152,154)}\text{Eu}$  and  $^{234}\text{Th}$  with FA, and the BC of  $^{(152,154)}\text{Eu}$  with peat HA were determined using the SX technique.

## EXPERIMENTAL

### Chemicals and Materials

The chemicals used were of analytical purity. Di(2-ethylhexyl)phosphoric acid, HDEHP, was obtained from Union Carbide, and purified according to Peppard *et al.* [13]. FA was isolated from the agricultural soil of Orman garden, an old garden located at the West Bank of Nile river in Cairo, Egypt. The HA is isolated from a sample of peat. The method of separation and purification of FA and HA is the conventional method [14].

### Tracers

The radiotracer  $^{(152,154)}\text{Eu}$  was prepared locally by neutron activation of  $\text{Eu}_2\text{O}_3$  in the Egyptian reactor (ARE-RR-1).  $^{234}\text{Th}$  was separated from natural uranium by SX using 30% TBP diluted in benzene [15]. The radiochemical purity of  $^{234}\text{Th}$  and  $^{(152,154)}\text{Eu}$  was checked by measuring the respective  $\gamma$ -spectrum with Ge(Li) detector using a multichannel analyzer. The  $\gamma$ -emissions of both tracers was counted with a NaI(Tl) well counter of ORTEC type.

### Procedures

The FA and HA samples were characterized by elemental analysis, potentiometric titration, and visible spectroscopy. The acid-base behavior of FA and HA was determined at an ionic strength ( $\mu$ ) of 0.1 M by direct titration [16]. The absorption in the visible region was measured using a Shimadzu recording spectrometer 160A.

For the SX experiments, the organic phases consisted of toluene containing HDEHP. Because of the precipitation problems encountered when contacting HA solutions with organic phase [15], the latter was pre-equilibrated several times against equal volumes of the corresponding buffer solutions before use. This pre-equilibration was continued until no pH change was observed in the fresh aqueous phase. The aqueous phases were prepared by using the suitable buffer solutions for the desired pH values. These buffer solutions also contained the necessary quantity of  $\text{NaClO}_4$  to make the total ( $\mu$ ) 0.1 M.

Primary distribution experiments were performed to evaluate the time needed for equilibration for each of the ligands. For both  $\text{Eu}^{3+}$  and  $\text{Th}^{4+}$ , the obtained results showed that the equilibrium is reached within 2.5 h in case of FA and 1.5 h in case of HA. A working solution of FA or HA was prepared by dissolving ca. 0.1 g in 10 ml of 0.1 M NaOH with overnight stirring under nitrogen gas. The solution was titrated to the desired pH with 0.1 M  $\text{HClO}_4$ , and diluted to 100 ml with the suitable buffer solution [4] of the same pH. Aliquots of this working solution were diluted with the buffer to obtain solutions of varying HA concentrations. The free humate concentration (in eq/l) was determined by multiplying the concentration (g/l) by the total capacity (eq/g) and by the degree of ionization corresponding to the pH of the investigation.

Five ml of each phase and 10  $\mu$ l of tracer were added to 20 ml glass scintillation vials (coated with silicon compounds [17] to minimize the adsorption of activity by the wall of the vial). Five ml of the buffer solution, without FA or HA, was used as a blank for each experiment. The vials were vigorously shook in a thermostated shaker at room temperature ( $25 \pm 1^\circ\text{C}$ ) for the suitable time, then they were centrifuged and the phases separated and centrifuged before removing aliquots for counting. The remainder of the aqueous phases was used to measure the final pH and the final HA concentrations in the HA experiments.

## RESULTS AND DISCUSSION

The elemental analysis of FA and HA samples indicated that the ratios of C, O, H, N and S are 51.0, 38.2, 4.4, 2.8 and 3.6% for FA and 48.5, 41.7, 5.4, 1.2 and 3.2% for HA. The higher atomic ratios O/C and H/C of HA than FA may reflect higher amounts of COOH and show that aliphatic C may be more abundant in FA.

Figures 1 and 2 give the potentiometric titration curves and the first derivatives of FA and HA samples. The curves have double inflections and, in general, they are similar to those obtained for weak acids. The first derivatives indicate that each sample has two maxima, which implies two kinds of ionizing functional groups. This phenomenon has been explained [4] by the presence of two carboxylate groups; the stronger acid group is located ortho to phenolic groups on aromatic rings, while all the other carboxylates fall in the second, weaker group. The first maxima occurs at 2.5 and 4.0 meq/g for FA and HA, respectively. The total carboxylate capacities are calculated from the second maxima and found to be 4.0 and 6.0 meq/g for FA and HA, respectively. The first maxima occur at pH 5.89 and 6.83, while the second maxima occur at pHs 8.37 and 9.16 for FA and HA, respectively.

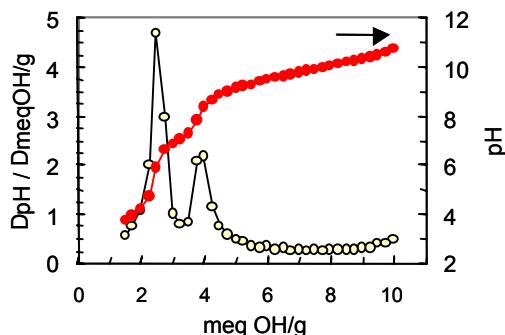

Figure 1. The titration and derivative curves of FA.

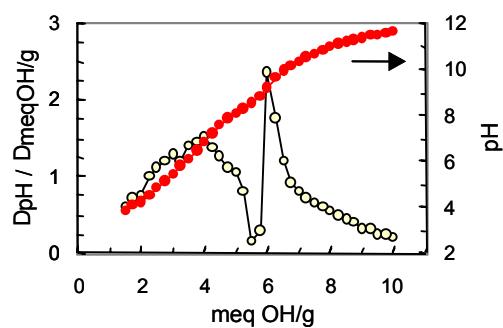

Figure 2. The titration and derivative curves of HA.

The dissociation of an acidic functional group (HA) from the humic or fulvic molecule proceeds as:

For which the ionization constant ( $K$ ) is:

$$K = [\text{A}^-][\text{H}^+]/[\text{HA}] \quad (2)$$

The titration data provide estimates for ( $\text{A}^-$ ) and ( $\text{HA}$ ) at any given pH, from which the ionization constant can be determined. Since  $K$  is normally of a very small value, the negative logarithm ( $pK$ ) is often recorded:

$$pK = -\log [\text{A}^-][\text{H}^+]/[\text{HA}] \quad (3)$$

$$= \text{pH} - \log [\text{A}^-]/[\text{HA}] \quad (4)$$

At half-neutralization,  $pK = pH$  and this is commonly referred to as  $pK_a$  of the acidic group. A variety of equilibrium functions have been developed to characterize the acid-base behavior of polyelectrolytes; the most common one is the Henderson-Hasselbalch equation [18] which was applied to evaluate the  $pK_a$  of FA and HA samples:

$$pH = pK_a + n \log [\alpha / (1-\alpha)] \quad (5)$$

where  $pK_a$  and  $n$  are constants depend on concentration as well as ionic strength, and  $\alpha$  is the degree of ionization. The  $pK_a$  values at 50% ionization ( $\alpha = 0.5$ ) was found to be 3.86 and 5.4 for FA and HA, respectively (at  $\mu = 0.1 M$  in sodium perchlorate medium).

The ratio of absorbances of dilute aqueous sample solutions at 465 and 665 nm, defined as  $E_4/E_6$  ratio, is widely used for characterization purposes. This ratio is independent of the concentration of the humic compound, but varies for different humic substances. As pointed out by Chen *et al.* [19], the magnitude of  $E_4/E_6$  ratio is inversely proportional to the degree of condensation or the molecular weight, i.e., the high  $E_4/E_6$  ratio indicates a smaller molecule which contains less carbon, but more oxygen and -COOH groups. The  $E_4/E_6$  ratios are found 4.14 and 5.93 for FA and HA, respectively. Comparing the deduced results of  $E_4/E_6$  ratio with that of elemental composition and potentiometric titration indicate that they are in good agreement with each other.

### Determination of the Binding Constants

The following equation is used to measure the binding constants for FA and HA [15]:

$$(D_o/[L])(1/D_2 - 1/D_1) = \beta_1 + \beta_2[L]$$

where  $D_o$  is the distribution ratio of the investigated cation,  $D_1$  and  $D_2$  are the distribution in presence of the buffer anion and the ligand (FA or HA), respectively, L is the ligand (FA or HA) and  $\beta_1$  and  $\beta_2$  are the binding constants. Therefore, a plot of  $(D_o/[FA \text{ or } HA])(1/D_2 - 1/D_1)$  vs.  $[FA \text{ or } HA]$  gives a straight line of intercept  $\beta_1$  and a slope of zero (or negative) if only a 1:1 complex is formed, or a straight line of intercept  $\beta_1$  and a slope of  $\beta_2$  if a 1:2 complex is formed.

### Binding of Eu<sup>3+</sup> and Th<sup>4+</sup> with FA

The plots of  $(D_o/[FA])(1/D_2 - 1/D_1)$  vs.  $[FA]$  showed linear curves with negative slopes in case of both Eu<sup>3+</sup> and Th<sup>4+</sup> (Figure 3 is an example). Thus, the binding function required analysis with one constant  $\beta_1$ , which implies the formation of 1:1 complex only. This result agrees with the potentiometric titration of FA, where the first maximum, occurring at pH 5.89, is stronger than the second one indicating that the sample has mainly one kind of ionizing functional groups.

The obtained binding constants for Eu<sup>3+</sup> and Th<sup>4+</sup> are plotted against the degree of ionization ( $\alpha$ ) of the fulvate polyelectrolyte, Figure 4. The strength of binding of both Eu<sup>3+</sup> and Th<sup>4+</sup> to FA increases with the degree of ionization, which is a function of pH. FA acts as weak-acid polyelectrolytes in which ionization of COOH groups is controlled by pH. Increasing pH of the solution results in additional ionization of the acidic functional groups of FA, and causes the increase in the binding constant.

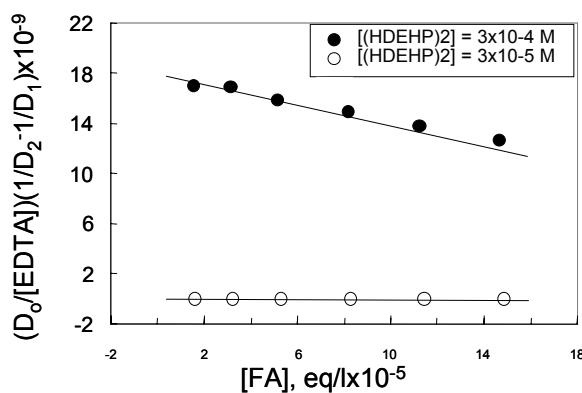

Fig. (3): Effect of [FA] on the extraction of Eu by HDEHP

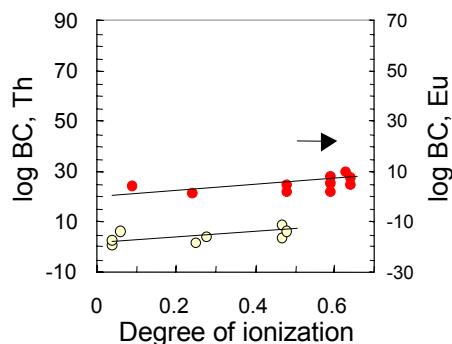

Fig. (4): Variation of log BC for Eu(III) and Th(IV) with the degree of ionization of FA

From the straight lines in Figure 4, the following equations could be derived for the value of the binding constant as a function of the degree of ionization of FA:

$$\text{For Eu}^{3+}: \text{Log } \beta_1 = 1.07 + 7.807 \alpha$$

$$\text{For Th}^{4+}: \text{Log } \beta_1 = 2.23 + 7.28 \alpha$$

Thus, the values of the binding constant at 50% ionization ( $\alpha = 0.5$ ) are 4.974 and 5.87 for  $\text{Eu}^{3+}$  and  $\text{Th}^{4+}$ , respectively. As expected, the binding constant of  $\text{Th}^{4+}$  is higher than that of  $\text{Eu}^{3+}$  since tetravalent cations are bound in greater amounts than trivalent ones, for any given pH and ( $\mu$ ). These values are in good agreement with those reported. By comparing the values of  $\text{log } \beta_1$  and  $\text{pK}_a$  of fulvic acid obtained in this work and in previous works, it is noted that the binding constants of  $\text{Eu}^{3+}$  and  $\text{Th}^{4+}$  increase with increasing  $\text{pK}_a$ .

### Binding of $\text{Eu}^{3+}$ and $\text{Th}^{4+}$ with EDTA

For confirmation, both  $\text{Eu}^{3+}$  and  $\text{Th}^{4+}$  were extracted by HDEHP from an aqueous phase containing EDTA, as a ligand form 1:1 complex, at the same conditions. The plots of the factor  $\{\text{D}_o/[\text{EDTA}]\}\{(1/\text{D}_2-1/\text{D}_1)\}$  against [EDTA] is illustrated in Figure 5. As the figure shows, the curves are linear with negative slopes, the same behavior like fulvic acid. This result confirms the formation of 1:1 complex for the binding of both  $\text{Eu}^{3+}$  and  $\text{Th}^{4+}$  with fulvic acid.

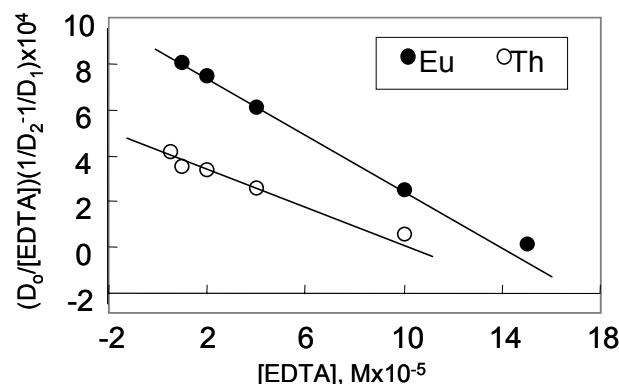

Fig. (5): Effect of [EDTA] on the extraction of Eu and Th by HDEHP

### Binding of Eu<sup>3+</sup> with HA

The BCs for Eu<sup>3+</sup> with HA are elucidated at the same conditions for comparison with FA. The maximum binding capacity of humic materials for any given metal ion is approximately equal to the content of acidic functional groups, primarily COOH. The first derivative of the potentiometric titration curve of HA, Figure 2, indicates the presence of two kinds of functional groups. The second maximum occurs at pH 9.16, which is a suitable value for the ionization of phenolic groups.

The plots of  $\{D_0/[HA]\}\{(1/D_2 - 1/D_1)\}$  versus [HA], (Figure 6 is an example), were linear with positive slopes. In these curves, the intercepts represent the values of  $\beta_1$  and the slopes represent the values of  $\beta_2$ . This result implies the formation of 1:1 and 1:2 complexes. The variation of the BC's of Eu<sup>3+</sup> with the degree of ionization of HA is illustrated in Figure 7. As previously indicated in case of FA, the BC increases with increasing the degree of ionization, which is a function of pH of the solution. From Figure 7, the following equations are derived as a relation between the BC's and the degrees of ionization:

$$\log \beta_1 = 3.402 + 13.045 \alpha$$

$$\log \beta_2 = 7.696 + 12.225 \alpha$$

Thus, the values of the BC's (at  $\alpha = 0.5$ ) are:  $\log \beta_1 = 9.925$  and  $\log \beta_2 = 13.809$ . The same behavior is observed where the BC of HA (which has higher  $pK_a$ ) is higher than that of FA (of lower  $pK_a$ ).

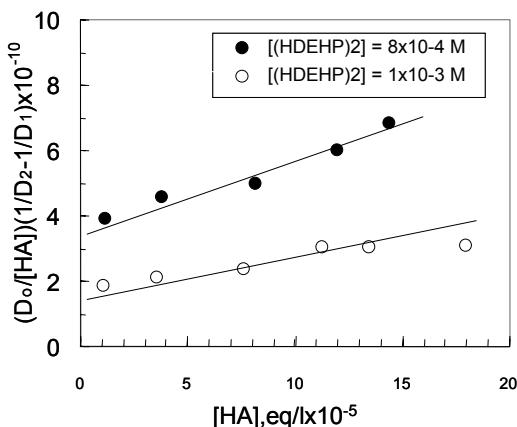

Fig. (6): Effect of [HA] on the extraction of Eu by HDEHP

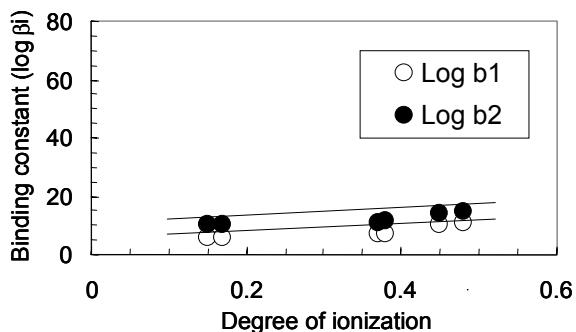

Fig. (7): Variation of log BC for Eu<sup>3+</sup> with the degree of ionization of HA

### CONCLUSIONS

In light of the preceding results, the following conclusions could be obtained:

1. Solvent extraction was found a suitable technique for measuring the binding constants of radionuclides used in tracer level.
2. FA and HA act as weak acid polyelectrolytes in which ionization of COOH groups is controlled by pH, thereby affecting their ability to bind metal ions.
3. Both Eu<sup>3+</sup> and Th<sup>4+</sup> bound to the carboxylate site in FA forming 1:1 complex only, while Eu<sup>3+</sup> bound to HA forming 1:1 and 1:2 complexes.
4. The binding constants were found to increase with  $pK_a$  of the ligand and valency of the metal ion.

## ION-PAIR EXTRACTION AND ONE-DROP FLAME ATOMIC ABSORPTIOMETRIC DETERMINATION OF SILVER WITH BENZO-MONOTHIACROWN AND BROMOTHYMPOL BLUE

Wakayama University, Wakayama, Japan

Ion-pair extraction of silver ion into chloroform has been studied with benzo-monothia-15-crown-5 (5,6-benzo-1,4,7,10-tetraoxa-13-thiacyclopentadeca-5-ene, B-15TC) in the presence of a counter anion. B-15TC was synthesized from catechol via 1,2-bis(2'-hydroxyethoxy)-benzene and 1,2-bis(p-toluenesulfonyl-oxyethoxy)-benzene in three steps. Counter anions studied were perchlorate and picrate ions, bromothymol blue (BTB), bromocresol green (BCG), ethyl orange (EO), cobalt(III)-dihydroxyazobenzene complex (Co-DHAB). The order of percent extraction was BTB > Co-DHAB > BCG > picrate ion > EO > perchlorate ion at pH less than 4 and BTB > Co-DHAB > BCG > EO > picrate ion > perchlorate ion at pH larger than 4. Silver ion was quantitatively extracted into chloroform at pH of 4.5-5.2 in the presence of BTB. The compositions of the extracted species are  $\text{Ag}^+ : \text{B-15TC} : \text{BTB}^- = 1:1:1$  and 1:2:1. With the combined use of the extraction concentration and one-drop flame atomic absorption spectrometry using 50 $\mu\text{l}$  volume of the chloroform extract, silver in a standard botanical sample of National Institute of Environmental Studies, NIES-CRM No. 9 Sargasso, was determined.

### INTRODUCTION

Thiacrown ethers obtained by replacing oxygen atoms in crown ethers with sulfur atoms have a great affinity for softer metal ions such as silver, copper(I) and mercury and extract these metal ions as ion-pair complexes in the presence of a bulky and univalent organic or inorganic anion [1-4]. In addition, 1,2-bis(alkylthia)ethanes were also used as a good extractant for these metal ions in the presence of a counter anion [3,5]. Of these reagents, a commercially available 3, 6-dithiaoctane (8-2S) was well applied to the selective extraction of silver and copper(I) in some standard reference materials and to the determination of silver [6-8] and copper [9] by one-drop flame atomic absorption spectrometry with a direct nebulization of 50  $\mu\text{l}$  volume of the chloroform extract. On the other hand, owing to the unpleasant odor specific to the sulfur compound, the use of 8-2S is disliked for chemist.

The present paper describes the selective extraction of silver ion with a non-odor 5,6-benzo-1,4,7,10-tetraoxa-13-thiacyclopentadeca-5-ene (B-15TC) in the presence of BTB and the determination of silver in a certified reference material (NIES-CRM No. 9, Sargasso) by one-drop flame AAS with the direct nebulization of 50  $\mu\text{l}$  of the chloroform extract without the deuterium background correction.

## EXPERIMENTAL

### Preparation of B-15TC

B-15TC was synthesized in a similar way described previously [10,11] in three steps, as is shown in Figure 1. Only the final synthetic step, *i.e.*, cyclization reaction, is described here. Bis(2-hydroxyethyl)sulfide (1.10 g, 0.01 mol) was dissolved in 400 ml of dry dioxane. To this solution, NaH (69% in oil, 600 mg, 0.025 mol) was added and then the resulted solution was refluxed. To this refluxing solution, 1,2-bis(p-toluenesulfonyloxyethoxy)benzene (5.1 g, 0.01 mol) dissolved in 50 ml of dry dioxane was dropwise added for 8 h and the mixture was refluxed for 2 d under a nitrogen atmosphere. The solvent was evaporated off under a reduced pressure. After the residue was dissolved in water (50 ml), the extraction with chloroform (25 ml) was done five times. The chloroform extract was dried over MgSO<sub>4</sub>. A crude white crystal obtained after the evaporation of solvent was dissolved in benzene and was recrystallized. The yield was 22%. M.p.131-132°C; <sup>1</sup>H-NMR(CDCl<sub>3</sub>) δ=6.88(s, 4H), 3.78-4.12(m, 12H), 2.82(t, J=6.8 Hz, 4H).

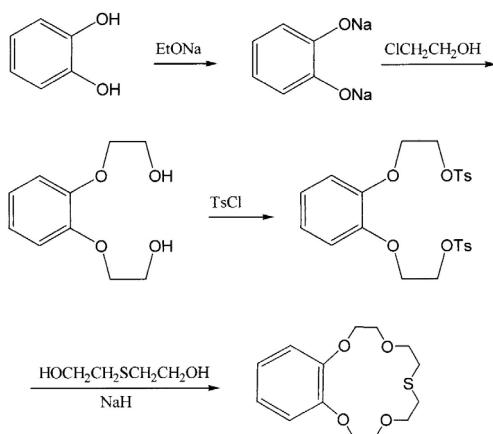

Figure 1. Synthetic route of B-15TC.

### Apparatus

An atomic absorption spectrometer equipped with 100 mm burner head (Seiko Model SAS-727, Chiba, Japan) was used with a discrete nebulization technique using a fuel-lean air-acetylene flame at 328.1 nm under the same operating conditions previously reported [8]. The signal intensity was recorded on a strip-chart recorder (National, VP-6612a, Osaka, Japan). Sample was decomposed in a closed double PTFE digestion bomb with a polypropylene jacket (San-ai Kagaku, Nagoya, Japan) by microwave-assisted heating (Hitachi MRH-4 microwave oven for kitchen use). The pH of the solutions was measured with a Radiometer (Copenhagen, Denmark) Type PHM-22 pH meter with a combined electrode.

### Reagents

A silver standard solution (2 mg/g in 0.5 M HNO<sub>3</sub>) was prepared by dissolving a silver metal of 99.99% purity (Nacalai Tesque, Kyoto) in HNO<sub>3</sub> directly in a PTFE bottle of 120 ml capacity, followed by diluting by mass with water. Working aqueous silver solutions were prepared by diluting the stock solution to the appropriate concentrations by mass with 0.05 M H<sub>2</sub>SO<sub>4</sub>. B-15TC was directly dissolved in chloroform (0.01 M). Chloroform of analytical-reagent grade (Wako Pure Chemicals, Osaka, Japan) was used without further purification. Anion solutions of bromocresol green (BCG, 10<sup>-3</sup> M), bromothymol blue (BTB, 3 × 10<sup>-3</sup> M), picric acid (Pic, 10<sup>-2</sup> M) and ethyl orange (EO, 10<sup>-2</sup> M) from Wako were prepared by dissolving in water or in an alkaline solution. The solution of cobalt-dihydroxyazobenzene complex (Co-DHAB, 3.3 × 10<sup>-3</sup> M) was prepared, as was described in [8]. To control the extraction pH, an ammonium acetate of analytical-reagent grade (2.0 M) was used. The acids used for sample

digestion and dilution were of analytical-reagent grade (Wako). Water purified by a Milli-Q system (Millipore, USA) was used throughout.

### Sample Decomposition

A dry sample of 300 mg was decomposed with an acid mixture by microwave-assisted heating, as was done in a previous study [8]. After the complete evaporation of the digest to dryness, the dry residue was dissolved in 3 ml of a 0.05 M H<sub>2</sub>SO<sub>4</sub> solution in the same vial and the total mass was weighed.

### Extraction Procedure

Into a 10 ml stoppered glass test-tube, 1 ml of the sample solution (weighed), 0.5 ml of the anion solution, 1 ml of an ammonium acetate solution, 2.5 ml of water and 0.3 ml (weighed) of the chloroform solution of B-15TC were placed. Silver ion was extracted by shaking for 15 min by a Ayela cute mixer (CM-1000, Tokyo Kikai, Tokyo). For a complete phase separation, the centrifugation at 3000 rpm was used. A 50 µl of chloroform extract was used for a FAAS measurement, as was described in a previous paper [8].

## RESULTS AND DISCUSSION

### Equilibrium Treatment

Suppose that the extracted species of silver ion with B-15TC (L) in the presence of BTB (X<sup>-</sup>) is the same as that obtained in the extraction with 1,2-bis(alkylthio)-ethane [3,5,12] or thiacrown ether [13,14] in the presence of perchlorate or picrate ion, i.e., two monomeric 1:1:1 and 1:2:1 complexes for Ag<sup>+</sup>:B-15TC:X<sup>-</sup>, then the extraction equilibria can be written as:

where the overall extraction constant, K<sub>ex</sub>, and the formation constant, K<sub>1</sub>, are given by

$$\text{K}_{\text{ex}} = [\text{AgLX}]_{\text{org}} / [\text{Ag}^+] [\text{L}]_{\text{org}} [\text{X}] \quad (3)$$

$$\text{K}_1 = [\text{AgL}_2\text{X}]_{\text{org}} / [\text{AgLX}]_{\text{org}} [\text{L}]_{\text{org}} \quad (4)$$

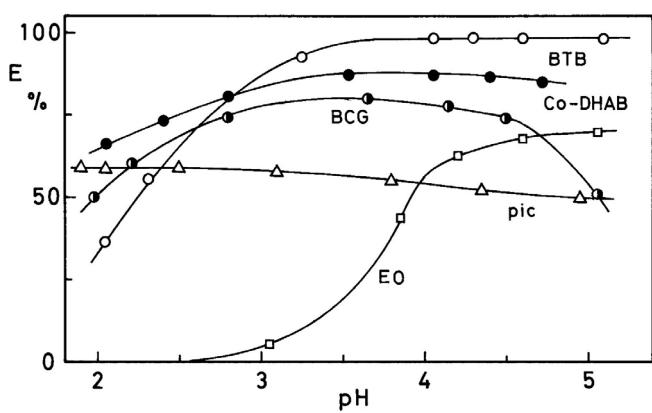

The subscript, <sub>org</sub>, refers to the organic phase. The distribution ratio of silver, D, is given by

$$\begin{aligned} \text{D} &= \text{E V}_{\text{aq}} / \{(100 - \text{E})\text{V}_{\text{org}}\} \\ &= \text{K}_{\text{ex}} [\text{L}]_{\text{org}} [\text{X}] \{1 + \text{K}_1 [\text{L}]_{\text{org}}\} \end{aligned} \quad (5)$$

where V<sub>org</sub> and V<sub>aq</sub> refer to the organic and aqueous volumes used for extraction equilibrium study, respectively, and E refers to the percent extraction of silver ion into chloroform. Then the plot of log D against log [X] at a constant concentration of B-15TC in chloroform should yield a straight line with a slope of unity and the plot of log D against log [L]<sub>org</sub> should yield a curve varying from slope of 1 to 2.

### Extraction Behavior

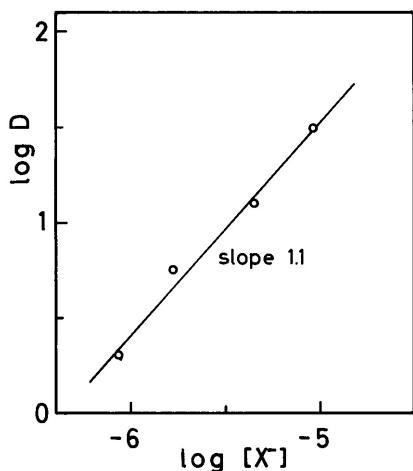

The extraction behavior of silver ion from the aqueous solution of a constant anion concentration was examined in a pH range less than 5.5. The results obtained with different anions are shown in Figure 2. The order of percent extraction of silver ion was BTB > Co-DHAB > BCG > picrate ion > EO > perchlorate ion at pH less than 4 and BTB > Co-DHAB > BCG > EO > picrate ion > perchlorate ion at pH larger than 4. Only BTB gave a quantitative extraction of silver ion at pH range larger than 4.5. Taking into account of these results, the effect of BTB concentration was tested. The quantitative extraction of silver ion (>99%) was observed at the BTB concentration larger than 3 × 10<sup>-4</sup> M. In addition, the effects of perchlorate and sulfate ion concentrations were also tested. Even with perchlorate ion, the percent extraction was low (5% at 0.1 M and 17% at 1.0 M), while silver ion was not extracted with hydrogensulfate ion.

*Figure 2. Extraction of silver ion in the presence of anions.*  
 BTB :  $2 \times 10^{-4} M$ ; BCG :  $10^{-4} M$ ; Co-DHAB :  $3.3 \times 10^{-4} M$ ; Pic :  $10^{-2} M$ ; EO :  $10^{-3} M$ ; Vorg : Vaq = 0.5 ml : 5.0 ml; CAg,aq :  $1.0 \times 10^{-6} M$ .

### Composition of Extracted Species

At a constant B-15TC concentration of 0.01 M and at a pH of 4.5, a plot of log D against log [X] is shown in Figure 3.

*Figure 3. A plot of log D against log [X] at [B-15TC]org = 0.01 M.*  
 Vorg : Vaq = 0.5 ml : 5.0 ml ; n = 1.

Similarly, a plot of log D against log [L]org at a constant BTB concentration of  $2 \times 10^{-4} M$  and at a pH of 4.5 is given in Figure 4. A straight line with a slope of 1.1 in Figure 3 and a curve in Figure 4 were obtained. With the same data in Figure 4, a plot of  $(\log D - \log [X]) - \log [L]_{org}$  against  $\log [L]_{org}$  is shown in Figure 5. As is evident from Figure 5, this plot gave a curve. Comparing this plot with a normalized curve obtained with  $Y = \log(1 + x)$  and  $X = \log x$ , a reasonable fit with  $\log K_{ex} = 8.06$  and with  $X = 0$  at  $\log K_1[X]_{org} = -1.90$  was obtained. These results show that the extracted species are 1:1:1 and 1:2:1 and the values of  $\log K_{ex}$  and  $\log K_1$  are 8.06 and 1.90, respectively.

### Determination of Silver in Sargasso

On the basis of the previous facts [6,7], the proposed method was applied to the determination of silver in a certified reference botanical material (NIES-CRM No. 9, Sargasso) from National Institute of Environmental Studies (Japan). The analytical results obtained are  $0.305 \pm 0.005 \mu\text{g/g}$  ( $n=6$ , Vorg : Vaq = 0.3 ml : 5.0 ml). The results agreed well with the certified value ( $0.31 \pm 0.02 \mu\text{g/g}$ ) and also were very reproducible.

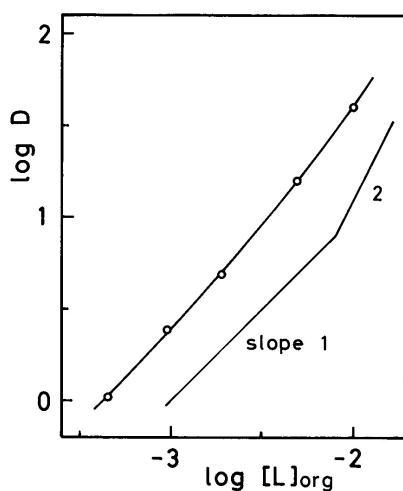

Figure 4. A plot of  $\log D$  against  $\log [L]_{\text{org}}$  at  $[BTB] = 2 \times 10^{-4} \text{ M}$ .  
 $V_{\text{org}} : V_{\text{aq}} = 0.5 \text{ ml} : 5.0 \text{ ml} ; n = 1$ .

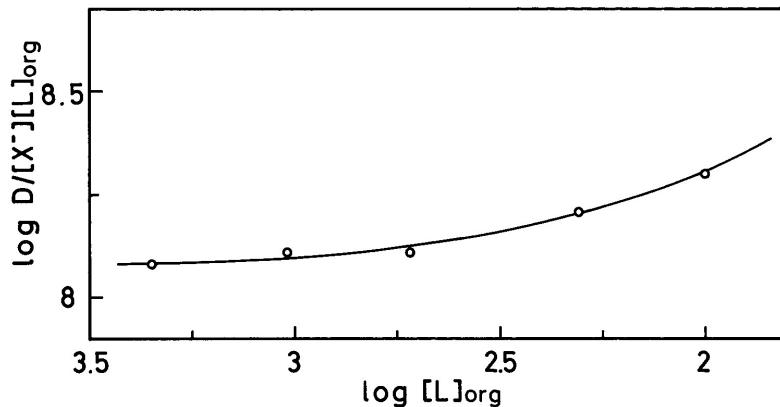

Figure 5. A plot of  $(\log D - \log [X] - \log [L]_{\text{org}})$  against  $\log [L]_{\text{org}}$ .  
 $V_{\text{org}} : V_{\text{aq}} = 0.5 \text{ ml} : 5.0 \text{ ml}$ .

## EXTRACTION AND SPECTROPHOTOMETRIC DETERMINATION OF COPPER(II) WITH 3-ISONITROSO-5-METHYL-2-HEXANONE AND 5-METHYL-2,3-HEXANEDIONE DIOXIME

S.P. Tandel, S.B. Jadhav and S. P. Malve

Institute of Science 15, Mumbai, India

Simple and selective methods are proposed for the extraction of copper(II) and its spectrophotometric determination using 3-isonitroso-5-methyl-2-hexanone (HIMH) and 5-methyl-2,3-hexanedione dioxime ( $H_2MHDDO$ ). Copper(II) forms greenish-yellow coloured complexes with both reagents, which can be extracted into isoamyl alcohol at pH 6.5-8.5 (HIMH) and into chloroform at pH 7.0-8.5 ( $H_2MHDDO$ ). The extracted species show absorption maxima at 390 (HIMH) and 370 nm ( $H_2MHDDO$ ), and the calibration curves are linear in the concentration ranges 0.1-7.0 and 0.1-10.0  $\mu\text{g ml}^{-1}$  of copper(II), respectively. The molar absorptivities of the complexes are  $1.001 \times 10^4$  (HIMH) and  $6.61 \times 10^3 \text{ l mol}^{-1} \text{ cm}^{-1}$  ( $H_2MHDDO$ ), and the Sandell's sensitivities of the proposed methods are 6.1 and 9.2 ng  $\text{cm}^{-2}$  respectively. These methods are applied for the determination of copper in synthetic mixtures, pharmaceuticals, dyes and alloy samples.

### INTRODUCTION

The significance of copper as a transition metal lies in its wide spectrum of applications, covering many frontier areas of studies, such as medicine, industry, food and beverages. It is also present in all body tissues, but liver, brain and kidney contain the highest amounts. Both deficiency and excess concentration of copper can cause adverse effects on the human body. Hence owing to the significance of copper, it was considered worthwhile to explore the possibilities of developing a simpler, sensitive, selective and rapid method for the determination of traces of copper in various synthetic mixtures, dyes, alloy and pharmaceutical samples.

Various substituted and unsubstituted ketoximes have been surveyed in the literature for spectrophotometric determination forming coloured chelates, especially with transition metal ions, and which were easily extractable in most common organic solvents [1-3]. The literature survey reveals that a wide variety of reagents have been employed for its spectrophotometric determination but most of them suffer from limitations such as heating time, long time of colour development, long time of equilibration, critical pH, and interference from many ions.

Owing to the increasing commercial importance, in the present communication, 3-isonitroso-5-methyl-2-hexanone (HIMH) and 5-methyl-2,3-hexanedione dioxime ( $H_2MHDDO$ ) have been proposed as new analytical reagents for the extractive spectrophotometric determination of copper. These methods are simple, selective, rapid and accurate.

## EXPERIMENTAL

### Apparatus

A Shimadzu model UV/VIS 1601A spectrophotometer and a digital ELICO (model LI-120 type) pH meter with combined glass electrodes were used.

### Reagents

All chemicals used were of analytical grade unless otherwise stated. Double distilled water was used throughout.

### Copper(II) Solution

A stock solution of copper ( $10\ 000\ \mu\text{g ml}^{-1}$ ) was prepared by dissolving an accurately weighed amount of Merck copper sulphate (9.8228 g) in 250 ml double-distilled water with a few drops of concentrated sulphuric acid and standardized by a known method [4].

### Synthesis of Ligands

#### *3-Isonitroso-5-methyl-2-hexanone (HIMH)*

The ligand was synthesized by the procedure reported in the literature by reaction of n-amyl nitrite with 5-Methyl-2-hexanone (Merck) [5].

#### *5-Methyl-2,3-hexanedione dioxime (H<sub>2</sub>MHDDO)*

The ligand was synthesized by the procedure reported in the literature by reaction of HIMH with hydroxylamine hydrochloride under alkaline conditions [6].

A 0.5% reagent solution of HIMH or H<sub>2</sub>MHDDO was prepared in absolute ethanol for all extraction studies.

### General Extraction Procedures

#### *3-Isonitroso-5-methyl-2-hexanone (HIMH)*

To an aliquot of solution containing 1- 100 µg copper in a 50 ml separating funnel, a solution of 0.3 ml of 0.5% alcoholic HIMH and 1 ml of buffer solution was added and the volume was made to 10 ml with double distilled water. The aqueous medium was equilibrated with 10 ml isoamyl alcohol for 20 s. The two layers were allowed to separate. The absorbance of the organic extract was measured at 390 nm against a reagent blank.

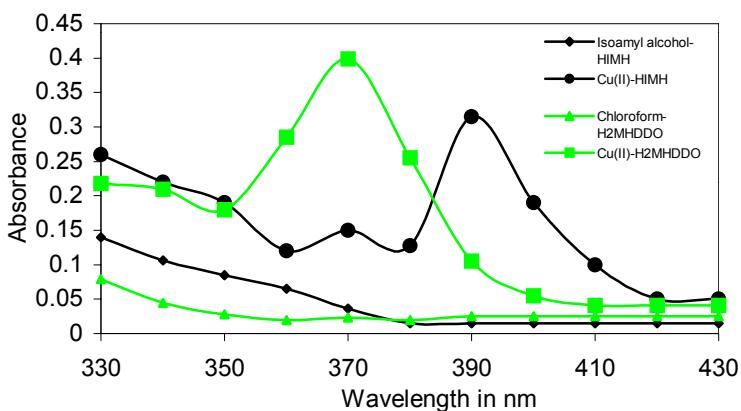

#### *5-Methyl-2,3-hexanedione dioxime (H<sub>2</sub>MHDDO)*

To an aliquot of solution containing 1- 100 µg copper in a 50 ml separating funnel, a solution of 0.4 ml of 0.5% alcoholic H<sub>2</sub>MHDDO and 0.6 ml of buffer solution was added and the volume was made to 10 ml with double distilled water. The aqueous medium was equilibrated with 10 ml chloroform for 25 s. The two layers were allowed to separate. The absorbance of the organic extract was measured at 370 nm against a reagent blank.

## RESULTS AND DISCUSSION

### Absorption Spectra

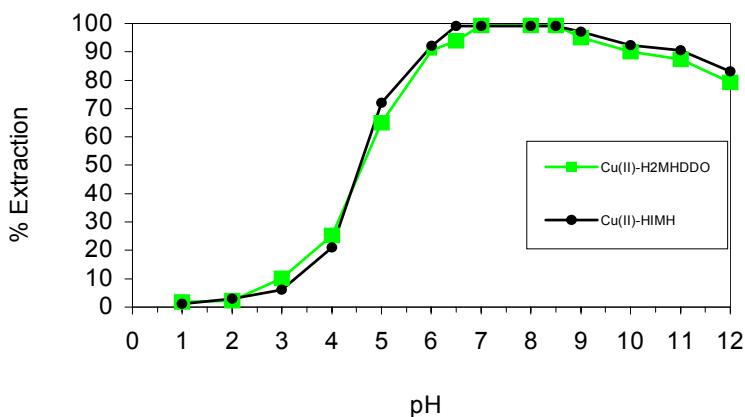

The absorption spectra of copper(II) complexes with HIMH and H<sub>2</sub>MHDDO are shown in Figure 1. The copper(II) complexes with HIMH and H<sub>2</sub>MHDDO show maxima at 390 nm and 370 nm, respectively.

*Figure 1. Absorption spectra of copper complexes.*

### Extraction Conditions

A preliminary study showed that the formation of extractable copper-HIMH/H<sub>2</sub>MHDDO complexes is affected by the hydrogen ion concentration. The optimum pH range for the absorbance was studied by means of the standard procedure. The results are shown in Figure 2. A maximum and constant absorbance was observed over the pH range 6.5-8.5 for the Cu(II)-HIMH complex and 7.0-8.5 for the Cu(II)-H<sub>2</sub>MHDDO complex.

*Figure 2. Effect of pH on extraction of copper.*

### Effect of Ligand Concentration

The influence of ligand concentration on the absorbance of the extracted complexes was studied, with the variation of HIMH (H<sub>2</sub>MHDDO) concentration (0.005%-0.05%) the extraction of 20 µg (40µg) copper(II) showed increasing absorbance up to 0.015 (0.020%). Further increase in ligand concentration has no effect on the extraction.

### Choice of Extracting Solvent

Copper(II) was extracted with HIMH and H<sub>2</sub>MHDDO into various solvents. The results are given in Table 1. The extraction of the copper(II) complexes was quantitative only in isoamyl alcohol and chloroform, respectively.

### Shaking Period and Stability

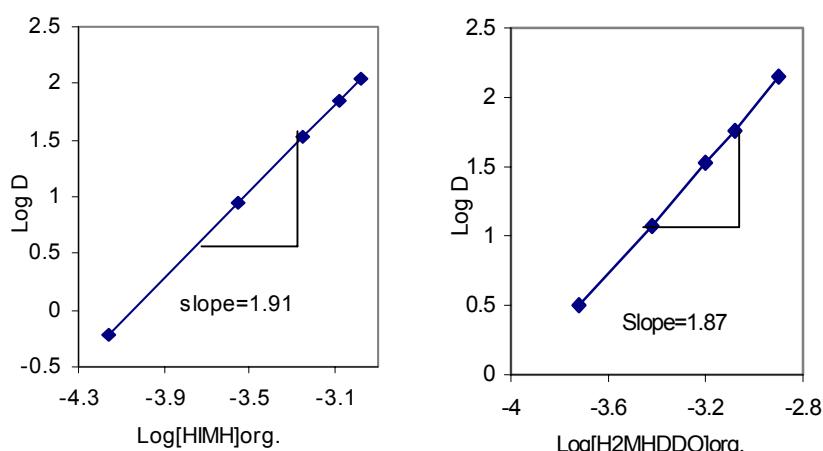

Copper(II)-HIMH (H<sub>2</sub>MHDDO) complexes were extracted with varying periods of shaking in the range of 5-40 s. The optimum period of shaking required for the complete transfer of complex into organic phase was found to be 20 s (25 s). The extracted complexes are stable for 7h (10 h).

*Table 1. Extraction of copper(II) complexes with various solvents.*

Solvent	Extraction with H <sub>2</sub> MHDDO (%)	Extraction with HIMH (%)
Chloroform	99.3	80.1
Toluene	94.2	96.0
Benzene	90.1	94.0
Carbon tetrachloride	79.0	75.4
Iso-amyl alcohol	76.4	99.1
Dichloromethane	55.6	40.1
1-Octanol	44.7	35.0
Monochlorobenzene	42.1	25.0
Xylene	24.3	22.6
Cyclohexane	10.1	7.8

### Nature of the Extracted Species

To ascertain the nature of the extracted species, a fixed amount of copper(II) was extracted with varying ligand concentration. The distribution coefficient (D) of copper(II) was calculated at different molar concentrations of ligands. The logarithmic plots of D against [Ligand]<sub>M</sub> gave a straight line with a slope close to 2 indicating the composition of the extracted species as 1:2, i.e., Cu(HIMH)<sub>2</sub> and Cu(H<sub>2</sub>MHDDO)<sub>2</sub> are shown in Figure 3.

*Figure 3. Logarithmic plots of D against ligand concentration.*

### Beer's Range and Sensitivity

A calibration graph for the copper(II)-HIMH complex was prepared for the determination of copper(II) under optimum experimental conditions, i.e., 1ml of buffer solution of pH 8.0, 0.015% HIMH, shaking time 20 s and isoamyl alcohol as solvent. Beer's law was obeyed in the concentration range of 0.1-7.0  $\mu\text{g ml}^{-1}$  of copper(II). The molar absorptivity and Sandell's sensitivity were calculated to be  $1.001 \times 10^4 \text{ l mol}^{-1} \text{ cm}^{-1}$  and 6.1 ng  $\text{cm}^2$ , respectively.

A calibration graph for copper(II)-H<sub>2</sub>MHDDO complex was prepared for the determination of copper(II) under optimum experimental conditions, i.e., 0.6 ml of buffer solution of pH 8.0, 0.020% H<sub>2</sub>MHDDO, shaking time 25 s. and chloroform as solvent. Beer's law was obeyed in the concentration range of 0.1-10.0  $\mu\text{g ml}^{-1}$  of copper(II). The molar absorptivity and Sandell's sensitivity were calculated to be  $6.61 \times 10^3 \text{ l mol}^{-1} \text{ cm}^{-1}$  and 9.2 ng  $\text{cm}^2$ , respectively.

### Precision and Accuracy of the Method

These methods were applied for 10 replicate determinations of 20  $\mu\text{g}$  or 40  $\mu\text{g}$  copper(II). The relative standard deviation for HIMH was 0.89% and for H<sub>2</sub>MHDDO 0.95%.

### Effect of Foreign Ions

Copper(II) was extracted in the presence of large number of foreign ions. The tolerance amount of an ion was taken as the amount which causes an error of not more than  $\pm 2\%$  in the recovery of Cu(II). The results are given in Table 2.

*Table 2. Effect of foreign ions on the extraction of 20  $\mu\text{g}$  / 40  $\mu\text{g}$  copper with HIMH and  $\text{H}_2\text{MHDDO}$ , respectively.*

### Determination of Copper in Synthetic Mixtures

The developed method has been applied for the extraction and determination of copper 20  $\mu\text{g}$  / 40  $\mu\text{g}$  from various synthetic mixtures which contain copper, selenium, manganese, sodium, rhodium, zinc and magnesium. The results are shown in Table 3.

*Table 3. Determination of copper in synthetic mixtures.*

Sample	HIMH		$\text{H}_2\text{MHDDO}$		RSD %	
	Pre.Meth	NaDDTC*	Pre.Meth	NaDDTC*	HIMH	$\text{H}_2\text{MHDDO}$

### Analysis of Pharmaceutical Samples

To a Supradyn / Fersolate CM / Theragran-M tablet add, 10 ml aqua-regia and heat nearly to dryness followed by 2 ml of  $\text{HClO}_4$  to decompose organic matter. Finally the residue was treated with dilute HCl and the solution was evaporated nearly to dryness. The residue was dissolved in 10 ml double-distilled water and a suitable aliquot of this solution was used for copper analysis by the developed method. The results are shown in Table 4.

### **Estimation of Copper from Dye Sample**

To about 0.1 g of the dye sample, 10 ml of liquid formulation of concentrated sulfuric and nitric acids was added and evaporated nearly to dryness. It was treated with hydrogen peroxide (5ml, 30 V) every time, until the solution became colourless. Finally, it was treated with dilute HCl and the solution was evaporated nearly to dryness. The residue was extracted in distilled water and a suitable aliquot of this solution was used for copper analysis by the developed method. The results are shown in Table 4.

### **Estimation of Copper from Brass Sample**

About 0.2 g of an oven dried ( $110^{\circ}\text{C}$ ) brass sample was dissolved in 10 ml of aqua-regia and heated to nearly dryness. The residue was treated with 5 ml concentrated HCl. The residue was extracted in distilled water and a suitable aliquot of this solution was used for copper analysis by the developed method. The results are shown in Table 4.

*Table 4. Determination of copper in real samples.*

a---- Certified values in milligrams.

b---- Average of five determinations.

c---- Values are in percentage.

### **CONCLUSIONS**

The proposed methods are highly sensitive and selective for the spectrophotometric determination of microgram amounts of copper. They offer advantages like reliability and reproducibility in addition to their simplicity and instant colour development, and suffer from less interference. They have been successfully applied for the determination of palladium/copper at trace level in synthetic mixtures, pharmaceutical samples, dyes and alloy samples. An R.S.D. less than 1.50% for sample analysis underlines the versatility of the developed method.

## EXTRACTION BEHAVIOR OF SOFT METAL IONS WITH POLYTHIOETHER DERIVATIVES CONTAINING O OR N DONOR ATOMS

Kenji Chayama, Kenta Adachi, Tomoaki Mori and Haruo Tsuji

Department of Chemistry, Faculty of Science and Engineering,  
Konan University, Kobe, Japan

Three new polythioether derivatives containing an oxygen or a nitrogen atom in the molecules were synthesized. The liquid-liquid extraction of several metal ions with 1,9-diphenyl-2,5,8-trithianonane (9-2Ph-SSS), 1,9-diphenyl-5-oxa-2,8-dithianonane (9-2Ph-SOS) and 1,9-diphenyl-5-aza-2,8-dithianonane (9-2Ph-SNS) were examined. The aqueous solution containing the metal ion and counter anion such as picrate ion were shaken with a 1,2-dichloroethane solution of the reagent. Soft metal ions such as silver(I), copper(I), palladium(II), mercury(II) and gold(III) were extracted well with these three reagents. On the other hand, the hard and the intermediate metal ions were not extracted at all with these reagents. The extraction efficiency of copper(I) and palladium(II) were relatively low in the case of 9-2Ph-SOS. The extraction behaviors of soft metal ions with these reagents were characterised by the kind of donor atom in the center position of the molecules.

### INTRODUCTION

Organic analytical reagents used for the solvent extraction of metal ions have several types of donor atoms, such as oxygen, nitrogen and sulfur. The selectivities of reagents are mainly dependent on the kind of donor atoms in the reagents. The reagents that have sulfur atoms are selective for soft metal ions such as gold, silver, copper, palladium and mercury. These metals are important for the industries of electronic devices, catalysts or as jewels and coins. However, reagents containing sulfur atoms as mercapto groups are not stable because of the oxidation of the mercapto groups to form disulfide groups. Therefore sulfur-containing reagents are limited to use in reducing conditions. Reagents containing sulfur as thioether groups are much more stable than the reagents with mercapto groups, because the oxidation rate of sulfide to sulfoxide is slower than that of the mercapto group to sulfide.

We have synthesized reagents containing the thioether group [1-6]. Some of them are cyclic compounds called thiacrown ethers which have a cavity that loads a metal ion of appropriate size [1,2,7]. In order to separate a specific metal ion from others, it may be effective to create a reagent which has a host site to incorporate the guest ions. However it is difficult to synthesize the rigid cavity in the molecules. Thiacrown ether has a flexible structure so that it apparently does not work as a specific reagent for a soft metal ion. On the other hand, acyclic polythioether is also selective for the soft metal ions as well as cyclic ones, because the thioether groups acts as a softer Lewis base than the mercapto group [5-10]. It is clarified that the selectivity of the polythioethers depend on the character of the donor atoms,

nevertheless of the structures. There is another way to separate the soft metal ions from each other, by synthesizing polythioethers that have a donor atom other than sulfur. The combination of donor atoms such as oxygen, nitrogen and sulfur may enable the separation of soft metal ions from each other. Inserting the hetero atoms into the thioethers might change the selectivity of the reagent or weaken the binding ability of the reagent for the metal ion in some cases. In this study, we synthesize three reagents, 1,9-diphenyl-2,5,8-trithianonane (9-2Ph-SSS), 1,9-diphenyl-5-oxa-2,8-dithianonane (9-2Ph-SOS) and 1,9-diphenyl-5-aza-2,8-dithianonane (9-2Ph-SNS), as solvent extraction reagents. The extraction behaviors of metal ions with these reagents were examined.

## EXPERIMENTAL

### Synthesis of the Reagents

The reagent 1,9-diphenyl-2,5,8-trithianonane (9-2Ph-SSS) was synthesized as described previously [8]. The reagent containing an oxygen atom in the molecule 1,9-diphenyl-5-oxa-2,8-dithianonane (9-2Ph-SOS) was synthesized by the reaction of di-(2-mercaptoethyl)ether with benzyl bromide. The reaction gave a crude product which was then purified by column chromatography. The reagent containing a nitrogen was synthesized by the reaction of bis(2-chloroethyl)amine hydrochloride with benzyl mercaptane. The product was crystallized as the salt with HCl. These synthetic routes are shown in Figure 1.

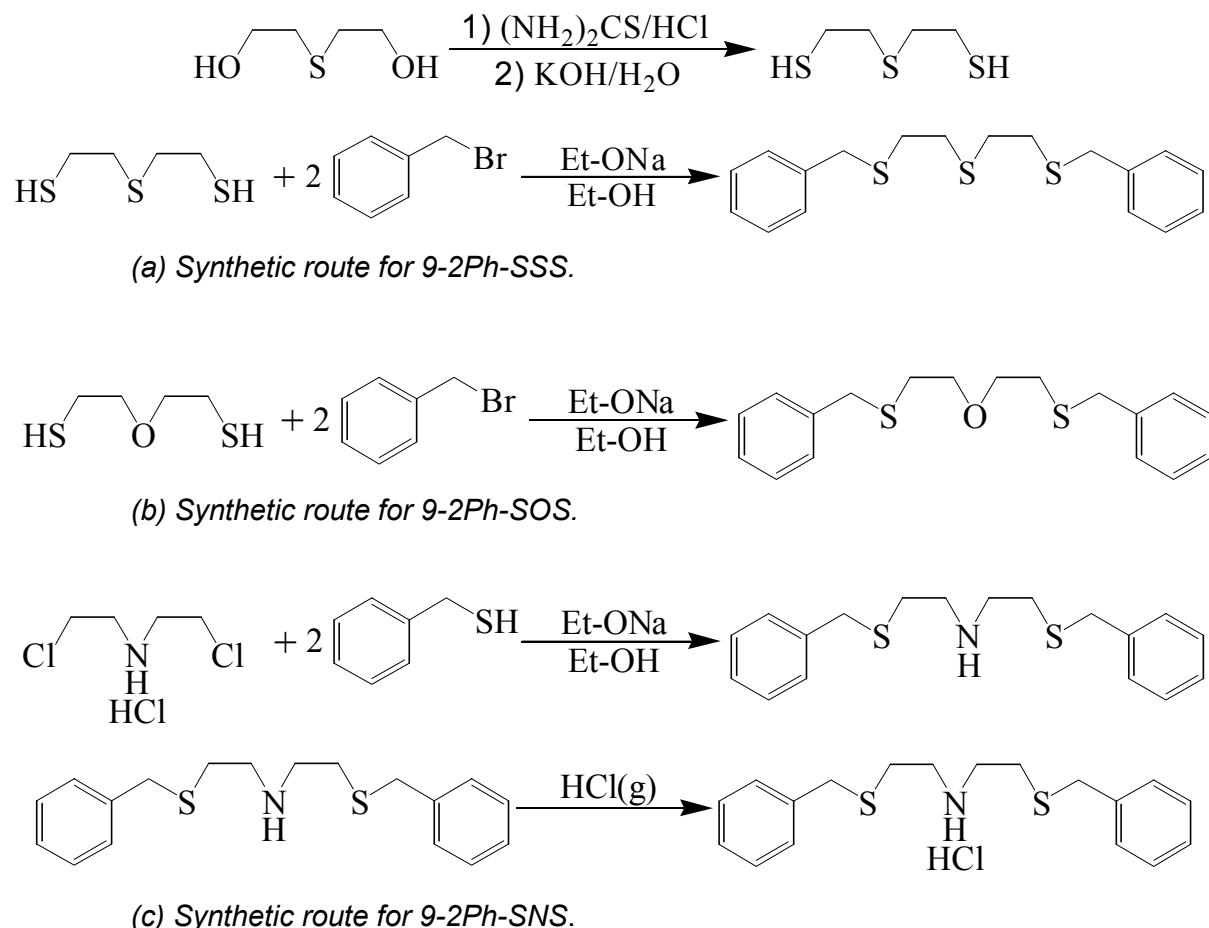

Figure 1. Synthetic routes for 9-2Ph-SSS, 9-2Ph-SOS and 9-2Ph-SNS.

## Other Reagents and Apparatus

The reagents used for liquid-liquid extraction were of reagent grade except 1,2-dichloroethane. The extraction solvent 1,2-dichloroethane, was shaken three times with 2 M (mol/dm<sup>3</sup>) potassium hydroxide solution followed by shaking three times with water, dried over calcium chloride, and distilled. Extraction was carried out in a Taiyo M incubator. A Hitachi Z-8000 atomic absorption spectrophotometer was used to determine the concentration of metal ions in the aqueous solutions. The pH of the aqueous solutions was measured with a Hitachi-Horiba M-7 pH meter.

## Liquid-Liquid Extraction of the Metal Ions

An aliquot (10 ml) of aqueous solution containing the metal ion ( $5 \times 10^{-5}$  M), picrate ion ( $1 \times 10^{-3}$  M) and acetate buffer ( $1 \times 10^{-2}$  M) was adjusted to an ionic strength of 0.1 M with sodium sulfate. This solution and 10 ml of the reagent solution in 1,2-dichloroethane in a stoppered cylindrical tube were shaken (180 strokes min<sup>-1</sup>) for 30 min at  $25 \pm 0.1^\circ\text{C}$ . The mixture was then centrifuged for 5 min at 2000 rpm. After the two phases were separated, the pH of the aqueous phase was measured and the concentrations of the metal ion in the aqueous and organic phases determined by atomic absorption spectrophotometry.

## RESULTS AND DISCUSSION

### Liquid-Liquid Distribution of 9-2Ph-SNS

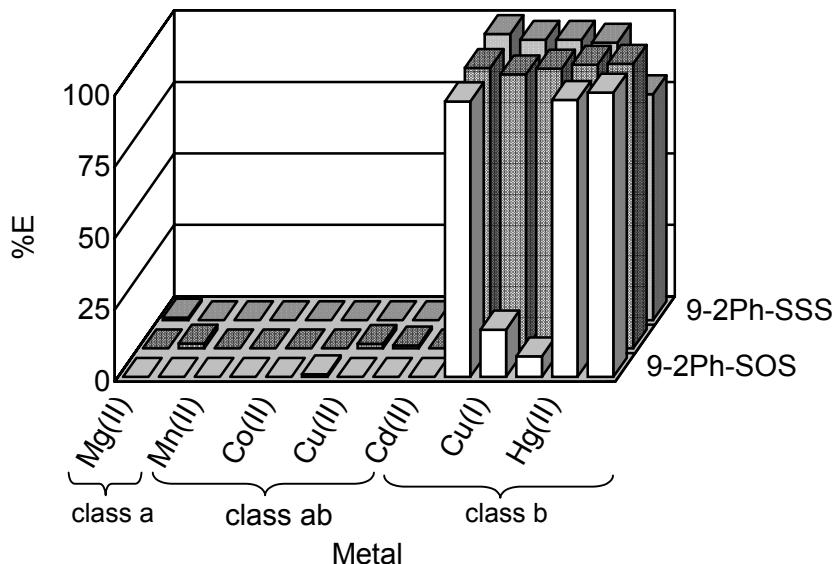

The cyclic and acyclic polythioethers are insoluble in water. However the monoazapoly-thioethers are soluble in acidic aqueous solution. The distribution behavior of 9-2Ph-SNS between 1,2-dichloroethane and water was different from that of polythioethers which do not contain any nitrogen atoms. Protonated 9-2Ph-SNS distributed to the aqueous phase from 1,2-dichloroethane phase at pH less than 1. As the pH in aqueous phase increased, 9-2Ph-SNS was transferred to the organic phase. More than 99% reagent distributed to an organic phase at pH over 6.0. In this study, picrate ion was used as the counter anion to form the ion pair with the metal complex cation. However the protonated reagent 9-2Ph-SNS forms an ion pair with picrate ion, even in the case of the absence of the metal ion. This causes the reduction of picrate ion concentration in the aqueous phase, and results in a decrease of the extraction efficiency of metal ions. Then, the extraction behavior of picrate ion with 9-2Ph-SNS was examined. It is clarified that picrate ion formed an ion pair with 9-2Ph-SNS and distributed to the organic phase below pH 1.0.

### Liquid-Liquid Extraction of Metals

Liquid-liquid extraction of the metals Mg(II), Ca(II), Mn(II), Zn(II), Co(II), Ni(II), Cu(II), Fe(II), Cd(II), Ag(I), Cu(I), Pd(II), Hg(II) and Au(III) was performed. As shown in Figure 2, soft metal ions such as Ag(I), Cu(I), Hg(II) and Au(III) ions which are classified [11] as class *b* metal ions were selectively extracted with these reagents. On the other hand, hard (class *a*) and intermediate (class *ab*) metal ions such as Mg(II), Ca(II), Mn(II), Zn(II), Co(II) and Ni(II) were not extracted at all. Although Cu(II) ion belonging to class *ab* was slightly extracted, Cd(II) ion belonging to class *b* was not extracted at all. Copper(II) was extracted slightly with 9-2Ph-SNS. However, 9-2Ph-SOS or 9-2Ph-SSS did not extract Cu(II) at all.

### Liquid-Liquid Extraction of Silver(I)

Liquid-liquid extraction of silver(I) was examined. Figure 3 shows the plots of percent extraction of silver(I) versus pH in the aqueous phase. Silver(I) ion was extracted more than 99% with each reagent above pH 4.0. In the case of 9-2-Ph-SNS, the percent extraction decreases with the increase of the acid concentration. It is thought that the distribution of the reagent containing a nitrogen atom might be shifted to the aqueous phase, and the protonated species forms an ion pair with picrate ion which causes a decrease of the picrate ion as a counter anion for the metal complex cation.

**Figure 2.** Extraction of metal ions with three polythioether derivatives.  
Initial concentration: Metal ion;  $5 \times 10^{-5}$  M, Picrate ion;  $1 \times 10^{-3}$  M,  
Reagent;  $5 \times 10^{-4}$  M. pH 5.0. Extraction time: 30 min.

The molar ratio methods was performed to clarify the composition of the extracted species. The results indicate that the molar ratio of the silver(I) ion to 9-2Ph-SOS, 9-2Ph-SNS and 9-2Ph-SSS is 1:2 for all three reagents. For each reagent, the molar ratio of the silver(I) to picrate ion were examined, and found to be 1:1 for each reagent. Therefore the molar ratio of the extracted species for each reagent silver(I):reagent:picrate ion was 1:2:1. It is thought that the extracted complex might be formed as a 1:2 complex of silver to ligand in which the silver ion takes an octahedral configuration.

#### Liquid-Liquid Extraction of Copper(I)

Liquid-liquid extraction of copper(I) ion was examined with 9-2Ph-SSS and 9-2Ph-SNS. Figure 4 shows the plots of percent extraction of copper(I) ion versus pH in the aqueous phase. As copper(II) in the aqueous solution was transformed to copper(I) by a reducing agent such as hydroxyl amine, the decrease of percent extraction of copper below pH 4.5 may depend upon the decrease of reducting power of hydroxyl amine in acidic media. The composition of extracted species were examined by means of the molar ratio method and slope analysis. The relationship between the extraction constant  $K_{ex}$  and the distribution ratio  $D_{Cu(I)}$  is expressed as follows:

$$\log D_{Cu(I)} = \log K_{ex} + m \log [L] + n \log [\text{Pic}] \quad (2)$$

When the reagent 9-2Ph-SNS was used, the plots of  $\log D_{Cu(I)}$  vs.  $\log [\text{Pic}]$  gave a straight line with slope 1, suggested "n" in Eqn. (1) and (2) is taken as  $n = 1$ . These results suggest that the composition of the extracted species with 9-2Ph-SNS were  $Cu(I) : \text{Pic}^- = 1:1$ . The plots of  $\log D_{Cu(I)}$  vs.  $\log [L]$  gave a straight line with slope 2, suggested "m" in Eqn. (1) and (2) is taken as  $m = 2$ . Therefore the composition of extracted species might be  $Cu(I):L:\text{Pic}^- = 1:2:1$ . However, the extracted species of copper(I) with 9-2Ph-SSS was  $Cu(I):L:\text{Pic}^- = 1:1:1$ . As shown in Figure 2, the extraction efficiency of copper(I) with 9-2Ph-SOS was about 15% at pH 4.5, much less than that for 9-2Ph-SSS (98.0% at pH 4.9) and 9-2Ph-SNS(95.0 at pH 4.9). It shows that the replacement of the central donor atom from sulfur to oxygen decreases the extraction efficiency. It is thought that the copper(I) ion usually takes the tetrahedral configuration in the complex. The results suggest that the 9-2Ph-SNS reagent acts as a bidentate ligand; on the other hand, the 9-2Ph-SSS reagent acts as a tridentate ligand in the copper(I) complex.

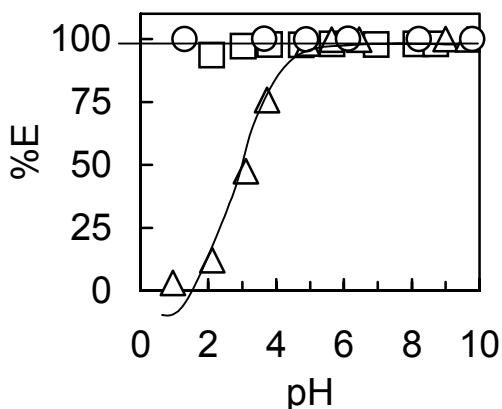

Figure 3. Plots of %E vs. pH for the extraction of silver(I) with 9-2Ph-SXS. □: 9-2Ph-SOS, Δ: 9-2Ph-SNS, ○: 9-2Ph-SSS.

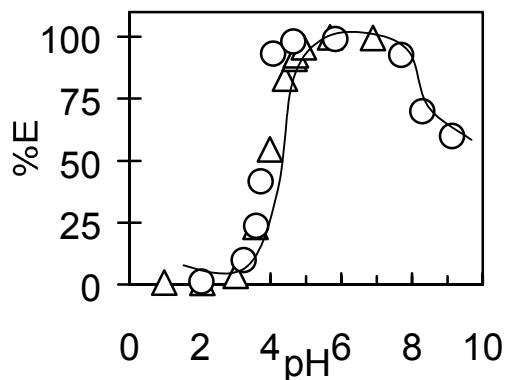

Figure 4. Plots of %E vs. pH for the extraction of copper (I) with 9-2Ph-SXS. Δ: 9-2Ph-SNS, ○: 9-2Ph-SSS.

## CONCLUSION

The liquid-liquid extraction of several metal ions with 9-2Ph-SSS, 9-2Ph-SOS and 9-2Ph-SNS was examined. Soft metal ions such as silver(I), copper(I), palladium(II), mercury(II) and gold (III) were extracted well with these three reagents. On the other hand, the hard and the intermediate metal ions were not extracted at all with these reagents. The result shows the selectivity of these reagents for the soft metal ions did not change even when the central sulfur atom was replaced with oxygen atom or the nitrogen atom. The extraction efficiency of copper(I) and palladium(II) was relatively low in the case of 9-2Ph-SOS. These results suggest that the replacement of the sulfur donor atoms by an oxygen or nitrogen may change the extraction tendency of soft metal ions. There may be a possibility to separate soft metal ions from each other with the use of such polythioether derivatives containing other kinds of donor atoms.

## APPLICATION OF COURIER 30SX ANALYSER TO NICKEL LATERITE SOLVENT EXTRACTION

**David Hughes, Matti Kongas and Kari Saloheimo**

Outokumpu Mintec, Espoo, Finland

The paper covers the application of an on-line process analyser to solvent extraction in a laterite nickel ore treatment process in Australia. It covers the considerations in design of a sample multiplexing system specifically engineered for this process type.

The paper shows the considerations in the choice of sample handling in the solvent extraction stages of iron, zinc, and copper removal from nickel-cobalt solution and subsequently in the preparation of purified nickel and cobalt solutions for metal reduction. The wavelength-dispersive X-ray analyser equipment is described. The considerations in installation of the analyser and its sample handling in the industrial area of the plant are also described.

The project was among the first in which this analyser was installed and started up with this sample system. During the implementation of the project, the design of the sample handling and its operating program were firmed up based on deepening understanding of the design parameters of the process. Both the process solution characteristics, solution pumping parameters and the climate of the semi-arid environment affected the final design choices. The lessons learned in this project are reviewed. They can be applied to similar projects both in nickel laterite processes, and in copper oxide heap-leach, solvent extraction, electrowinning (SXEW) plants.

### CONSIDERATIONS IN DESIGN OF THE SAMPLE HANDLING SYSTEM

Outokumpu Mintec and its predecessors in the Outokumpu concern have manufactured on-line X-ray fluorescence analysers since 1969. The majority of these have been delivered to froth flotation plants, for which a gravity flow sample presentation system was developed, since keeping solids in suspension was an important part of the implementation of on-line analysis. For nickel and zinc refineries in which a number of analyser systems have been installed, the critical function of sample presentation was the extraction of solids from the sample to enable analysis of the trace elements remaining in solution. This need led to the development of a batch sampling and filtration system that is still in use. This system has been perceived to be too complicated and slow for solvent extraction plants. When the boom in copper heap-leaching, solvent extraction and electrowinning came in Chile in the early 1990s, it became necessary to rethink the approach to analysis needs and sample handling for plants of this kind. [1]

The project to design an X-ray analyser system aimed specifically at solvent extraction plants was originally specified with the Chilean copper plants in mind. Typical copper heap-leach, solvent extraction plants under construction in the Chilean copper field cover a much larger area than flotation plants for similar copper production. Sixteen to twenty sample points are scattered over an area as large as 250 m by 150 m. Usually most of these can however be located at the edge of the tank farm area. The floor of the tank farm on larger sites is 10 to 15 m lower than the level of the mixer settlers. Sample transport must be designed to operate over the long distances and with the small head or hydraulic gradient available.

The process streams to be sampled must all be solids free, unless crud formation is a big problem, but the danger exists of blockage due to crystallization, especially at high altitudes where winter temperatures can be below zero. System design must counteract the tendency of solution flowing in small pipes to cool and crystallise.

The need has also been seen to limit to a minimum the quantity of valuable solution, electrolyte that has to be discarded or recycled by pumping.

A fourth goal is to provide prompt and frequent analyses. To give sufficiently frequent data for effective control of the process, whether automatic or manual, repeating analyses every ½ hour is perceived to be necessary. Since the equipment is designed for 16 sample streams, this implies making a new measurement every two minutes. With a measurement time of 1 minute, that leaves 1 minute for rinsing the parts of the system intimately connected to the measurement cell or cuvette.

Chemically the solutions are aggressively corrosive. The acid content of electrolytes can be as high as 200 g/l H<sub>2</sub>SO<sub>4</sub>, and the REDOX potential may be 400 to 550 mV relative to the standard hydrogen electrode. The PLS and raffinates contain much less acid, but in Chile they are marked by high contents of chloride since chloride salts have not been naturally leached out of the ore bodies in the extremely arid climate.

In the design process this all led to the idea that the samples could be taken from gravity fed fast loops terminating in the tank farm area, or from process pipes in which the solution was being pumped to the mixer settlers. The flow of samples would be driven by the hydraulic gradient of 5% to 10%, or by process pump pressure, and the maximum pressure at the analyser site would be between 1 and 2 bar. This was determined by the topography of the mixer-settler pad and the tank farm.

The need to minimise the amount of sample taken into the sample multiplexer of the system, and the desire to keep sample handling time to a minimum has led to a much simplified sample multiplexing system based on using small bore piping with a minimal dead volume. The total sample take-off from a fast loop or a process pipe is envisaged to be no more than 1 ½ litre for short final pipes. The design of the sampling system, now designated COURIER 30SX, also includes stringent rinsing to forestall the possibility of crystallisation. A carefully planned rinsing sequence has been designed to meet the criterion that for a system with an X-ray analyser alone the time between successive analyses in the sample sequence should be no more than 2 minutes. Further, to reduce the cooling of the samples as they enter the multiplexer the rinsing water is hot, or at least warm. Since the water consumption is small and water in a fixed pipe cools as it stands in the pipe, a local water heater has been chosen to supply hot water on demand.

The design launched in 1997 is very compact compared with earlier COURIER 30-series analyser implementations. It includes the basic analyser with a measurement cuvette that was adapted for corrosive solution samples, a simple sample presentation connection (PSM – Probe Sample Multiplexer) consisting basically of two valves and a surface level sensor to

detect the presence of sample in the cuvette, and a multiplexer for sixteen incoming sample streams. This is a block of PVDF (polyvinylidifluoride) in which the bodies of the sample valves, rinsing and draining valves are machined and all the channels are drilled. Valve actuators from a major valve supplier are used. The multiplexer, affectionately known as the "cheese", permits grouping incoming samples in four manifolds or groups that can be disposed of to the drain separately, and are well isolated from each other. Thus samples containing only traces of an element whose analysis is important are not contaminated by samples in which this element is present in large quantities. These are connected to a main channel from which the COURIER analyser is fed. The main channel also communicates with an optional header tank and valves for feeding two small titrators that are tightly integrated in the system. This tank can also be used for de-aerating frothy samples before feeding them to the COURIER analyser to maintain adequate analytical accuracy. See Figure 1.

*Figure 1. The sample multiplexer SXM, water heater and COURIER analyser, Area 37, Murrin Murrin.*

The design of the system and its software included pressure tests of the valve block and valves, which demonstrated that it would stand up to the demands of the copper SX-EW plant installation for which it was designed. In other tests the feasibility of measuring loaded organic and aqueous solutions in the same measuring cuvette was established. The system program was thus designed to allow measuring organic (up to 4 streams) and aqueous solutions in the same installation. With this design marketing of the new system began in 1997.

## FIRMING THE SPECIFICATIONS FOR THE MURRIN MURRIN PROJECT

Although the main target of the development project had been copper solvent extraction plants, at least half of the first enquiries were from Australian laterite nickel acid-leach SX plants, of which Anaconda's Murrin Murrin project showed firm interest.

Discussions with Fluor, Anaconda's engineers, and with Anaconda staff brought a rude awakening to the fact that the process conditions in the laterite nickel plant to be built on the flat plain of the Australian outback are quite different from those in a copper SXEW plant built in the Andes. The crystallization temperature of the process solutions is tens of degrees higher, due to the different chemical composition of the solutions. The pressure in transport lines is not maximum 1 ½ bar but maximum 6 bars, because gravity cannot be used for transport in the same way as in mountainous territory. The cooling of the X-ray tube and electronics in the analyser cannot be left to circulating plant water, since that might be hotter than the upper limit for proper working of the analyser. And it might rain!

Over a period of a few months a range of typical process sample connections was developed that answered most conceivable needs in both copper SXEW plants and the nickel laterite plants. At the same time the changes made in the sample connection specifications were implemented in revisions of the design of the installation during successive rounds of correspondence with Fluor and Anaconda. Existing types of heavy-duty sample valves have been applied in these connection schemes. To comply with the concept of a system that could be started up quickly and would not need on-site programming of sample handling, the use of these was specified and built into the standard sample handling software and configuration tools. This meant a second round of programming as the specifications were firmed up, and by the time the system was started up the software was ready.

Chilean users welcomed a system pre-installed in an analyser shelter, and delivered as one package. For Australian customers specifications were drawn up by the engineering companies, and locally built shelters were fitted out by the Outokumpu subsidiaries that sold the systems. Lessons learnt from experience of these have been written into revised specification sheets. Common needs are to protect the equipment, which is comparable to laboratory equipment, from cold, direct solar radiation variations in temperature in general, and from dust and rain. The special nature of the industrial environment means that both the outer cladding and the inner floors and walls of the shelter must resist the acid in electrolytes if spills occur. This means being resistant to up to 200 g/l acid.

Forced cooling of circulating water has been applied previously in Australian installations of Outokumpu analysers to ensure reliable temperature control of the analyser. The temperature control of the analyser is important to ensure repeatable measurements, since thermal expansion or contraction changes the measurement geometry. It was decided at the start of the Murrin Murrin project that the circulating cooling water should be cooled in an auxiliary circuit through a commercially available chiller, rather than be running plant water through the heat exchanger.

## APPLICATION OF COURIER TECHNOLOGY TO THE NI-CO PROCESS

Outokumpu has used wavelength-dispersive X-ray fluorescence technology since the first COURIER 300 analyser was installed in the Pyhäsalmi flotation plant in 1969. Although we have manufactured energy-dispersive analysers over the years and do so at this moment, the wavelength-dispersive technology offers significant advantages in on-line analysis for metallurgical processes. The most important is the ability to distinguish the fluorescent radiation of trace elements in concentrated metal salt solutions, for instance in solutions of nickel sulphate containing 100 g/l Ni the detection limits of iron, cobalt, copper and zinc are between 1 and 2.5 mg/l. The X-ray tube used as a source of primary radiation excites so

high an intensity of fluorescent radiation that actual measuring times can be 60 seconds, or even less for measuring higher contents. Another advantage is that the structure of the Johansson-type curved fixed-crystal spectrometers is so robust that after 13 years of use spectrometers from an analyser being replaced have been transferred to the new analyser.

Every technology has its limits, and in the case of wavelength dispersive X-ray fluorescence the major limitations are the long air-path in the spectrometer that limits the usefulness of the analyser to elements heavier than titanium, and the fact that elements whose fluorescent X-rays have an energy 50% or more of the tube voltage, such as cadmium, have higher detection limits because of the scattered primary radiation background visible in their spectrometers.

In 1997 a number of on-line analysers using the sampling technology current at the time were installed in the new solvent extraction process at the Harjavalta nickel plant of Outokumpu Oy (this plant is now OMG Harjavalta Nickel Oy). [2] The requirements for control as expressed in the Harjavalta plant are shown in Table 1. The analysers installed at Harjavalta met these requirements to the satisfaction of the plant.

*Table 1. Requirements for control of nickel cobalt solvent extraction.*

Process stage	Purpose of control
Atmospheric and autoclave leach	Minimising trace contents of Fe, Cu, As in range 1 – 10 mg/l
Solvent extraction	Monitoring separation of cations Fe, Cu, Zn from Ni and Co in ranges 1 – 10 mg/l
	Monitoring separation of cations Co from Ni so that trace content of either in the other's solution is 1 – 10 mg/l
Reduction	Control of metal ion / ammonia ratio so that molar ratio is 1.00 ±1%

The enquiry from Murrin Murrin covered solvent extraction, in two stages: separation of magnesium, iron copper and zinc from nickel and cobalt in the first, and of cobalt from nickel in the second. The two analyser systems were installed in 1999, and commissioning and precalibration was performed in March 2000. The levels of accuracy achieved during precalibration are shown in Table 2.

*Table 2. Results of precalibration at Murrin Murrin.*

Sample type / Element	Minimum (g/l)	Maximum (g/l)	Error (1 SD) (g/l)	Error relative to average content (%)
Area 39 / High Ni				
Fe	1.0	2.0	0.0304	1.89
Co	1.0	2.0	0.0488	3.05
Ni	80.0	100.0	0.699	0.777
Area 39 / Low Ni				
Co	10.0	30.0	0.354	1.55
Ni	5.0	10.0	0.166	2.18
Area 37 / High Ni				
Co	0.10	0.20	0.0034	2.64
Ni	70	90	1.18	1.46
Area 38 High Co				
Co	70	90	0.423	0.529
Ni	0.00	0.20	0.013	10.9

Of the other chemical quantities of interest, an integrated titrator was supplied to measure ammonia (*i.e.*, dissolved ammonia gas present as ammonium hydroxide) by titration with acid. Compared with setting up the X-ray fluorescence analyser, tuning the titrator requires more work to define titration algorithm parameters, such as dose increment in ml, time between doses in seconds, maximum drift between successive pH readings before making a new dose increment, etc. Titration of ammonia showed itself repeatable over the whole range of ammonia content to an acceptable degree of accuracy. The results of some test titrations were compared with the given laboratory contents of the test solutions are shown in Figure 2.

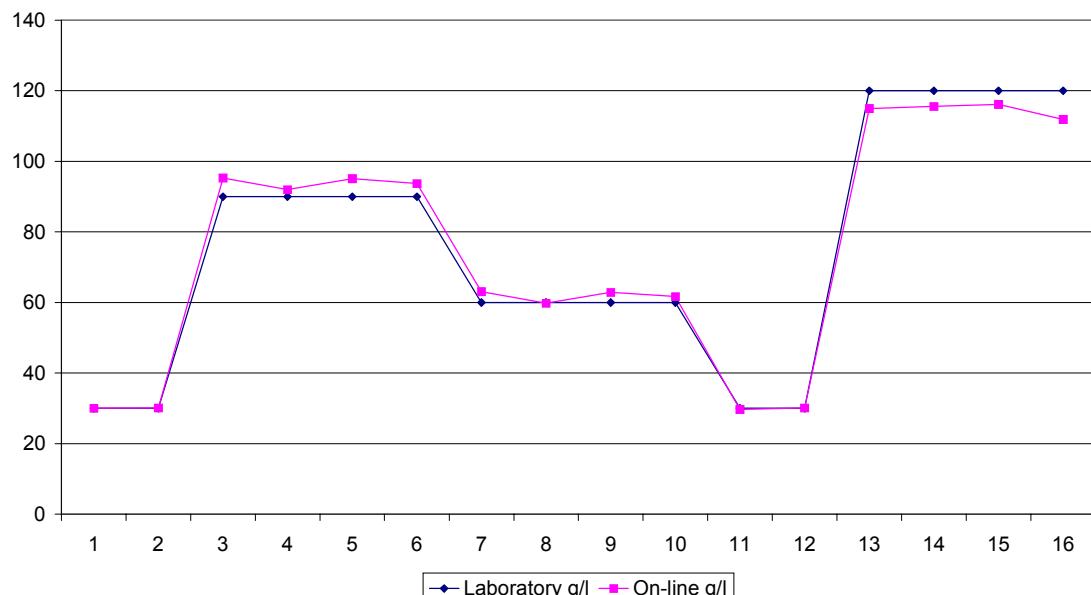

Figure 2. Titration of ammonia during precalibration at Murrin Murrin.

The precalibration described above was made with artificial samples provided for the plant laboratory for the purpose. At the time of the commissioning process material was not available and comparison with the plant laboratory could not be made. Later, information on the current performance of the on-line analysers relative to the corresponding laboratory analyses of the samples has become available. This is presented in the conclusion of the paper.

## CONCLUSION

Cooperation between equipment supplier, end-user and the engineering office has proved valuable to all parties and enabled supply of a system which takes the demands of industrial analyser applications into account.

Comparisons made of the analyses from the COURIER analysers and the plant laboratory following the precalibration and plant start-up show good correspondence between the two. The following examples are from the nickel sulphate stream, showing equally good performance at approximately 100 g/l Ni in Figure 3, and at less than 1 g/l Co in Figure 4. For the purpose of monitoring the trace elements in strong salt solutions, the performance of the on-line analysers is satisfactory.

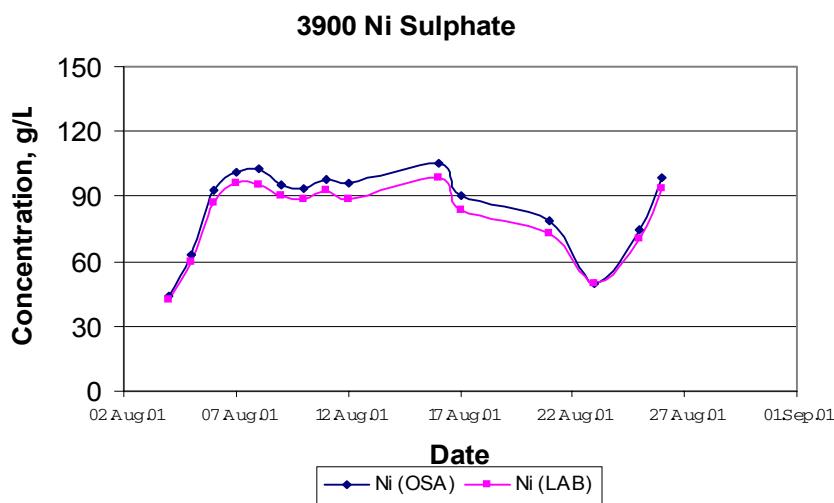

Figure 3. Correspondence of COURIER and laboratory for nickel in nickel sulphate stream.

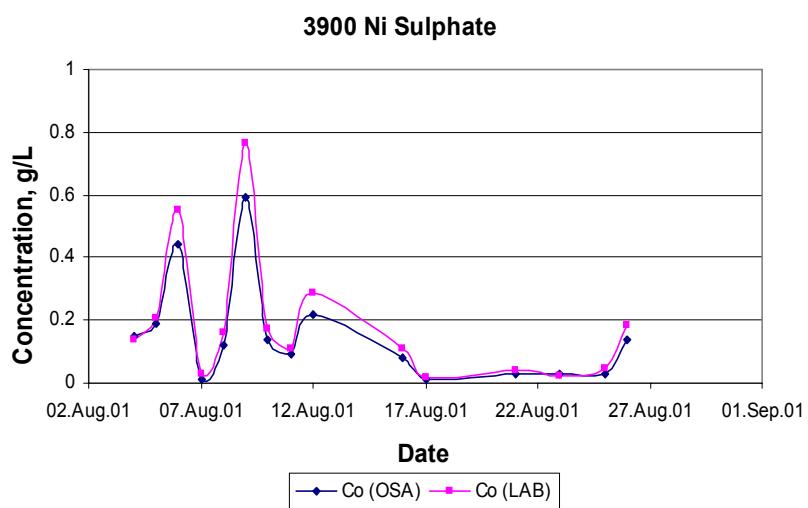

Figure 4. Correspondence of COURIER and laboratory for cobalt in nickel sulphate stream.

## ACKNOWLEDGEMENTS

Outokumpu Mintec Oy gratefully acknowledges the permission of Anaconda's Murrin Murrin Operations to publish precalibration and performance comparison data.

## OPPORTUNITIES FOR EXTRACTION TECHNOLOGY IN CHIRAL SEPARATIONS

André B. de Haan, Norbert J.M. Kuipers, Maartje Steensma

University of Twente, Enschede, The Netherlands

The availability of optically pure enantiomers is a key issue for the life-science industry. In this field extractive resolutions may become a competing technology for the separation and purification of optical isomers provided that the reported technical limitations are resolved. Most of the studied systems suffer from low productivities due to the applied low enantiomer and chiral selector concentrations. Transformation into a feasible process requires significantly increased productivities by using high feed and selector concentrations applied in a fractional extraction concept to obtain complete separation combined with maximum process flexibility. One of the key issues will be the development of industrial scale contacting equipment that can provide up to 100 equilibrium stages to cope with the inherent low selectivities (1.5-4) encountered in extractive resolutions while keeping the inventory of the expensive chiral selector to a minimum.

### INTRODUCTION

Chirality is a key issue for products within the life-science industry [1-5]. Very often the two mirror images (enantiomers) of a molecule will show different interactions with a biological receptor or enzyme, and only one single enantiomer is responsible for the desired biological activity of a compound while the other enantiomer represents a 50% impurity that often leads to unwanted (harmful) side effects. However, because suitable single-isomer manufacturing technology was not available in the past, most of the drugs, agrochemicals, flavors and fragrances used nowadays are marketed as racemic mixtures. Increased pressure on companies to develop and produce enantiomerically pure products has made the efficient and economical production of enantiomerically pure chiral products one of the major challenges facing the modern life-science industry (fine-chemicals, pharmaceuticals, agrochemicals, nutraceuticals, flavors, fragrances).

There are two main routes to the production of optically pure enantiomers: resolutions and stereoselective syntheses [1-5]. In principle asymmetric synthesis is the most cost-effective method for producing single-enantiomer products, because the entire precursor is converted to the desired enantiomer. Despite this obvious advantage, stereoselective synthesis can be particularly difficult because the stringent requirements for enantiomeric purity require exceptional enantioselectivity (>100) from the catalyst system and a final purification step is usually required to remove residual undesired enantiomer from the final product. Due to this inherent limitation of asymmetric synthesis, most processes use resolution methods for the production of synthetic single enantiomer products. A resolution process uses the competitive advantage that it is relatively straightforward to synthesize a racemic mixture that can always be resolved into a product with the desired enantiomeric purity. The industrially applied resolution methods can be divided into selective crystallization, selective conversion and preparative chromatography [1-5]. Although most widely applied for its high selectivity, diastereomeric salt crystallization is relatively inflexible and requires considerable efforts in development. Selective conversion suffers from the same limitations as asymmetric synthesis. Finally industrial scale preparative chromatography for chiral separations still suffers from low productivity and high capital costs.

These limitations of the currently available resolution technologies have initiated many attempts to develop new competing chiral separation technologies. Within this field of chiral separations, extraction technology may become an industrially attractive option. This is mainly because, although the selectivity of a single extraction is usually small, staging of multiple extractions is easily achieved and well established. In this paper we explore recent developments in various extraction technologies for the separation of chiral components.

## PRINCIPLES OF ENANTIOSELECTIVE EXTRACTION

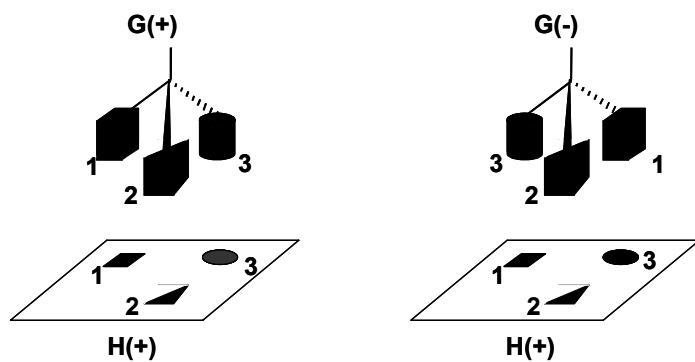

Chiral discrimination requires at least three points of interaction between the selector and one of the guest enantiomers [6,7]. This so-called “three-point model” is schematically illustrated in Figure 1. In this model, the three interaction points of one enantiomer G(+) cannot be situated in the same locations as the corresponding three points of the other enantiomer G(-) and can therefore not be recognized in the same way. Although chiral solvents are the simplest way to achieve enantioselective recognition, most methods make use of a chiral additive (chiral selector, carrier, reagent) that is added to an achiral solvent. An obvious advantage of these systems is the possibility of tailoring the selector molecules to the applications. Chiral separation is achieved by the formation of diastereomeric complexes (host-guest, HG) between the chiral selector (host, H) and racemic solute (guest, G):

Enantioselectivity,  $\beta$ , arises from the difference in the equilibrium constants  $K^+$  and  $K^-$  of both diastereomeric complexation reactions and is expressed as:

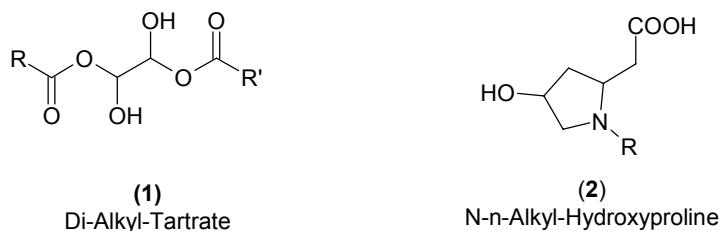

$$\ln \beta = \ln \frac{K^+}{K^-} = -\frac{\Delta \Delta G}{RT}$$
(3)

where  $\Delta \Delta G$  is the difference in the Gibbs energy of complexation for both diasteromeric complexation reactions. The simplest way to classify chiral selectors is to distinguish them by their size and the shape of their binding sites. The first class consists of molecules that complex with specific groups on the guest surface. Most of such selectors are based on derivatives from naturally occurring optical active compounds such as tartaric acid alkyl esters (**1**) and various amino acids such as L-proline and L-hydroxyproline (**2**). To improve enantioselectivity the selectors are often employed as transition metal complexes with Cu(II), Co(II), Ni(II) or various lanthanides. The main function of the metal ion is to enhance the enantioselectivity of the starting compound by creating a three-dimensional optically active complex that can be used for enantioselective extraction by ligand-exchange.

*Figure 1. Schematic representation of the Three-Point interaction model.*

The second class of chiral selectors consists of molecules that form an inclusion complex with the guest by interacting at many different points over the guest surface. Important examples are  $\alpha$ -,  $\beta$ -, or  $\gamma$ -cyclodextrins that are composed of six, seven or eight optically active glucopyranose units [8]. Besides cyclodextrins, linear polysaccharides such as maltodextrins and maltooligosaccharides might also be effective to incorporate the required enantioselectivity into one of the two phases. A group of synthetic chiral resolution agents that exhibit stereoselective inclusion complexation are chiral crown ethers [9]. Chirality is introduced by attaching two halves of the macrocyclic ether ring to chiral side groups, such as tartaric acid derivatives, dinaphthyl compounds etc. Analogous to cyclodextrins aqueous micellar aggregates are also able to provide a pseudophase with a hydrophobic interior. Micellar chiral recognition has been shown possible by either using chiral surfactants or by comicellar systems in which chiral selectors are solubilized in the hydrophobic interior [10].

## EXTRACTIVE RESOLUTON TECHNIQUES

### Liquid-Liquid Extraction

In liquid-liquid extraction optical isomers are separated by enantioselective partitioning between two liquids. In most other studies reported until now, the enantioselectivity is obtained by dissolving a suitable chiral selector in an organic solvent with minimal physical solubility of the enantiomers. The main classes that have been studied are amino acids, amino alcohols and organic acids because two simultaneous hydrogen bond interactions can provide relatively high enantioselectivity. Of these three groups most of the reported work is related to the extractive resolution of amino acids with selectors such as N-n-alkyl-L-proline copper(II) complexes [11,12]. The use of copper (II) is essential to create a selector that is capable of an enantioselective ligand exchange reaction with amino acids (AA):

According to this mechanism the overall distribution ratio is then determined by the combined solubility of the physically dissolved and complexed amino acid:

$$D = \frac{[\overline{AA}] + [\overline{AA - Cu - L}]}{[AA]} \quad (6)$$

In most studies concerning the separation of amino alcohols and organic acids dialkyl-tartrate esters have been used as chiral selectors [13,14].

### Liquid Membranes

In liquid-membrane separations enantioselective transport through the membrane is possible if chiral carriers are used that preferentially transport one of the two enantiomers. Pickering [15] studied emulsion liquid membranes for the separation of racemic phenylalanine with copper(II) N-decyl-L-hydroxyproline as the carrier dissolved in a decane/hexanol mixture as the membrane phase. Unfortunately, the enantioselectivity reduces during the course of extraction due to loss of the desired D-isomer from the source phase. This observation clearly indicates that the emulsion liquid membrane process is not sufficiently selective to achieve full separation in one stage due

to the inherent strong depletion of the enantiomer in the feed. Staging however is expensive and complicated by the required emulsification and de-emulsification steps. Related selectors have also been employed in supported and contained liquid membranes. As expected, the stability of the supported liquid membrane appeared the main issue. Long-term stability is achieved in a contained liquid membrane system. Pirkle [16] used selectors based on N-(1-naphthyl)leucine to separate the enantiomers of amino acid derivatives. As with the emulsion liquid membranes, the initially high enantioselectivity dropped quickly because the feed phase was depleted in the desired enantiomer.

### Supercritical Fluid Extraction

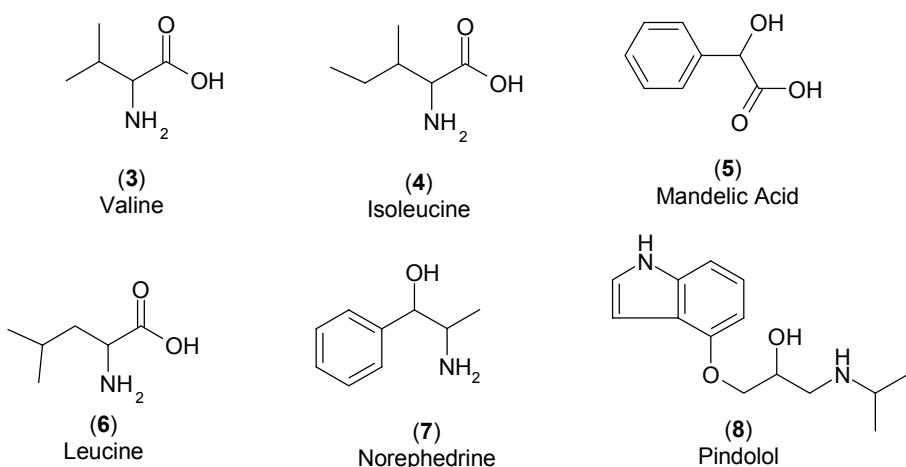

Enantioselective extraction by supercritical fluids (SFE) is possible by adding less than one equivalent of a resolving agent to establish a complex equilibrium of both free enantiomers and their diastereomeric salts [17]. The enantioselectivity of extraction arises from the preferred complexation of the resolving agent with one of the enantiomers combined with poor solubility of the diastereomeric complex in supercritical CO<sub>2</sub> that permits the selective extraction of the free optically active enantiomer. Published results indicate that SFE might be more selective for the separation of enantiomeric mixtures than conventional extraction because differences in solubility, dissociation constants and stability are larger in supercritical carbon dioxide than traditional solvents.

### Aqueous Two-Phase Extraction

Introduction of chiral differentiation in aqueous two-phase systems requires the incorporation of enantioselective interactions. This can be accomplished by the introduction of a selector that partitions preferentially into one phase or by the attachment of a chiral ligand to one of the polymers. In a dextran-PEG system 95% of the bovine serum albumin selector (BSA) dissolved in the dextran-rich phase and provides an enantioselective environment for the resolution of racemic tryptophan [18]. Besides BSA other chiral selectors such as monosaccharides, disaccharides, peptides, proteins, antibodies and optically active amino acids may be used as was disclosed by Hsu [19].

### Membrane Filtration Assisted Extraction

An alternative to separate the selector molecules the raffinate may be the use of membrane filtration. To be effective the membrane pores should retain the selector molecules and selector-enantiomer complex while the free enantiomer molecules can freely exchange phases. Complete retention is possible with sufficiently large selector molecules or aggregates such as enantioselective micelles [20], dendrimers, proteins or cyclodextrins [21]. Again the obtained selectivities (1.5-4) for the separation of amino acids with nonionic micelles containing a Cu(II)-amino acid derivative selector [20,22] are not sufficient to obtain >99% pure enantiomers with a single-stage separation process.

## FRACTIONAL EXTRACTION

The characteristic feature of enantiomer resolution is that the mixture has to be separated into two fractions consisting of the individual nearly pure enantiomers. Because of the low selectivities, mostly 1.2 up to 4, a series of extraction stages are required to obtain high optical purities. As shown in Figure 2, classical countercurrent extraction suffers from the disadvantage that only one of the two enantiomers can be obtained with sufficient purity by removing the other more or less selectively from the raffinate. For most chiral separations the recovery will be low because the extract composition is limited by the equilibrium between the racemate feed and the chiral selector containing solvent. In order to combine complete separation and high recovery of the enantiomers in two optically pure fractions, fractional extraction is the most promising liquid-liquid separation technique. Figure 2 illustrates that two solutes can be separated nearly completely by isolating one solute in the extraction solvent and the other solute in the raffinate by applying a wash solvent. Takeuchi [23] used a N-n-dodecyl-L-hydroxyproline copper(II) complex dissolved in n-butanol to resolve racemic valine (**3**) in rotating segmented glass columns. Yokouchi [24] demonstrated that the same selector could also be used for the full separation of racemic isoleucine (**4**) in a setup based on a cascade of 21 small mixer-settler units. An analytical vertical rotating column setup was used by Nishizawa [25] to achieve full (>99.9%) separation of ( $\pm$ )-mandelic acid (**5**) with N-n-dodecyl-L-proline copper(II) complex in butanol. In all three examples water was used as the wash fluid. N-n-dodecyl-L-hydroxyproline was used in octanol by Ding [26] to separate DL-leucine (**6**) into its pure enantiomers with microporous hollow fibre modules in which the polypropylene pores were filled with a cross-linked polyvinylalcohol gel. Complete separation could be obtained, provided that the velocity of the water and solvent flow are low enough to provide sufficient contacting stages. All four examples demonstrate that full separation and recovery of pure enantiomers from racemic mixtures can be achieved when fractional extraction is used.

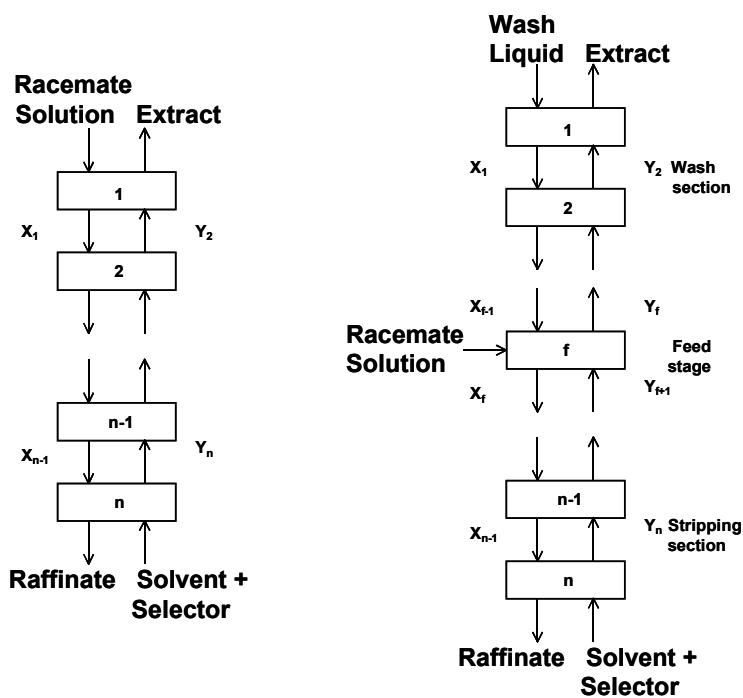

Figure 2. Countercurrent and fractional extraction.

## FUTURE OUTLOOK

The presented overview illustrates that extraction based technologies are in principle able to achieve full separation of enantiomer mixtures when the concept of fractional extraction is applied. Absolutely essential in the design of such extractive resolution installations is their application within a flexible multi-purpose environment used for the production of the majority of enantiopure products. Being unable to develop new selector systems with high selectivity for each new product within the common time-frame available for process development, the extractive resolution installation should be able to separate whole classes of products (amino acids, organic acids, amines, alcohols etc.) with a single selector system in one extraction unit. As illustrated in Table 1 for the separation of various amino acid enantiomers [23] this requires design and operation at limited selectivities, typically in the range of 1.2-4.

*Table 1. Effect of amino acid on minimum number of stages required for separation with copper(II) N-n-dodecyl-L-hydroxyproline at 25 °C.*

Amino acid	Selectivity [23]	N <sub>min</sub> (-)
Alanine	1.41	20
Valine	2.86	7
Norvaline	2.40	8
Leucine	2.04	10
Norleucine	2.50	8
Isoleucine	3.54	6
Methionine	1.62	14
Tyrosine	1.25	30
Phenylalanine	1.83	11

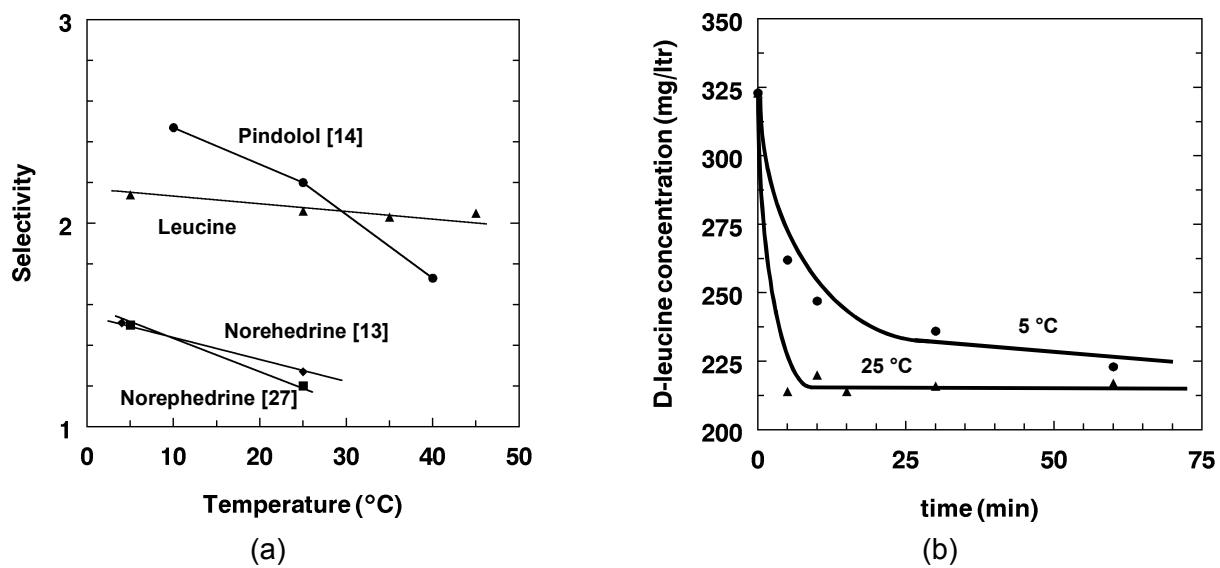

This challenge, encountered in virtually all chiral separation processes, strongly limits the application of the various technologies to those that can be staged relatively easily. The development of suitable contactors that provide competitive and reliable staging concepts will be one of the main challenges to initiate the application of extraction technology for the industrial separation of optical isomers. An idea about the minimum number of stages such contactors should provide can be obtained from the Underwood-Fenske relation. From Table 1 it can be seen that for the reported selectivities a minimum of 30 theoretical stages is required to separate all amino acid enantiomers into a 99% pure extract and raffinate containing the other enantiomer in 90% purity. This means that under practical operating conditions one can expect to need around 60 stages. Furthermore Table 1 illustrates that especially at low selectivities, a small increase in selectivity results in a significant decrease in the number of stages required. Such desired increases in selectivity are easily obtained by reducing the extraction temperature as illustrated by Figure 3a. However, as illustrated in Figure 3b, care has to be taken not to enter into a kinetically determined region where the reduction in number of stages by increased selectivity is outweighed by a larger increase in the size of each stage to allow sufficient time for mass transfer.

*Figure 3. Effect of temperature on (a) the selectivity of norephedrine (7), pindolol (8) and leucine (6) resolution with various selector systems and (b) the extraction kinetics of D-leucine with Cu(II) N-n-dodecyl-L-hydroxyproline.*

Looking at the operating conditions of various fractional extraction studies reported so far (Table 2) one easily sees that only very low racemate and selector concentrations have been applied. It is therefore not surprising that extractive resolutions have so far been discarded as uneconomical due to the reported very low overall productivities. However, besides selector and racemate solubility there is no particular reason to operate the process at such low concentrations. Even for the reported studies the racemate as well as the selector solubility easily allow operation at more than 10 times higher concentration levels. However, to be economically attractive, even higher concentration levels comparable to conditions applied in reactive extraction processes for metals recovery and purification need to be achieved. Operating the extractive resolution process at selector concentrations in the 20-30 wt% range would correspond to 0.3-0.5 M and results in approximately 100 times higher productivities. As illustrated by Figure 4, the use of higher selector concentrations has the additional advantage of increased operational selectivities because the contribution of the non-selective physical distribution of the enantiomers is reduced.

*Figure 4. Effect of selector concentration on the apparent selectivity for the resolution of DL-leucine (10 mM) with Cu(II) N-n-dodecyl-L-hydroxyproline at 25 °C.*

## CONCLUSIONS

Separation of enantiomers by extractive resolution has been proven technically feasible for the resolution of amino acids, amino alcohols and organic acids. However, a large amount of work still needs to be done to transform the reported analytical concepts into an industrially applicable multi-purpose technology. The encountered intrinsically low selectivities limit the possible technologies to those that are easily staged in a fractional extraction concept with up to 100 stages. For economical operations of such extractive resolution processes it is essential to increase the enantiomer and selector concentrations to levels common in the reactive extraction of metal ions. Under these conditions productivity increases up to 100 times come within reach. Finally it is of great essence to extend the application of extractive resolution towards other classes of enantiomers such as amines, alcohols, esters and ethers to be able to deal with the broad variety of products originating from the life-science industry.

## MASS TRANSFER PERFORMANCE OF TWO-PHASE ELECTROPHORESIS WITH AN EMULSION SOLUTION AS ORGANIC PHASE

J. G. Liu, G. S. Luo, S. Pan, S. L. Zhai and J. D. Wang

Department of Chemical Engineering, Tsinghua University, Beijing, China

A two-phase electrophoresis process has been applied to the treatment of dilute organic acid solution. An electric field can both affect the primary distribution equilibrium state and enhance the mass transfer performance of a system. However, due to the low electric conductivity of the organic phase, the electrical efficiency can be low. In order to achieve higher efficiencies, a new system has been proposed. In this system the organic phase has been replaced with an emulsion solution of 49.9 wt% kerosene / 49.9 wt% water / 0.2 wt% Tween. Results show that the electrical resistance is significantly reduced. In addition electro osmosis is shown to be much lower than for an electrodialysis process, and the concentration of acid is increased severalfold. The effects of initial concentration and current density on current efficiency and on the recovery of organic acid are discussed.

### INTRODUCTION

The recovery of organic acids from dilute solutions is important, because of the negative environmental impact posed by their disposal. Nonetheless there are at present few efficient ways to treat these dilute solutions.

Solvent extraction is a technique commonly used in the recovery of organic acids due to high selectivities exhibited by solvents. Organic solvent requirement can however be high, and high recoveries are difficult to achieve. Electrodialysis is another technique that can be used. It can be operated in a continuous way, and does not need any regeneration steps. However, the electro osmosis in this process is a serious problem [1]. Two-phase electrophoresis is a novel separation technique, which combines the advantages of traditional extraction and electrophoresis [2-5]. It can effectively control water osmosis. In this process the heat generated by the electrode reactions can be removed utilizing the two-phase flow. Also applying an electrical field into a separation system can enhance separation efficiency. Electricity can serve as a driving force to enhance mass transfer. However the relatively low electrical conductivity of organic solvents results in a high voltage requirement for a given current density.

This work focused on the two-phase electrophoresis process where the organic phase was replaced with an emulsion solution to improve the conductivity of the whole system. The effects of initial concentration of organic acid and current density on current efficiency and on recovery of organic acid were explored. In addition electro osmosis in the two-phase electrophoresis process was investigated and compared to the case for electrodialysis.

## EXPERIMENTAL

### Reagents

All reagents were purchased from Beijing Chemical Products Company and used without any further purification. Acetic acid was of AR grade.

### Anion Exchange Membranes

AM-203 anion-exchange membrane was obtained from Shanghai Shengle Chemical Plant. The exchange capacity was 1.9 meq/g, the membrane resistance was about  $10\Omega/cm^2$ ; and the selectivity was 96%. In order to keep the size of membrane the same during the experiments, the anion-exchange membrane was immersed in the acid solution for more than 12 hours.

### Experimental Setup and Procedures

Figure 1 shows a schematic diagram of the experimental setup used. For the two-phase electrophoresis experiments, one phase was the water solution, and the other was an emulsion solution consisting of 49.9 wt% kerosene / 49.9 wt% water / 0.2 wt% Tween. To improve the electrical conductivity of the emulsion solution, a quantity of organic acid was introduced into it prior to use. The cathode was located in the water phase and the anode in the emulsion phase. Peristaltic pumps were used for circulating water and emulsion solutions. The constant current required in the operation was achieved using a DYY-III DC power supply. During the two-phase electrophoresis experiments, samples of the water phase were removed at specific intervals and analyzed by titration. A stirrer was used on the emulsion solution side to prevent phase separation of the emulsion solution.

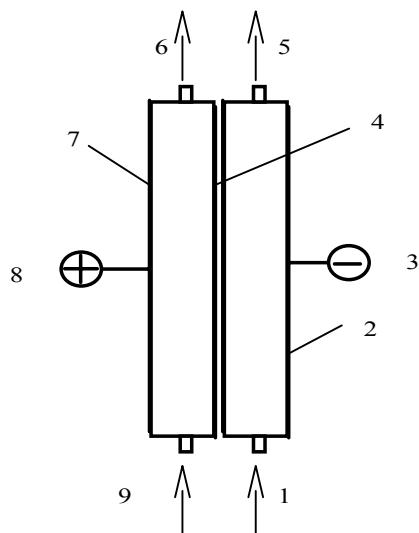

Figure 1. Schematic diagram of experimental set-up.

(1) inlet of water phase; (2) water phase chamber; (3) cathode; (4) anion-exchange membrane; (5) outlet of water phase; (6) outlet of emulsion phase; (7) emulsion phase chamber; (8) anode; (9) inlet of emulsion phase.

The current efficiency ( $\eta$ ) and recovery (R) were the two parameters used to evaluate the performance of the two-phase electrophoresis process. They were defined as follows:

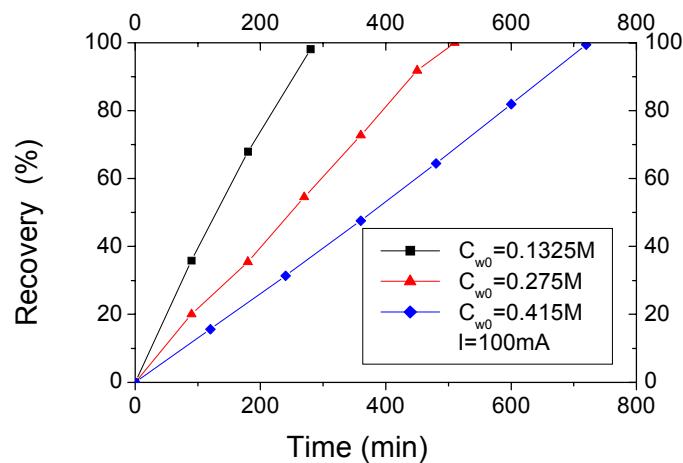

$$\eta = \frac{(C_0 V_0 - C_1 V_1)F}{It} \times 100\% \quad R = \left(1 - \frac{C_1}{C_i}\right) \times 100\%$$

where F is Faraday's constant, I the applied current, and t the time.  $V_0$  and  $V_1$  are the volumes of water phase at different times.  $C_0$  and  $C_1$  are the organic acid concentrations associated with the volumes of water phase.  $C_i$  is the initial concentration of organic acid in the water phase.

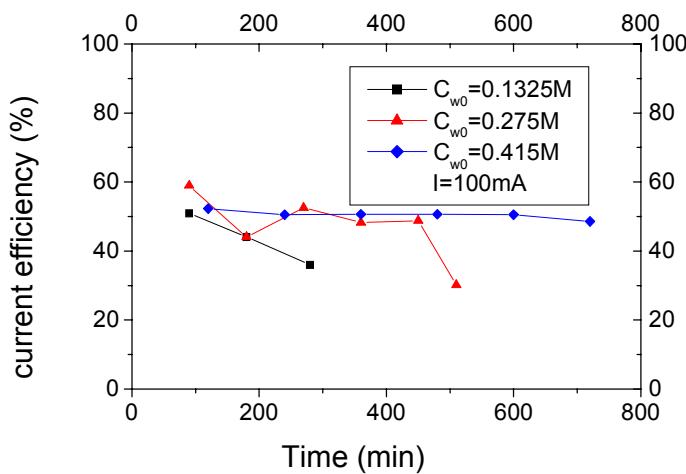

## RESULTS AND DISCUSSIONS

### **Effect of Initial Concentration on Current Efficiency and Recovery**

The effects of initial organic acid concentration on recovery and current efficiency are shown in Figures 2 and 3. In the process of two-phase electrophoresis, acid ions and hydrogen ions play an important role in current conducting. Current density plays an important role on the mass transfer rate of organic acid. To keep the same current density and change the initial concentration in water solution, the time for achieving the same recovery is increased with an increase of initial concentration. The reason is that the total amount of acid in the water phase increases but the solute transfer rate does not increase in proportion.

*Figure 2. Influence of initial concentration on recovery.*

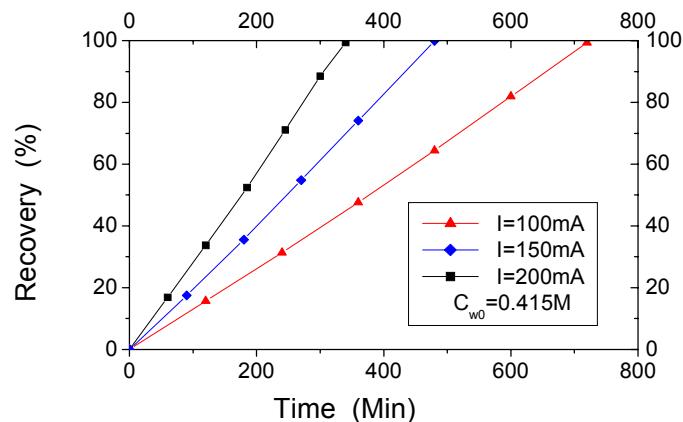

*Figure 3. Influence of initial concentration on current .*

Figure 3 shows that the overall current efficiency increases slightly with the increase of initial organic acid concentration in the water phase, which may be due to the higher electrical conductivity at the high initial acid concentration.

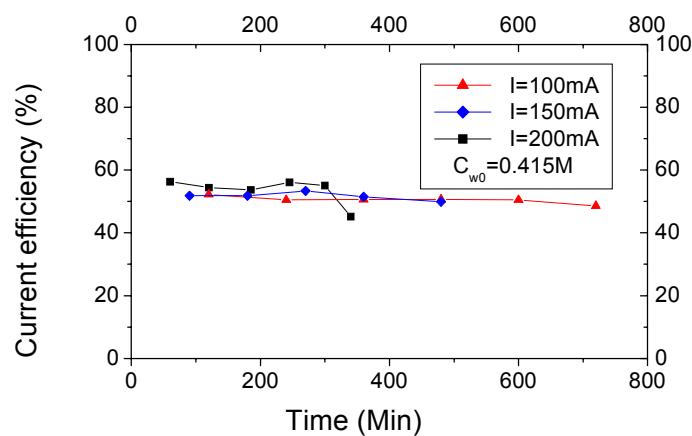

In the process, acid ions move into the emulsion phase continuously under the action of the electric field. The solute concentration of the water phase decreases during the course of the experiment. The electrical conductivity of the emulsion increases while the conductivity of the water phase decreases. When nearly all the solute in the water phase has passed into the emulsion solution, the ions that then play the greatest role in conducting current come from the electrolysis of water. As shown in Figure 3, at this time, the conductivity of the whole system decreased along with the current efficiency.

### **Effect of Current Density on Current Efficiency and Recovery**

The effects of current density on the recovery and on the current efficiency are shown in Figure 4 and Figure 5. The experimental results showed that for the same concentration, the rate of change of recovery increased with the increase in current density. To achieve a given recovery of organic acid, a shorter time is required due to the high solute transfer rate passing through the anion-exchange membrane under high current density.

*Figure 4. Influence of current density on recovery.*

*Figure 5. Influence of current density on current efficiency.*

Figures 4 and 5 showed that the effects of current density on current efficiency were relatively minor. For the same initial organic acid of water solution, the current efficiency was nearly stable during the operation for each current density.

### **Effect of Current Density on Water Electro-osmosis**

The volumes of electro-osmosis water for electrodialysis and two-phase electrophoresis are compared in Table 1. The electro-osmosis water for electrodialysis is serious. It increased with the increase of current density. In electrodialysis, electro-osmosis effects limited the concentration of organic acid on the anode side. In the process of two-phase electrophoresis, the electro osmosis is negligible and poses no limitation on acid concentration.

*Table 1. Effect of current density on water electro-osmosis.*

	Electrodialysis (0.55 M)			Two-phase electrophoresis (0.415 M)		
	50	100	150	100	150	200
Current density (mA)	50	100	150	100	150	200
Initial volume of cathode side (ml)	60	80	80	60	60	60
Initial volume of anode side (ml)	40	40	40	60	60	60
Operation time (min)	540	520	120	720	480	340
Vol. of electro-osmosis water (ml)	15	31	45	~0	~0	~0

### **CONCLUSIONS**

This study showed that when the organic phase is replaced with an emulsion solution in two-phase electrophoresis the electrical conductivity increases. When compared with electro dialysis, the electro osmosis in two-phase electrophoresis was very low. The current efficiency was about 50% in the cases of different initial acid concentrations. From the experimental results it may be concluded that the recovery of organic acid was high. Nearly complete removal of the organic acid from water phase can be achieved if the operating time is long enough. The two-phase electrophoresis process can be applied to treat dilute acid solutions with high recoveries and current efficiencies.

## STUDY ON THE THREE-PHASE EXTRACTION OF PENICILLIN G WITH A SINGLE-STEP METHOD

J. Chen, H. Z. Liu, B. Wang, Z. T. An and Q. F. Liu

Young Scientist Laboratory of Separation Science and Engineering,  
State Key Laboratory of Biochemical Engineering, Institute of Chemical Metallurgy,  
Chinese Academy of Sciences, Beijing, China

A novel three-phase extraction with a single-step method is developed for the extraction of penicillin G from the whole fermentation broth and filtered supernatant. The three phases are composed of organic solvent and two aqueous phases, which were traditionally composed of polymer and corresponding polymer or salts. The organic solvent must have low solubility compared to the polymers. In the extraction process, the extraction and purification was finished with a single step in the three phases. The color grade, water content and contamination index of butyl acetate in the first circle are used for estimating the extraction ratio and purification degree. For average results for the filtrate of fermentation broth, the color grade is 2, the water content is less than 1.03 and the contamination index is less than 0.3. For whole-broth processing, the color grade is 5, the water content is less than 1.2 and the contamination index is less than 0.28. The extraction processes, such as flocculation, demulsion, decoloration and freezing dehydration, are integrated into the three-phase extraction. The novel three-phase extraction can be recognized as an advanced method for complex systems, such as the purification of bioproducts from fermentation broths.

### INTRODUCTION

An important step in the production of antibiotics is the recovery and concentration of product from the fermentation broth in which it is produced. The physicochemical properties that distinguish the desired solute from other fermentation products must be exploited in the selection of an appropriate separation technique for this step. Physical sorption, ion-exchange (IX) and solvent extraction (SX) have all been employed successfully in isolation of different antibiotics. For the extraction of penicillin G, the simple adsorption operation has the characteristics of low selectivity, high labor need and low reversibility. Although IX has higher selectivity and yield, it is not suitable for the low stability of the penicillin due to the long cycle. SX is an important method with relatively high selectivity and yield.

Impetus for the large-scale use of SX for antibiotics recovery was provided by the critical need for increased supplies of penicillin during the Second World War. Since that time, refinements in extractor design and improvements in fermentation technology have yielded considerable increases both in equipment throughput capacities and in overall product yields, although the basic technology itself has changed little over the years[1]. But SX requires some complex processes, such as flocculation, demulsion, decoloration and freezing dehydration, for the further purification of antibiotics, and it is still necessary to operate the costly podbielniad, Alfa-Laval and other centrifugal contractors in the plant.

During the past decades, the main progresses of antibiotics industry have been focused on solvent selection. Treybal [2] and King [3] have documented several criteria that should be considered in the selection of solvents for extraction processes in general. Yang [4] has reported that a new mixed solvent can be used to increase the yield by improving the pH values to 2.5 - 5 to minimize the solute degradation by acid hydrolysis. Yang [5] has also patented a new extractant used in the extraction process without demulsifier. Qi [6] has studied the extraction by alcohol, which was superior to the BA solvent in some aspects. With the development of antibiotics, there are urgent needs for the new extraction methods such as UF membrane separation showing high extraction ratios and low demulsion to the penicillin extraction. But these are only used to clarify fermentation broths instead of rotary pricoat filters, and do not give any downstream benefits [7]. Pan *et al.* [8] reviewed the progress of aqueous two-phase extraction in antibiotic separations, but low extraction ratio and high cost limited its application.

In this paper, a new method of three-phase extraction with a single step is presented to overcome the defects of present techniques for both filtered broth and whole fermentation broth. The extraction and purification of penicillin G in the three-phase system will be finished with single step, and the target product and by-products will be separated into different layers together. The product quality was improved and the technique was greatly simplified.

## EXPERIMENTAL

80 g clean, filtered supernatant or whole fermentation broth, 12.5 g polyethylene glycol and 15 g ammonia sulphate were placed together in a stoppered tubes. These were shaken for half an hour, then the aqueous two phases were formed. 50 ml BA was added into the mixture solution, and 10% sulfuric acid was added to adjust the pH to 1.8~2.2. The centrifugation was needed after drastic agitation. There were four layers for the filtered supernatant: clear organic phase at topside, a very thin layer of emulsion at second layer, a deep color aqueous phase at the third layer, and a clear aqueous phase at the bottom phase. The clear organic phase was taken out to check its penicillin concentration, color grade, water content and contamination index. For the whole fermentation broth, three layers can be seen clearly: clear organic phase at topside, the liquid and solid mixture of mycelium and dark color matter at middle phase, and a clear aqueous phase at the bottom phase.

Penicillin concentration was measured by polarimeter for its polarizability, which was in proportion to its concentration. Micro-water content was measured by Karl-Fischer titration. Color degree was determined through the method of comparing the standard color degrade. Contamination index was the ratio of foreign acid to penicillin acid, and the foreign acid was the difference between the total acid and penicillin acid in the loaded organic phase. The present techniques standard of first cycle BA check was provided by North China Pharmaceutics Company.

## RESULTS AND DISCUSSION

As shown in Tables 1 and 2, the results of the organic solvent in three-phase extraction with the single step was all better than the present standard at different batch filtered supernatant and different molecular weights of PEG. The quality of the organic phase after first circle was improved and the process was simplified. The emulsion during the extraction process was still lowered deeply. The quality of the product by the three-phase extraction is shown in Table 3.

*Table 1. Extraction results of the filtered supernatant with three-phase extraction (O/A=1/2, T=18°C).*

Molecular weight of PEG	Organic phase	Biological activity (u/ml)	pH	Extraction (%)	First circle butyl acetate measurement		
					Color degree	Water (%)	Contamination index
6000	BA	35181	2	97.1	Pure Penicillin G solution		
1000	BA	31486	2	95.1	2 <sup>-</sup>	1.01	0.29
2000	BA	31486	2	97.7	2 <sup>+</sup>	0.99	0.27
4000	BA	32800	2	91.1	2	1.02	0.21
6000	BA	28896	2	90.0	2	0.93	0.26
6000	BA + 2.5% butyl alcohol	33800	4	84.3	2	1.32	0.34
4000	BA+T <sub>2</sub> Demulsifier	32800	2	88.5	3	1.24	0.30
Mixing 1000, 2000, 4000 and 6000	BA	32425	2.5	83.0	1 <sup>+</sup>	1.00	0.26

*Table 2. Comparison between three-phase extraction with present standard techniques.*

	Color degree	Water (%)	Contamination index	Emulsion status	Extraction (%)
Present techniques	4~5	1~ 1.3	0.3 ~ 0.4	Demulsifier and centrifugation was needed to demulsify	> 95% in 3-step extraction
Three-phase extraction with single step	2	< 1.03	< 0.3	Without demulsifier, centrifugation was enough	see Table 1

*Table 3. The crystallization of potassium salt of penicillin G.*

Biological activity (u/mg)	Appearance	pH	Density (g/cm <sup>-3</sup> )	Melting point (°C)	264 nm	280 nm	325 nm	400 nm
1598 (1597)	White crystal powder	6.0 (6.0)	4.28 (4.26)	215 (215)	0.870 (0.890)	0.071 (0.067)	0.116 (0.176)	0.894 (0.922)

The data in brackets show typical values for the product using the current extraction method.

The extraction and purification were finished in the single step since the steps of demulsion, freezing dehydration and decoloration in present techniques were omitted. Because the aqueous two phases were formed by adding high polymer PEG and ammonia sulphate, the effect of adsorption of color matter, sedimentation of protein and flocculation of protein was enhanced. The aqueous two phases were used as the liquid filtration membrane, which hold back the color matter, protein and other organic acid, while the penicillin acid can pass through it smoothly.

Compared with the aqueous two phase extraction, penicillin asymmetrically partitioned in the system of 11.6% PEG 6000, 13.9% ammonia sulphate aqueous two phases. The partition coefficient was 18.7, and the volume ratio of top phase to bottom phase was 0.34. The extraction of the top phase was 42.7%. The complex back treatment and longer phase separation time were still limitations to its application [9], although low emulsion and denature in aqueous two phases were prominent characteristics for penicillin extraction. In the three-phase system of the same weight of PEG and ammonia sulphate, the percentage of extraction was 90.0%, water content 0.93, contamination index 0.26, color degree 2 (Table 1). In the three-phase system, the viscosity of aqueous two phases was lowered, and the extraction speed was enhanced.

It is shown in Table 4 that the quality of the first stage BA was also better than the present techniques for the whole fermentation broth, and nearly equal to the standard for the filtered broth. Three-phase extraction with single step will still improve the penicillin quality of extraction from the whole fermentation broth.

*Table 4. The extraction result of the fermentation broth with three-phase extraction  
(O/A=1/2, T=18°C.)*

Molecular weight of PEG	Organic phase	Biological activity (u/ml)	pH	Extraction (%)	First stage butyl acetate check		
					Color degree	Water (%)	Contamination index
6000	BA	52000	2	80.1	4 <sup>+</sup>	1.10	0.25
6000	BA	50960	2	83.2	5 <sup>-</sup>	1.10	0.22
1000	BA	52100	2	76.1	5 <sup>-</sup>	1.06	0.24
2000	BA	52100	2	73.0	5 <sup>-</sup>	1.06	0.27
4000	BA	52100	2	78.0	5 <sup>-</sup>	1.23	0.28

Filtration was omitted during its extraction for the whole fermentation broth, during which the biological activity loss will be 10~20% at this step. So, extraction directly from the whole fermentation broth was a tendency for its advanced development. The costly advanced Decantor extractors are widely used in the world, and it was necessary to select suitable demulsifier and control the solution viscosity to improve the extraction of Penicillin G. The three-phase extraction with single step method will omit the procedures of filtration, flocculation, demulsion and decoloration, and produce a higher quality product. The detailed comparison between the three-phase extraction with single step with present techniques is shown in Table 5.

There are complex phenomena for the aqueous two-phase extraction from the whole fermentation broth. Four layers appeared after the extraction: top phase, interface phase, bottom phase and solid phase. The multiple phases and low extraction coefficient will limit its application. With the three-phase system, the percentage of extraction was 77.0 %, water content 1.1, contamination index 0.25 and color degree 4<sup>+</sup>. Another advantage was that it is easier to deal with different phases respectively and recycle in the middle phase.

*Table 5. Comparison between three-phase extraction with present techniques for the whole fermentation broth.*

	Equipment	Pretreatment	After treatment	First stage BA check	Extraction ratio
Present standard technique	Decantor extractor	suitable demulsifer, and certain viscosity	Bulky solid and liquid volume	Color degree < 5 Water < 1.3 % Contamination index < 0.3	Higher
Three-phase extraction with single step	Simple stirrer and centrifugal equipment	Without pretreatment	The liquid and solid mixture of mycelium and dark color matter gather in the top aqueous phase with small volume	Equal to the present techniques of filtered supernatant (Water < 1.2%, contamination index < 0.28, color degree ≤ 5)	Higher than 73% in single stage

## CONCLUSIONS

The three-phase extraction with a single step has been shown at the laboratory scale to greatly improve the product quality of penicillin and simplify the present complex techniques. The novel three-phase extraction can be recognized as an advanced method for complex systems such as purification of bioproducts from fermentation broth and Chinese medicine.

## EXTRACTION OF DRUG TRACES WITH LIQUID MEMBRANE SYSTEMS

Manfred Grote, Bedia Haciosmanoglu, Jürgen Nolte\*

University of Paderborn, Paderborn, Germany

\* Institute of Spectrochemistry and Applied Spectroscopy, Dortmund, Germany

Bulk-membrane experiments were carried out in a three-compartment transport cell. The liquid membrane system consists of an aqueous feed solution containing drugs of environmental concern (Ibuprofen, Diclofenac, Carbamazepin and Sulfamethoxazol) as analytes, a liquid membrane (organic solvent combined with a mobile carrier) and an aqueous stripping solution (e.g., mineral acids, salts or alkalies). Different solvents, admixed organic amines or acids as well as a pH-gradient between feed and strip-phase have been used to optimize the efficiency and selectivity of the transport of drugs across the bulk membrane. Complementary permeation studies are carried out applying biological flat sheet membranes such as the small intestine of sheep.

### INTRODUCTION

Pharmaceuticals are released into the environment mostly through sewage. The concentrations of drugs and their metabolites found in sewage treatment plant's effluents or rivers are in the range of micrograms to nanograms per liter [1]. As a consequence there is an urgent need to improve the purification of water and waste-water and to monitor the drug input of the waterways particularly of surface and groundwater.

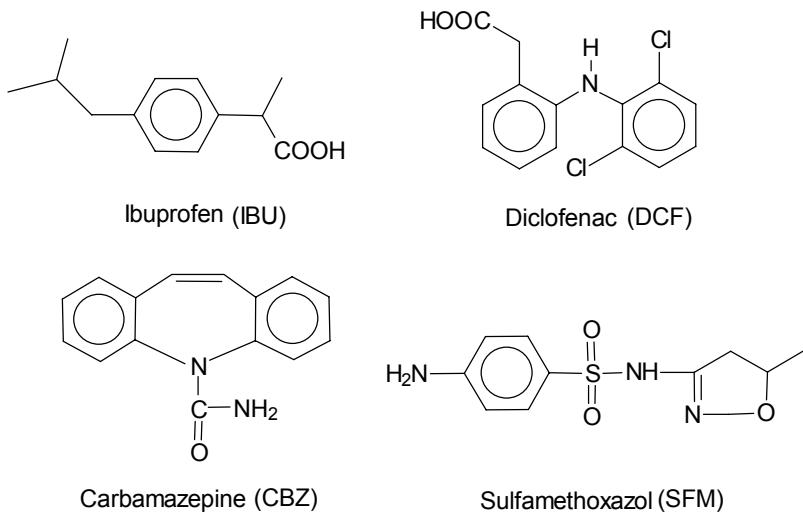

Figure 1. Drugs used for liquid membrane transport.

For this purpose reliable and efficient sample separation and preconcentration methods must be developed, which enable the reliable determination of trace amounts of drugs in complex matrices. As has been demonstrated in the analysis of herbicides in natural water samples by means of HPLC, liquid membrane techniques offer a more selective sample pretreatment compared to solid-phase extraction [2,3]. Furthermore, supported liquid-liquid extraction or membrane systems (SLP) can be used on-line with liquid chromatography [2,4]. Also badge-type passive samplers have been constructed applying different liquid trapping media for trace amounts of analytes in complex aqueous matrices [5].

The purpose of the present study is to examine the applicability of certain bulk three-phase liquid membrane-systems and also biological membranes for the separation of various basic and acidic drugs of environmental concern from dilute aqueous solution. The compounds selected were (Figure 1): *Ibuprofen*, *Diclofenac* (anti-inflammatory), *Carbamazepin* (antiepileptic) and *Sulfamethoxazol* (human and veterinary antibiotic).

The mass transfer of the analytes through the liquid phases (feed / membrane / strip) was carried out in a three-compartment cell equipped with an agitator. Such a bulk membrane cell was already operated for carrier facilitated transport of precious metal ions [6]. The results of these investigations are compared with the permeability of the drug mixtures through solid flat sheet membranes of biological origin. Details of this part of current research will be described elsewhere.

## EXPERIMENTAL

### Chemicals, Reagents and Stock Solutions

Carbamazepine (CBZ), Ibuprofen (IBU), Diclofenac (DCF) sodium salt and Sulfamethoxazol (SFM) were purchased from Sigma (Deisenhofen, Germany). The purity of the drugs was > 98%. The organic solvents used for the liquid-membrane-systems were decane, decanol and dihexylether (Sigma, Germany). Sodium octanesulfonic acid, tri-*n*-octylamine and tetrahexylammonium chloride used as carrier were of analytical-reagent grade (Merck, Darmstadt). Sodium dihydrogen phosphate monohydrate was used for mobile phase and was of analytical grade. Acetonitrile and methanol used for liquid chromatography were of HPLC grade.

Stock solutions of drugs were prepared in methanol. A series of standard solutions for calibration in the range 0.25-10 mg/dm<sup>3</sup> was obtained by diluting of aliquots of the appropriate stock solution with bi-distilled water.

### HPLC Analysis

Drug concentrations of the different liquid phases were determined by high performance liquid chromatography (HPLC). The samples were introduced into the chromatographic system by an autosampler (Gilson-Abimed Model 231 equipped with Dilutor 401) and an isocratic pump (Waters Model 590). A variable ultraviolet-visible detector 655 Å was connected to a chromato-integrator 2000-D (Merck-Hitachi). The analytical column used was LichroCART RP 18 (5µm, 250 x 4 mm; Merck). The flowrate of the mobile phase was 1.0 cm<sup>3</sup>/min with an average operating pressure of 130 bar. Detection was performed at 225 nm. The mobile phase consisted of a mixture of 60 mmol/dm<sup>3</sup> NaH<sub>2</sub>PO<sub>4</sub>: acetonitrile (50:50 v/v). Retention data (*t*<sub>R</sub>) of the analytes: SFM: 3.3 min, CBZ: 4.60 min, DCF: 10.68 min, IBU: 12.81 min.

### Membrane Equipment and Procedure

The liquid membrane system consisted of an aqueous feed solution containing the analyte, a liquid bulk-membrane (organic solvent with and without a dissolved mobile carrier) and an aqueous stripping solution (e.g., mineral acids, salts or alkalies). As shown schematically in Figure 2, the three-phase system was established in a home-made glass cell equipped with an agitator (PTFE). The cell consisted of two concentric chambers dividing it into separate compartments. Thus, the feed is allowed to contact the bulk-membrane and the strip solution to contact the membrane. The whole cell was covered by a fitting glass lid in order to minimize loss of solvent by evaporation.

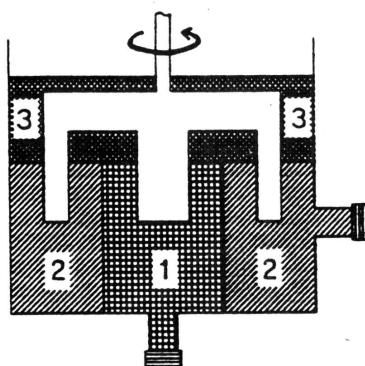

Figure 2. Three-phase liquid membrane system (1: Strip phase, total volume: 25 cm<sup>3</sup>; 2: Feed phase: 32 cm<sup>3</sup>; 3: Membrane phase, 20 cm<sup>3</sup>).

After careful loading of the cell with the three liquids the experiment was started under synchronously and continuously stirring at a fixed frequency of 60 rpm, so that the transport reactions were predominantly controlled by diffusion. In order to monitor the transport of the drugs through the membrane system by HPLC, aliquotes were taken from the phases in intervals by means of a microliter syringe which was introduced through self-closing seals and analyzed.

### RESULTS

In this work the transport of the acidic or basic drugs *Ibuprofen*, *Diclofenac*, *Carbamazepin* and *Sulfamethoxazol* (Figure 1) across different liquid membranes was measured. The membrane configuration employed (Figure 2) allows extraction and back-extraction in one unit. The experimental conditions were chosen by taking into account the following basic considerations. Among other factors the efficiency and selectivity of the bulk membrane is markedly influenced by the composition of the organic phase through which permeation will occur. Using common water-immiscible organic solvents the distribution of the analyte molecules governs the extent of extraction from the sample matrix. However, the mass transfer across the two feed/organic and organic/strip interfaces can be facilitated by mobile carriers. In such a case formation and dissociation reactions of ion-pair complexes near the interfaces are important for both the forward and back-extraction and, hence, the pH-gradient between the aqueous feed and strip phase will also influence the overall transport process. As a consequence for the present study the composition of each of the three liquid phases employed was adjusted to basic properties of the analytes such as their solubility in water and organic solvents, polarity and acid-base behaviour.

The extraction of the weak acid Ibuprofen and the amphoteric Diclofenac was determined by applying decane, decanol or dihexyl ether as membrane solvents, individually or combined. These solvents were used with and without admixed organic amines (tri-*n*-octylamine, TOA; tetrahexylammonium chloride, THAC) or octane-1-sulfonic acid (OcSA) as mobile carriers.

Furthermore a pH-gradient between feed and strip-phase has been used to optimize the effectivity of the extraction processes. As examples, the following results were obtained for the drugs investigated. If not otherwise stated, the concentration of each analyte in the aqueous feed was 10 mg/dm<sup>3</sup>.

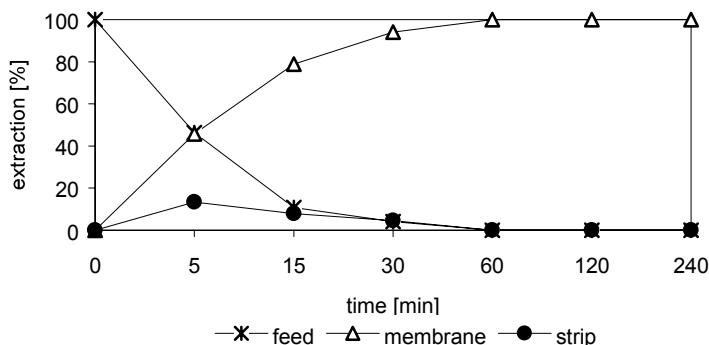

### Transport of Ibuprofen

Complete extraction of Ibuprofen from dilute aqueous solution was achieved within 1 hour simply by applying 1-decanol as the bulk-membrane (Table 1). Not unexpectedly, the rate of transport of the weak acidic analyte ( $pK_a = 4.41$ ) was markedly enhanced by adding of basic liquid surfactants such as tri-*n*-octylamine, TOA, or tetrahexylammonium chloride, THAC [7].

**Table 1:** Transport of Ibuprofen: effect of membrane composition on forward extraction.  
(Feed: 10 mg/dm<sup>3</sup> Ibuprofen; carrier: 1g/dm<sup>3</sup>; strip: 2 mol/dm<sup>3</sup> HClO<sub>4</sub>).

Membrane phase	Carrier	Time [min] to achieve ~100% extraction
1-decanol	-	~120
1-decanol	THAC	~60
1-decanol	TOA	~30
decane/decanol (8 : 2 v/v)	THAC	~30

Particularly, the presence of the tertiary amine TOA increases the effectivity of forward-extraction drastically. However, the THAC-modified systems behave similarly when a mixture of 1-decanol and an excess of non-polar decane was used as the membrane solvent.

**Figure 3:** Carrier-facilitated transport of Ibuprofen across a three-phase membrane.  
(Feed: 10 mg/dm<sup>3</sup> Ibuprofen in water, membrane: 1g/dm<sup>3</sup> THAC in 1-decanol,  
strip: 2 mol/dm<sup>3</sup> HClO<sub>4</sub>).

It is assumed that the formation of ion-pairs between the mono-carboxylic acid and the carrier-amines proceeds rapidly at the feed/organic interphase compared to diffusion across the liquid membrane (Figure 3).

Stripping of Ibuprofen from the loaded membranes is not possible by the action of dilute hydrochloric acid. Perchloric acid (2 mol/dm<sup>3</sup>) displaces the extracted analyte to some extent due to the strong competing effect of the perchlorate anion (Figure 3). Obviously, re-extraction occurs which is particularly pronounced when TOA dissolved in 1-decanol was used as bulk-membrane and sodium perchlorate as the stripping agent: after 4 hours ~ 25% of the loaded Ibuprofen were back-extracted and 8 hours later this value was diminished to 5%. However, the most efficient membrane transport was observed from a 0.1 mol/dm<sup>3</sup> HCl feed by using octane-1-sulfonic acid, OcSA, as liquid ion exchanger dissolved in dihexyl ether and sodium carbonate solution as the stripping phase (Figure 5).

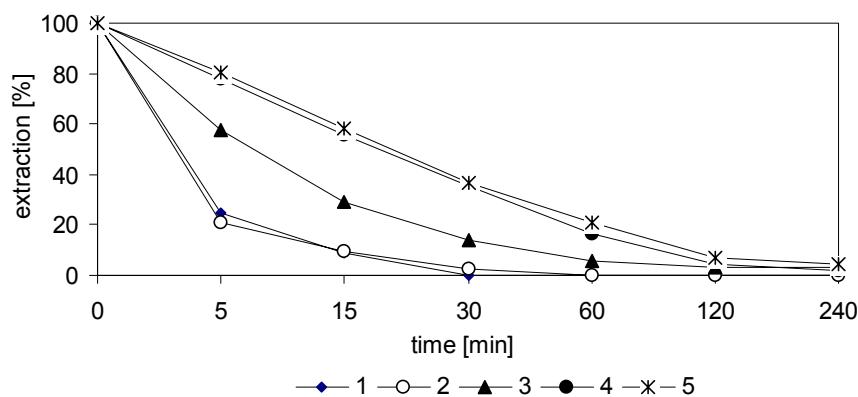

### Transport of Diclofenac

Diclofenac an amphoteric compound ( $pK_a = 4.18$ ) is sparingly water-soluble, therefore its sodium salt was used for preparing the aqueous feed [7]. Various membrane phases were composed utilizing decanol, decane and also dihexyl ether as solvents. Furthermore, amine based membrane-carriers were used and also OcSA, as an acidic ion-pairing reagent. In Table 2 some of the membrane systems employed are listed.

Figure 4 reveals clearly an order of extraction efficiency showing the carrier mediated transport by means of TOA and THAC dissolved in decanol or decane to be the most efficient one. Addition of the acidic carrier did not result in a higher extractability. By contrast, the transport of Diclofenac into the dihexyl ether phases proceeds much more slowly and to a lower extent compared to the latter systems.

*Table 2: Transport of Diclofenac: composition of three-phase membrane systems. (Feed: 10 mg/dm<sup>3</sup> Diclofenac sodium, basic carrier: 1g/dm<sup>3</sup> of amine, acidic carrier: 0.25 g/dm<sup>3</sup> OcSA).*

No.	Membrane phase	Carrier	Strip phase
1	Decanol	TOA	2 mol/dm <sup>3</sup> HClO <sub>4</sub>
2	decane:decanol (8:2 v/v)	THAC	2 mol/dm <sup>3</sup> HClO <sub>4</sub>
3	decane:decanol (11:1 v/v)	OcSA	0.1 mol/dm <sup>3</sup> NaOH
4	dihexyl ether	-	0.1 mol/dm <sup>3</sup> NaOH
5	dihexyl ether	OcSA	0.1 mol/dm <sup>3</sup> NaOH

*Figure 4. Forward-extraction of Diclofenac as a function of time: effect of membrane composition (membrane components: see Table 2).*

The affinity of these organic phases to the drug molecules seems to be very high as none of the acidic and alkaline stripping phases listed in Table 2 result any detectable traces of back-extracted analyte. However, by adjusting of a more pronounced pH-gradient between feed and strip phase remarkable transport effects were obtained for Diclofenac as Figure 5 demonstrates.

### Transport of Carbamazepine

In order to utilize the weak base character of Carbamazepine ( $pK_a = 13.94$ ) the membrane solvents used (Table 3) were modified by the liquid cation exchanger OcSA [7]. The highest efficiency of the carrier was achieved in the decan-decanol mixture. However, compared to the transport of Diclofenac (Figure 4) the course of forward-extraction of Carbamazepine is retarded. The extent of loading of the ether based membranes was always low.

It was found that the influence of feed acidity is small as the rates of extraction from 0.1 mol/dm<sup>3</sup> HCl are quite equal to those determined from water. However, rate and yield of stripping from the loaded decane/decanol membrane phase (Tab. 3: No. 1) by dilute sodium hydroxide solution can be increased up to ~20% (4 h) when the aqueous feed is acidified.

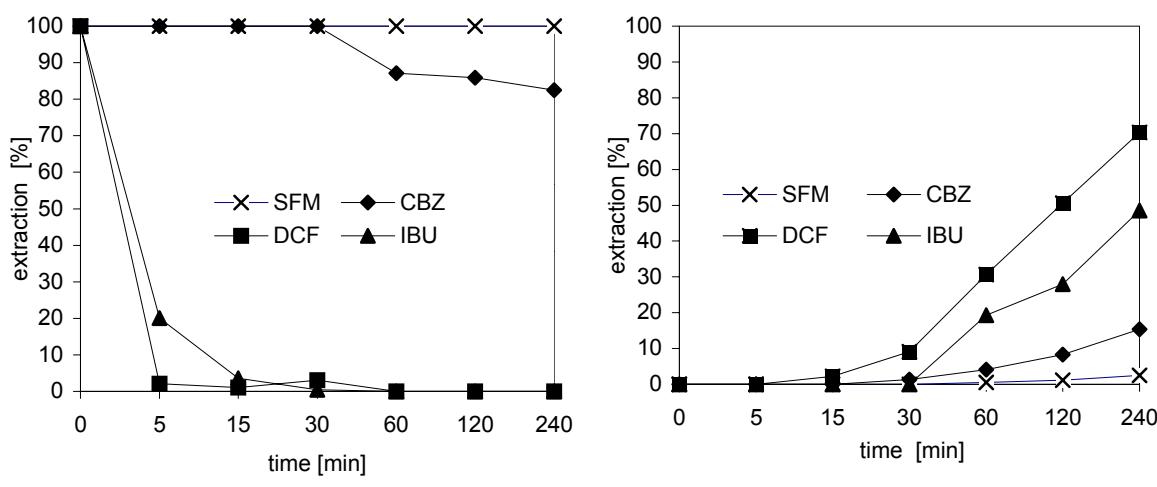

**Table 3. Transport of Carbamazepine: effect of membrane composition on extraction yields.**  
(Feed: 10 mg/dm<sup>3</sup> Carbamazepine in water, carrier: 0.25 g/dm<sup>3</sup> OcSA, strip phase: 0.1 mol/dm<sup>3</sup> NaOH; extraction time: 4h).

No.	Membrane phase	Carrier	Forward-extraction [%]	Back-extraction [%]
1	decane:decanol (11:1 v/v)	OcSA	73.2	11.0
2	dihexyl ether	-	31.0	20.3
3	dihexyl ether	OcSA	36.6	16.3

It was found that the influence of feed acidity is small as the rates of extraction from 0.1 mol/dm<sup>3</sup> HCl are quite equal to those determined from water. However, rate and yield of stripping from the loaded decane/decanol membrane phase (Table 3: No. 1) by dilute sodium hydroxide solution can be increased up to ~20% (4 h) when the aqueous feed is acidified.

### Transport of Sulfamethoxazol

Because Sulfamethoxazol, a highly water-soluble drug, contains both acidic and weak basic groups ( $pK_{a1} = 2$ ,  $pK_{a2} = 5.7$ ) transport facilitating interactions with acidic and basic carrier compounds may be possible [8]. In general, the extractability of the polar compound is poor. E. g., employing OcSA dissolved in dihexyl ether the maximum extraction yield obtained was only 13% (for comparison without acidic carrier: 5%, in decane-decanol (11:1 v/v) with OcSA: 3%). Under these conditions the extent of back-extraction by 0.1 mol/dm<sup>3</sup> NaOH was also negligible (< 3%). In contrast with Carbamazepine, Sulfamethoxazol was extracted less effectively into the liquid membrane.

**Figure 5: Transport of a drug mixture a) forward-extraction b) back-extraction.**  
(Feed phase: 10 mg/dm<sup>3</sup> of each drug in 0.1 mol/dm<sup>3</sup> HCl, membrane phase: 0.25 g/dm<sup>3</sup> OcSA in DHE; strip phase: 0.1 mol/dm<sup>3</sup> Na<sub>2</sub>CO<sub>3</sub>).

The results were improved by using TOA dissolved in decane-decanol (8 : 2 v/v) as the membrane, thus the yield of extraction could be raised to 29 %. In the alkaline strip liquor small amounts of the sulfonamide (~ 5%, 4h) were detected which were partly re-extracted after an extended time of reaction.

### **Simultaneous Transport of Drug Mixtures**

Based on the results described some three-phase membrane systems were selected for application to the transport of drug mixtures. Figure 5 reveals that the carrier mediated system based on OcSA and dihexyl ether enables the simultaneous and complete separation of Ibuprofen and Diclofenac from the acidic aqueous feed while the extractability of Sulfamethoxazol and Carbamazepin is negligible. It is striking that the extracted carboxylic acids can be stripped to a large extent by means of sodium carbonate solution.

Complementary experiments realized that the combined drugs permeate simultaneously but with different rates, however, through *biological flat sheet membranes* (e.g., the small intestine of sheep or the internal membrane of the appendix of cattle, both preconditioned by a special treatment).

### **CONCLUSIONS**

Certain types of three-phase bulk membranes employed offer a tool to separate selectively and efficiently various acidic and basic drug traces from aqueous solution. Most efficiently the carboxylic acids Ibuprofen and Diclofenac were extracted from neutral aqueous feed by combining amine based carriers and 1-decanol as the appropriate solvent. Also octane-1-sulfonic acid dissolved in dihexyl ether separates both drugs from acidic feed and makes stripping possible by alkaline liquor. This membrane phase also enables the enhanced forward-extraction of the weak base Carbamazepin from aqueous solution. In general, the extractability of Sulfamethoxazol in presence of acidic or basic carriers compound is rather restricted. The stripping of drugs from the loaded bulk-membranes by means of alkaline or acidic reagents show some differences that can be attributed to their different acid/base-behaviour.

The investigations aiming for sample preparation techniques in environmental analysis are continued including main metabolites of the drugs in order to optimize the membrane compositions and, thus their efficiency and selectivity. Developments of membrane systems based on supported liquid membranes and also solid natural and synthetic membranes are in progress.

## SELECTIVITY IN THE EXTRACTION OF CARBOXYLIC ACIDS BY AMINE-BASED EXTRACTANTS

Aharon M. Eyal, Betty Hazan, Riki Canari, Asher Vitner and Tali Reuveny

Casali Institute of Applied Chemistry, The Hebrew University of Jerusalem, Jerusalem, Israel

The selectivity of extraction from a solution containing both succinic and propionic acid by tertiary amine-based extractants was examined. The distribution coefficients for propionic acid at 30°C and 75 °C are about 2 and 0.94, while those for succinic are about 0.5 and 0.12, respectively. These values are true for all of the mixtures except for the case where the succinic acid level is the highest.  $K_{75C}$  for propionic acid is significantly lower,  $K = 0.71$ , and that of succinic acid is slightly higher,  $K = 0.15$ . The mutual influence of the addition of one acid to the extraction system of another was analyzed.

### INTRODUCTION

Fermentation broth solutions, like those in carboxylic acid production, are characterized by a large amount of various impurities. The most difficult impurities to separate from the product are other carboxylic acids, produced by the microorganisms or introduced with the nutrients. Hence, the selectivity in extraction of acids from aqueous solutions containing their mixture is an important issue. Only a few publications have dealt with the selectivity of extraction from a mixture of acids. Jagirdar and Sharma [1] studied the selectivity of extracting carboxylic acids by tri-n-octylamine in xylene (and in 2-ethyl-hexanol). Selectivity values (for the stronger acid) in the case of a mixture containing acetic and monochloroacetic acid were found to be in the range of 23.2 to 37.8; for monochloroacetic + dichloroacetic acid, 4 to 6.7; for dichloroacetic + trichloroacetic acid, 15.3 to 16.8; for formic + oxalic acid, 9.2 to 9.5, and for glycolic and oxalic acid, 2.3 to 4.8. Jagirdar and Sharma's conclusion was that the technique of "dissociation extraction" proposed by Anwar *et al.* [2,3] can be successfully adopted to separate dilute aqueous mixtures of organic acids. Anwar *et al.* used the dissociation extraction technique to selectively separate a stronger acid from a mixture of two acids present in an organic solvent by adding an aqueous medium containing a stoichiometric deficiency of a strong base. In their articles, they explain the advantage of using this technique in industry, and give a long list of examples for mixtures made up of two acids or two bases which can be separated successfully with the dissociation extraction technique.

Kirsch and Maurer [4] studied the distribution of citric, acetic and oxalic acids between their binary aqueous mixtures and an organic solution of tri-n-octylamine in a diluent. They found that when there is an excess of a carboxylic group in the feed over the amine, the stronger acid is preferably extracted. Moreover, based on a model which they developed for a single acid extraction, they calculated the extraction of citric and oxalic acid and found it to be in reasonable agreement with the experimental results. However, when acetic acid is one of the extracted acids, the extraction results are higher than predicted. They assumed that the higher extraction is a result of "mixed complexes" formation, *i.e.*, acetic acid molecules bind to an ion-pair of the stronger acid.

Malmary *et al.* [5] studied the extraction of tartaric and malic acids from their binary aqueous solution at several pH values. The extractants were tributylphosphate (TBP) in dodecane and triisooctylamine (TOA) in 1-octanol. They found that the weaker extractant (TBP) selectively extracts the weaker acid (malic acid) and that the amine-based extractant preferably extracts the stronger acid (tartaric acid). Their explanation was that TBP binds the undissociated acid, preferring, therefore, the weakest acid in the mixture. In the case of amine-based extractant, an ion exchange reaction take place so that the stronger acid is preferred.

The present paper adds to research done in our laboratory [6]. The selectivity of extraction from a solution containing both succinic acid and propionic acid was examined and compared with the extraction from their separate solutions.

## MATERIALS AND METHODS

### Materials

The extractant used was 0.5 mol/kg trilauryl amine - Alamine 304 (Henkel, 95%) + 10% 1-octanol (Merck, 99%) in a low aromatics kerosene, Isopar K (Exxon). The acids used were: propionic acid (BDH, 99%) and succinic acid (BDH, Analytical grade).

### Methods

2.5 g aliquots of the organic phase were mixed at 25°C for 30 min with 1 g aliquots of aqueous phases containing various concentrations of the carboxylic acids. The organic and aqueous phases were separated and centrifuged. The organic phases were washed with 1 N NaOH solution. The wash solutions and the aqueous phases were injected to the HPLC at 42°C where the column was Polyspher<sup>R</sup> OA KC (Merck), the mobile phase was 0.01 N H<sub>2</sub>SO<sub>4</sub> and the flow rate was 0.4 ml/min.

## RESULTS

Figure 1 shows the distribution of succinic acid at 30°C between the aqueous phase and the extractant, which contains 0, 0.01, 0.04 or 0.3 mol/kg propionic acid at equilibrium. In addition, it shows the distribution of succinic acid at 75°C where the organic phase contains 0 or 0.3 mol/kg propionic acid at equilibrium. This figure shows that the presence of the propionic acid in the system, up to 0.3 mol/kg in the organic phase, does not affect the distribution of succinic acid at both temperatures.

Figure 2 shows the distribution of propionic acid at 30°C in the presence of various concentrations of succinic acid (0.34 -1.3 mol/kg succinic acid in the aqueous phase and 0.17 - 0.65 mol/kg in the organic phase). It also shows the distribution of propionic acid at 75°C in systems where the succinic acid concentrations in the phases were 0.88 - 5.2 mol/kg in the aqueous phase and 0.1 - 0.78 mol/kg in the organic phase. Table 1 summarizes the data presented in Figure 2 (except for propionic acid distribution in the absence of succinic acid), as well as the calculated distribution coefficients ( $K = [acid]_{org}/[acid]_{aq}$ ) and the selectivity to propionic acid ( $K_{propionic}/K_{succinic}$ ).

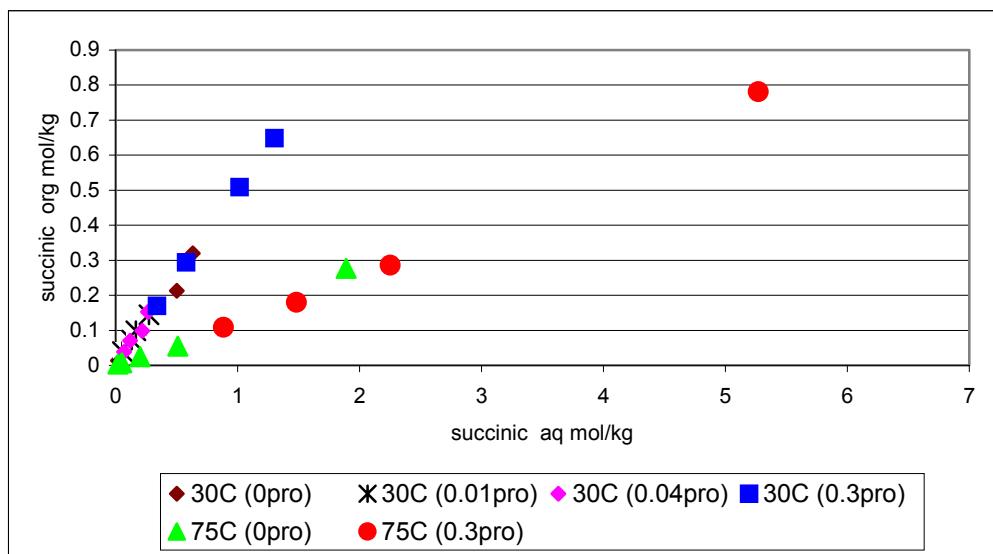

Figure 1. Extraction of succinic with or without propionic acid by Alamine 304 + 10% 1-octanol in kerosene.

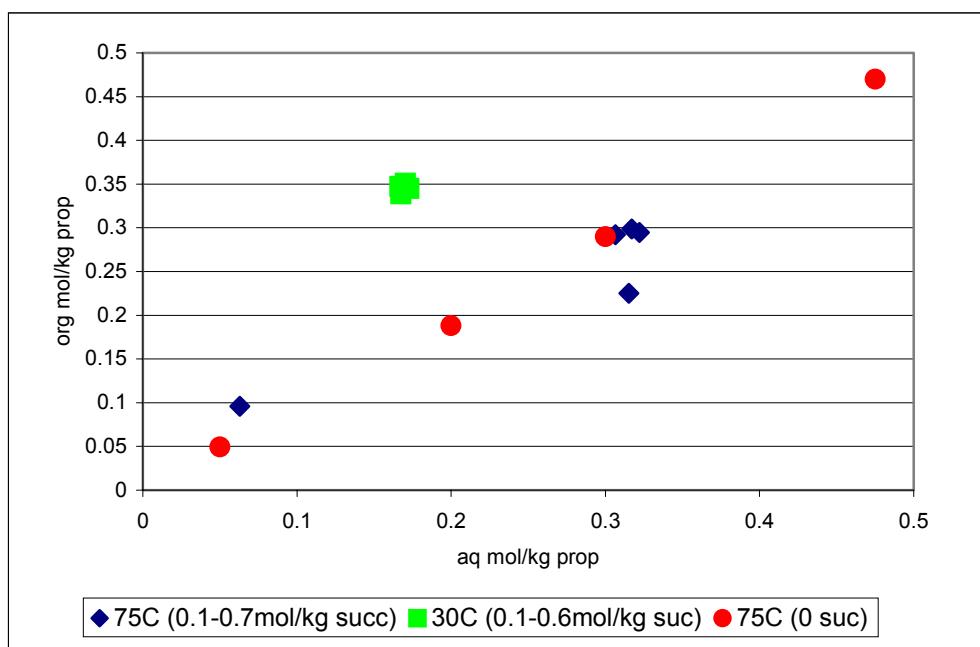

Figure 2. Extraction of propionic with or without succinic acid by Alamine 304 + 10% 1-octanol in kerosene.

Figure 2 and Table 1 show that:

1. The values of the distribution coefficients ( $K$ ) for propionic acid extraction at 30°C are about 2, while those for succinic acid at that temperature are about 0.5.
2. The  $K$  values of propionic acid at 75°C are about 0.94 and those for succinic acid at that temperature are about 0.12. These values are true for all of the cases except for the case where the succinic acid level in the system is the highest.
3. In that case (Exp. 4, 75°C, 0.78 and 5.27 mol/Kg succinic acid in the aqueous and organic phase, respectively) the propionic acid extraction is significantly lower,  $K = 0.71$  (compared with 0.94), and that of succinic acid is a slightly higher,  $K = 0.15$  (compared with 0.12).
4. Selectivity to propionic acid is about 4.0 at the lower temperature and about 7.6 at the higher one, except for case of the highest succinic acid level where it is 4.8.

## DISCUSSION

### Propionic Acid Extraction

The extraction of propionic acid by tertiary amine-containing extractants was examined in the past in our laboratory [7]. The IR spectrum of the loaded organic phase (where the amine:propionic acid molar ratio was 2:1) showed a large peak that refers to the undissociated acid (at about  $1720\text{ cm}^{-1}$ ). This result indicates that, although free amine molecules were present in the organic phase, ion pair formation is not the dominant mechanism and that the acid is preferably extracted through H-bond and/or dipole-dipole interactions in the organic phase. This conclusion was supported by the results of Yang and his co-workers [8] who found that propionic acid extraction by 100% Alamine 336 is similar to its extraction by 100% 2-octanol. The results presented here show that although the propionic acid is preferably extracted through H-bond or/and dipole-dipole interactions in the organic phase, its distribution constants are high,  $K(30^\circ\text{C}) \sim 2$ . This high distribution is due to its hydrophobic properties.

### Succinic Acid Extraction

The pH of half neutralization with HCl ( $\text{pH}_{\text{hn}(\text{cl})}$ ) of extractants containing the tertiary amine and low octanol content was determined to be about 4.5 [7]. Based on our conclusions (in the same publication), in a case where the  $\text{pH}_{\text{hn}}$  is higher than the  $\text{pK}_{\text{a}1}$  of the acid, ion pair formation will take place preferably over H-bond or/and dipole-dipole interactions. This is also true for the present case, since the  $\text{pK}_{\text{a}1}$  of succinic acid is 4.2 and since that acid is quite hydrophilic. Yet, since succinic acid is a relatively weak acid, its distribution constants, as found here, are relatively low -  $K(30^\circ\text{C}) \sim 0.5$ .

### Selectivity

In those cases where the presence of one acid does not affect the extraction of the other, the selectivity of extraction from a two-acids solution is equal to the ratio of their distribution constants in single-acid systems. That is the case in most of the extraction systems tested here and, as a result, the extraction is selective for the propionic acid ( $S(\text{propionic } 30^\circ\text{C}) \sim 7.6$ ).

### Mutual Influence

Adding an acid (II) to an extraction system of another acid (I) may affect both phases in various ways (see Table 2). The acids may compete with each other for their interaction with the amine and, as a result, the extraction of acid (I) will decrease. On the other hand, the extraction of acid (I) may increase since the organic phase hydrophilicity increases by the

addition of acid (II). In this case, acid (II) may act as a polar diluent (enhancer) in the system. Still another possible effect in the organic phase is increasing the above-stoichiometric extraction. Tamada *et al.* [9] showed that, in the case of propionic acid extraction by trioctylamine, the above-stoichiometric extraction is energetically favored over the stoichiometric extraction,  $K_{(1,1)} < K_{(2,1)}$  (where  $K_{(1,1)}$ ,  $K_{(2,1)}$  are the association constants for the stepwise reaction of 1:1 and 2:1 acid to amine in the organic phase). Thus, addition of another acid in the case of propionic acid extraction may increase the propionic extraction.

*Table 2. The effects of the adding acid (II) into solutions containing acid (I).*

	The effects of the adding acid (II) into solutions containing acid (I)	The effect on extraction of acid (I)
1	<b>Organic phase</b> Competition for the interaction with the amine	decrease
2	Increasing the hydrophilicity of the organic phase	increase
3	Increasing the over-stoichiometric extraction	increase
4	<b>Aqueous phase</b> decreasing the hydrophilicity of the aqueous phase	decrease
5	Salting out- reducing water activity	increase
6	Reducing the pH	increase

The addition of acid (II) at high concentrations also affects the properties of the aqueous phase. This addition decreases the hydrophilicity of that phase and thereby increases the interaction of organic acid (I) there. As a result, the extraction of acid (I) is expected to decrease. On the other hand, salting out affects the extraction in the opposite direction. Water molecules of hydration of acid (II) release acid (I) to transfer into the organic phase, increasing, thereby, the extraction of acid (I). Another effect may be on the pH of the aqueous phase. Harris and Geankoplis [10] showed that addition of sulfuric acid increases the propionic acid extraction by methylisobutyl ketone. Kertes and King [11] explained the increase by the suppressing of the dissociation of the weak carboxylic acid due to the pH decrease. In each extraction system, all these effects apply simultaneously. The net effect on the extraction is determined by the relative contribution of each effect.

The results here show that, in the system where the succinic acid concentration was the highest, propionic acid extraction was significantly lowered,  $K = 0.71$  (compared with 0.94), and that of succinic acid was slightly increased,  $K = 0.15$  (compared with 0.12). Therefore, the dominant effects in the case of propionic acid may be analyzed based on Table 2. The only two effects resulting in decrease of the extraction are No. 1 and 4: competition for the interaction with the amine and increase of the aqueous phase hydrophobicity. Which of these effects dominate our system? Based on the extraction mechanism of propionic acid, the first does not seem to be the main one since the propionic acid is preferably extracted through H-bond or/and dipole-dipole interactions and not through ion pair formation (see above). Moreover, the succinic acid loading in the organic phase at 30°C was very close to that at 75°C. Therefore, one would expect that, if the competition was the main effect, the same tendency of decrease in the propionic acid extraction would be seen. By elimination, in our case the main effect seems to be the increase of the aqueous phase hydrophobicity. One should keep in mind that at 75°C the acid solubility in the aqueous phase is extremely high and, that in the case discussed here, the succinic acid concentration in the aqueous phase was 5.27 mol/kg which is about 62%. A simple calculation shows that the concentration of the water in this aqueous phase is about 20 mol/kg (100% - 62% (succinic) - 2% (propionic)/18) and that of the carboxylic groups is about 11 equivalent COOH groups per kg aqueous solution (5.27 (succinic) \* 2 + 0.3 (propionic)). In this case, the molar ratio is less than two water molecules per one carboxylic group, which is a relatively hydrophobic medium.

# OPTIMISATION OF PROCESS CONDITIONS FOR INDUSTRIAL SEPARATION OF AMINO ACID ENANTIOMERS BY FRACTIONAL REACTIVE EXTRACTION

Maartje Steensma, Norbert J.M. Kuipers, André B. de Haan and Gerard Kwant\*

University of Twente, Enschede, The Netherlands  
\*DSM Research, Geleen, The Netherlands

The influence of process parameters on the chiral separation of amino acids by reactive extraction has been investigated experimentally. Compared to literature results for this separation, the process capacity can be increased substantially without much effect on the separation factor by increasing the concentration level of enantiomer and limiting the excess of extractant to a minimum. A slightly higher temperature, a pH of 6 and a polar solvent also have a positive effect on the process capacity. The separation factor could not be optimised much further. Careful selection of process conditions results in a potential productivity increase of 10-50 times.

## INTRODUCTION

In the life science industry, there is an increasing demand for optically pure substances. Direct synthesis of the pure enantiomers is desirable, but often impossible or difficult. As the current chiral resolution methods are either inflexible or not suitable for large-scale production, there is a need for a flexible industrial-scale chiral separation method. On lab scale, reactive fractional extraction has been shown to be a promising concept, but the productivity is yet far too low for commercial production [1-4]. From these studies, it has become clear that temperature, pH and solvent are important in process design, and it can be expected that concentration ratios and absolute concentrations of enantiomer and extractant also play an important role. Systematic study of the influence of these process parameters is therefore necessary for further development of this technique.

The aim of the current study is to determine experimentally the influence of parameter changes (concentrations, pH, temperature, and solvent composition) on selectivity and capacity in a single extraction step. The results can subsequently be used in process development and may be helpful in screening of new extractants for chiral separations. It will be shown that optimisation of process conditions results in a much more productive process.

The extraction operation proposed for this separation is fractional extraction. In this scheme, a stripping section and an additional wash section are present. In this way, two solutes can be separated completely from each other, so both enantiomers can be obtained at the desired purity. For low concentrations, the fractional extractor can be described with two Kremser equations [5], one for each section, and a feed stage mass balance. This model has been used to assess the influence of selectivity and process parameters on the number of stages and solvent requirements. A model valid for higher concentrations is under development.

## THEORY

The enantiomers to be separated are racemic amino acids and racemic amino alcohols. For the initial part of the study, the amino acid model system also reported by other authors was used: separation of leucine enantiomers with the copper(II) complex of N-dodecyl-L-hydroxyproline ( $C_{12}$ -Hyp, or 'HL') in systems of water and an organic solvent [3,4,6]. The copper complex which serves as enantioselective extractant consists of two chiral ligands 'HL' and a copper(II) ion (eq. 1. The overbar denotes organic-phase species). The ligands and the complex remain in the organic phase due to the long alkyl tail on the ligand [4,6]:

The separation mechanism is usually described as a reversible ligand-exchange mechanism. One of the organic ligands is exchanged for an amino acid enantiomer ( $HAA^+$  or  $HAA^-$ ) resulting in a mixed-ligand complex. In formula:

Enantioselectivity is obtained if one reaction equilibrium constant is larger than the other. The leucine enantiomers also partition between the aqueous and the organic phase. This is a physical, non-selective process, represented by a partition ratio  $P$ , which may vary with solvent composition and temperature. The total amount of extracted leucine by both mechanisms is characterised by the distribution ratio  $D$ .

In general, a fair number of other complex species may be present in the liquid phases and the complexation constants for reactions (2) and (3) cannot be determined easily. Under certain circumstances, namely at a large extractant/enantiomer ratio, a large ligand/copper ratio and a phase ratio of unity, free ligand HL is present (eqn. 1), no copper is left in the aqueous phase and virtually all copper in the organic phase is present in the form of  $CuL_2$ . In this situation, the distribution ratio for each HAA enantiomer can be expressed as [4,6]:

$$D = \frac{[\overline{HAA}] + [\overline{AACuL}]}{[\overline{HAA}]} = P(1 + R \cdot K) \quad (4)$$

The value of  $K$  can be obtained from a plot of  $D$  versus  $R$  ( $R < 0.5$ ). The partition ratio  $P$ , reaction equilibrium constant  $K$  and an additional variable  $R$  are defined as:

$$K_{AA} = \frac{[\overline{AACuL}][\overline{HL}]}{[\overline{HAA}][\overline{CuL_2}]} \quad P = \frac{[\overline{HAA}]}{[\overline{HAA}]} \quad \text{and} \quad R = \frac{[\overline{Cu}]_{total}}{[\overline{HL}]_0 - 2[\overline{Cu}]_{total}} \quad (5)$$

$[\overline{Cu}]_{total}$  denotes the total copper concentration, in all forms. The separation factor  $\alpha$  is the ratio of the distribution ratios for both enantiomers. The upper limit of this separation factor is the intrinsic selectivity  $\alpha_{int}$ , which equals the ratio of the reaction equilibrium constants. It is approached if only the enantioselective complexation process determines the total extraction.

## EXPERIMENTAL METHODS

The chiral ligands N-dodecyl-L-hydroxyproline ( $C_{12}$ -Hyp) and N-octyl-L-hydroxyproline ( $C_8$ -Hyp) were synthesised from dodecanal (98%, Merck) or octanal (99%, Acros) and L-hydroxyproline (99%, Fluka) according to a slightly adapted method from Takeuchi [6]. All other reagents were also obtained from Fluka or Merck. Distribution ratios were determined from equilibrium measurements. The aqueous solution was prepared by dissolving copper(II) acetate ( $Cu(Ac)_2$ ), sodium acetate ( $NaAc$ ) and DL-leucine in Q2-filtered water (Millipore) that was presaturated with the organic solvent to obtain a 0.2 M  $Ac^-$  solution with  $[\overline{Cu^{2+}}]_0$  ranging from 2.5-50 mM and  $[\overline{DL\text{-leucine}}]_0$  from 0-10 mM. The organic phase was prepared by

dissolving the chiral ligand C<sub>12</sub>-Hyp (0-100 mM) in the appropriate organic solvent, butanol or butanol/hexane, presaturated with water. The equilibrium measurements were carried out in jacketed 25-ml vessels at a constant temperature. 10 ml of both phases were mixed for 1-3 hrs with a magnetic stirrer to reach equilibrium and allowed to settle. Samples were taken from the aqueous phase with a syringe via a septum and analysed by HPLC. In initial experiments, the closure of the mass balance was confirmed. The HPLC set-up consisted of a Crownpak (+) chiral column (Daicel), post-column derivatisation with OPA/MCE reagent and fluorescence detection [7]. The Cu(II) concentrations in some of the aqueous samples were determined by AAS (Solaar 939, Unicam). The pH of the aqueous phase was determined at equilibrium (Inolab pH level 1, WTW) and was always between 5.5 and 6.

## RESULTS

### Influence of Copper Concentration

From the copper-ligand reaction combined with the ligand-exchange reaction, one may expect that an excess of copper ( $[Cu^{2+}]_0 > 0.5 [HL]_0$ ) will result in a very low free ligand concentration  $[HL]$ . Thus, the enantioselective equilibria are shifted to the right, resulting in formation of more mixed-ligand complexes. However, Takeuchi [1] showed for valine that the optimum copper concentration is  $[Cu^{2+}]_0 = 0.5 [HL]_0$ . From the experimental results in Figure 1, the same conclusion is obtained for DL-leucine: an excess of copper (copper present in the aqueous phase) causes a decrease in the distribution ratios and the separation factor. No straightforward explanation for this phenomenon has been found. Other complex species will have to be considered. All further experiments were carried out at the 'stoichiometric' copper concentration, except those for the determination of the complexation constant.

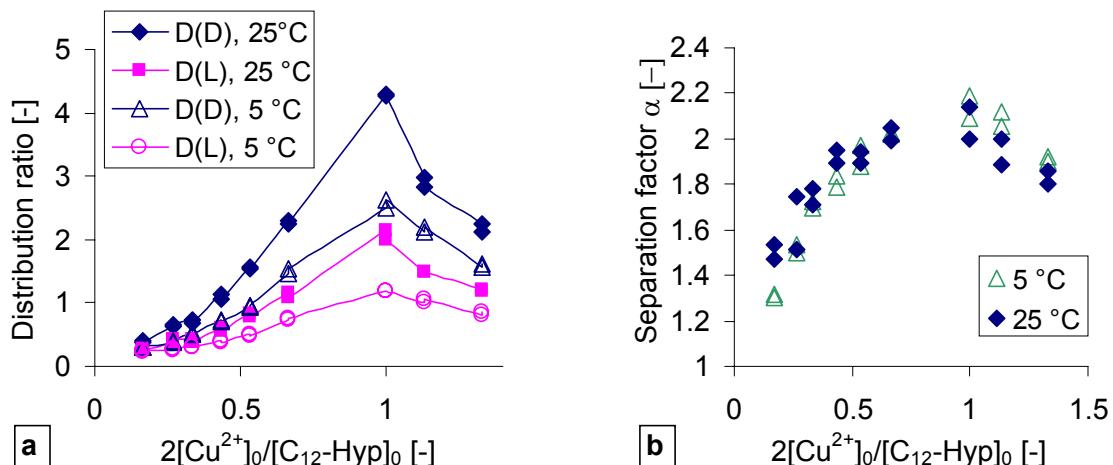

Figure 1. Influence of  $[Cu^{2+}]_0$  on (a) distribution ratio and (b) separation factor of DL-leucine. 5 and 25°C, butanol/water,  $[C_{12}\text{-Hyp}]_0 = 30 \text{ mM}$ ,  $[DL\text{-leucine}]_0 = 1 \text{ mM}$ ,  $[Cu^{2+}]_0 = 2.5\text{-}20 \text{ mM}$ .

### Influence of Excess Extractant and Concentration Level

In most studies reported so far, the enantioselective extraction has been investigated at a very large excess of extractant with respect to the enantiomers. This way of operation is not very economical and probably unnecessary. A series of experiments at constant enantiomer concentration and increasing chiral ligand concentration ( $[HL]_0$ ), with  $[Cu^{2+}]_0 = 0.5 [HL]_0$ , has been carried out. Figure 2a shows that there is no significant increase in D or  $\alpha$  once the excess extractant is large enough, i.e.  $[CuL_2]_0/[leucine]_0 > 3$ . Therefore, the large excess extractant (10-50) used by a number of authors [3,6] is not necessary.

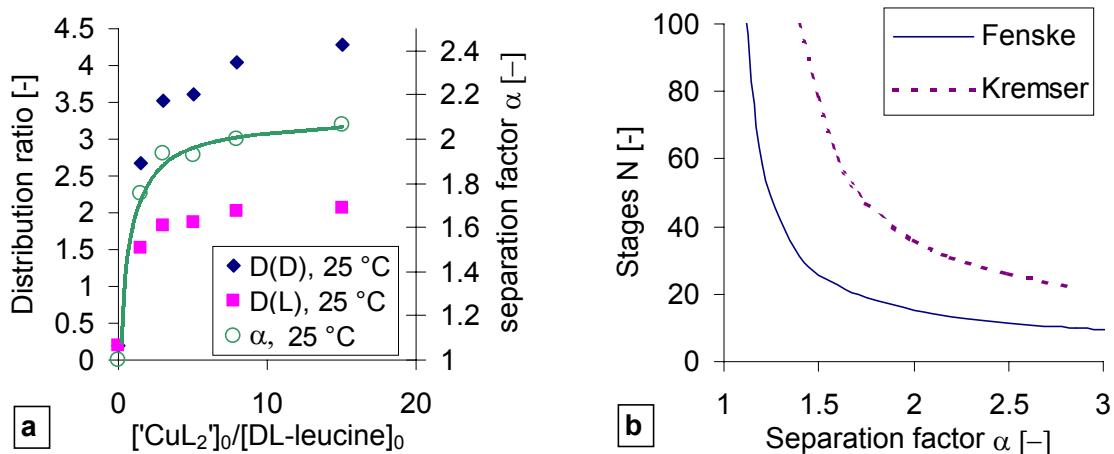

Figure 2. (a) Influence of excess extractant on  $D$  and  $\alpha$  at 25 °C; water/butanol,  $[DL\text{-leucine}]_0 = 1 \text{ mM}$ ,  $[C_{12}\text{-Hyp}] = 0\text{-}30 \text{ mM}$ ,  $[Cu^{2+}] = 0\text{-}15 \text{ mM}$  (stoichiometric) (b) Influence of  $\alpha$  on minimum number of stages, predictions by Fenske and Kremser equation [5], 99% purity.

Secondly, many studies are carried out at very low enantiomer concentrations (down to 0.1 mM). Higher concentrations of all components will increase the process capacity. The upper limit is the solubility. In our system, the leucine solubility decreases from > 50 mM in water to about 10 mM in 0.1 M Cu(Ac)<sub>2</sub>. Using less concentrated buffer solutions may partially prevent this. The ligand solubility varies with the solvent and the nature of the organic tail. In butanol, the solubility at 25 °C is about 0.1 M for C<sub>12</sub>-Hyp and 0.5 M for C<sub>8</sub>-Hyp. As expected, it can be concluded from the experimental data in Table 1 that a higher absolute concentration results in an almost unchanged separation factor but higher distribution ratios. Thus, a concentration level 10 times higher results in a process capacity 13-14 times higher.

Table 1. Influence of absolute concentrations (constant ratios), 25 °C, water/butanol.

$[leucine]_0 \text{ [mM]}$	$[Cu^{2+}]_0 \text{ [mM]}$	$[C_{12}\text{-Hyp}]_0 \text{ [mM]}$	$D(D) \text{ [-]}$	$D(L) \text{ [-]}$	$\alpha \text{ [-]}$
1	5	10	3.6	1.9	1.9
5	25	50	4.4	2.3	1.9
10	50	100	5.2	2.7	1.95

### Influence of Temperature

For chiral recognition systems, the enantioselectivity often increases with decreasing temperature [8,9]. Abe reports for a different system a decrease in  $D$  with increasing temperature [8].  $D$  and  $\alpha$  were determined at four temperatures at fixed concentrations (Table 2). Secondly, two data series were used to estimate  $K$  and  $P$  according to the 'R-method' (theory section). As expected,  $\alpha_{int}$  is slightly higher at the lower temperature.  $P$  varies slightly, but its value is small compared to the overall distribution ratios. At higher temperature,  $K$  and  $D$  for both enantiomers are higher. This is in contrast with the trend in Abe's results.

Table 2. Influence of temperature on leucine separation, water /butanol.

$D$  and  $\alpha$ :  $[leucine]_0 = 1 \text{ mM}$ ,  $[Cu^{2+}]_0 = 15 \text{ mM}$ ,  $[C_{12}\text{-Hyp}]_0 = 30 \text{ mM}$   
 $K$  and  $P$ :  $[leucine]_0 = 1 \text{ mM}$ ,  $[Cu^{2+}]_0 = 0\text{-}8 \text{ mM}$ ,  $[C_{12}\text{-Hyp}]_0 = 30 \text{ mM}$

	$D(D) \text{ [-]}$	$D(L) \text{ [-]}$	$\alpha \text{ [-]}$	$K_D \text{ [-]}$	$K_L \text{ [-]}$	$\alpha_{int}=K_D/K_L \text{ [-]}$	$P \text{ [-]}$
5 °C	2.6	1.2	2.1	7.9	3.3	2.35	0.17
25 °C	4.3	2.1	2.1	16.2	7.5	2.17	0.15
25 °C [5]				10.1	4.0	2.5	0.21
35 °C	5.0	2.5	2.0				
45 °C	5.9	2.9	2.0				

### Influence of pH

The pH has a complex influence on the performance of this process. From literature, it can be concluded that copper extraction by ligand L is favoured by a higher pH ( $> 5.5$ ) [4] and that the distribution ratios increase about five times when the pH increases from 4 to 6, but  $\alpha$  is not severely affected [1,3]. Therefore, all experiments were carried out at pH = 5.5-6. No further experiments at different pH values were performed at this stage.

### Influence of the Solvent

In the literature, several organic solvents and solvent mixtures have been applied. The solvent influences the solubility of all solutes, the partition ratios and possibly the reaction by acting as a ligand itself. It is reported that all solubilities are lower and the partition ratio is lower in a less polar solvent [4,6]. As an illustration, experimental results with two solvent mixtures are represented in Table 3. It can be seen that the separation factors are similar, but that the distribution ratio is lowered considerably in a less polar solvent mixture.

Table 3. Influence of solvent, 25 °C, [leu] = 1 mM,  $[Cu^{2+}] = 1.5\text{-}15 \text{ mM}$ ,  $[C_{12}\text{-Hyp}] = 3\text{-}30 \text{ mM}$ .

$[Cu^{2+}]_0 \text{ [mM] in 4:1 butanol/hexane}$	D(D) [-]	D(L) [-]	$\alpha$ [-]	$[Cu^{2+}]_0 \text{ [mM] in butanol}$	D(D) [-]	D(L) [-]	$\alpha$ [-]
1.5	1.6	0.9	1.7	1.5	2.7	1.5	1.75
5	2.9	1.5	1.9	5	3.6	1.9	1.9
15	3.1	1.5	2.0	15	4.3	2.1	2.05

### Reaction Kinetics

Preliminary time-dependent measurements were carried out in the equilibrium vessels in a totally dispersed system by interrupting the stirring movement at chosen intervals. It was observed that in some cases the equilibrium was approached more quickly at 25 °C than at 5 °C. This result indicates that reaction kinetics may be rate-limiting in this process, especially at low temperature. This deserves further investigation. For this purpose, a stirred cell of the adapted Lewis-type with constant interfacial area has been constructed.

## OPPORTUNITIES FOR OPTIMISATION & CONCLUSION

The focus of chiral extraction research in the past has been mostly on improving the separation factor and on designing lab-scale and pilot-scale extractors. For an industrial application, increasing the capacity without decreasing the selectivity is the most important issue. From previous studies, it is known that selectivities for chiral separations are usually below 2. From the Kremser model or the Fenske equation [5], the influence of the separation factor on the number of stages can be estimated (Figure 2b). For  $\alpha > 2$ , small changes in  $\alpha$  have a much smaller effect on the number of stages than if  $\alpha < 2$ . So, it is unwise to spend much effort on raising  $\alpha$  slightly if  $\alpha$  is already larger than 2. For the current model system at 25 °C, it can be concluded from Figure 2a that using an excess extractant [ $CuL_2$ ] larger than three is not justified. Accordingly, the process should not be carried out at 5 °C but at 25° or higher temperatures because the larger distribution ratios and the faster extraction kinetics at 25 °C more than compensate for the slightly higher separation factor at 5 °C. However, a too large temperature may cause other problems, such as extractant losses.

The required solvent flow and thus the process capacity increase proportionally with the enantiomer concentration and the absolute value of the distribution ratio. Therefore, the process should be carried out at the highest concentrations possible. For the model system, the leucine solubility is limiting (<10 mM at 0.1 M  $Cu(Ac)_2$ ). The solubility of the extractant is in the range of 0.1-0.5 M, which is much higher than applied in lab-scale experiments so far, and non-limiting given the low solubility of leucine. In most of the chiral fractional extraction

studies, large wash-to-feed and solvent-to-feed ratios have been applied. This practice has several drawbacks: dilution of the feed stream results in lower distribution ratios (table 1) and a large solvent flow causes much coextraction of the undesired enantiomer, thus requiring also a large wash stream. For two representative literature cases, the effects of parameter changes on the number of theoretical stages (N), the volumetric flow rate of feed (F), solvent (S) and wash fluid (W) and on the extractant inventory (C) have been estimated for a given capacity (kg/hr DL-leucine, product purity 99%) with the Kremser model, using the experimental results from this study (Table 4). It can be seen that both the total liquid volume (thus the extractor volume) and the extractant requirements can be decreased considerably.

*Table 4. Effect of process condition changes for two literature cases.*

<sup>1</sup>VR= total extractor Volume Reduction = [m<sup>3</sup> liquid hr<sup>-1</sup>]<sub>0</sub>·N<sub>0</sub> / [m<sup>3</sup> liquid hr<sup>-1</sup>]<sub>new</sub>·N

Concluding, fractional extraction of chiral components with copper-based extractants can be made much more efficient by working with high concentrations of enantiomers, using a stoichiometric amount of copper, working with a slight excess of extractant in a polar solvent, at a sufficiently high temperature and pH. Compared with literature results reported so far, an extractor volume reduction of 10-50 times maintaining the same productivity can be obtained without changing existing chemistry. We are currently increasing the extractor volume reduction to > 100 times and extending this work to the separation of amino alcohols.

## ACKNOWLEDGEMENT

This project is financially supported by PiT (Procestechnological Institute Twente) and DSM Research. The authors would like to thank Henny Bevers for his aid in setting up the chiral analysis and Anita Podt and Thijs van Delden for their assistance in experimental work.

## EXTRACTION OF BORAGE SEED OIL BY COMPRESSED CARBON DIOXIDE: EFFECT OF PROCESS PARAMETERS

Filipe Gaspar, Tiejun Lu, Regina Santos, Bushra Al-Duri

School of Chemical Engineering, University of Birmingham, Birmingham, United Kingdom

The extraction of oil from borage seeds using compressed CO<sub>2</sub> was studied. The effect of process parameters on the extraction rate and yield was investigated. In the first set of tests the effect of seed pre-treatment was considered, where mechanical and physical pre-treatments were applied. Both crushing and grinding under atmospheric conditions to particle sizes of 0.6 mm yielded the best results. On a second set of experiments, the effects of pressure and temperature were studied. The decrease in temperature led to a faster extraction rate when pressure was less than 200 bar. At 300 bar the reverse was observed. The trend observed was related to the solubility behaviour with pressure and temperature. Finally, the effect of solvent flow rate was studied. With the increase in the flow rate, a faster extraction was observed. The oil load, however, decrease with the increase in flow rate. This proves that extraction is not only controlled by solubility but also by the rate of mass transfer from the seeds.

### INTRODUCTION

The interest in oils from seeds arises from their high content of important unsaturated fatty acid constituents, some of which are in very short supply. The extraction of these oils from seed materials has traditionally been performed by cold pressing or by hexane extraction. However, the use of compressed CO<sub>2</sub> as the extracting agent presents significant advantages as opposed to the conventional methods. Compared to cold pressing, higher recovery of the oil is obtained, eliminating the need for further processing to recover the residual oil. On the other hand, the oil extracted by CO<sub>2</sub> routes presents a higher quality than that obtained by hexane extraction, since it is free of degradation artefacts and of hexane contamination. At present hexane-extracted oils have been subjected to severe market resistances such as stringent legislation regarding the residual contents of hexane that can be left in the product. For example, the maximum permitted residue for hexane in fats, oils and cocoa butter was reduced to 1 ppm to comply with Directive 97/60/EC.

For an efficient extraction of seed oil with compressed CO<sub>2</sub> some process parameters have to be optimised. The seed pre-treatment, extraction pressure and temperature and CO<sub>2</sub> flow rate are among the most important ones, since they severely affect the extraction rate. In the present work the effect of these parameters on the extraction yields and rates was investigated. The model seed material used was borage (*Borago officinalis*), which is a recognised source of essential fatty acids, specifically gamma-linolenic acid.

## EXPERIMENTAL PROCEDURE

### Seed Pre-Treatment

In addition to untreated seeds, seeds were subjected to different pre-treatment methods before extraction. These were:

Grinding – Seeds were grinded on a commercial blender (Kenwood BL 350 – dry grinder mill). Different degrees of grinding were obtained by varying the exposure to the blender. Two exposure times were applied namely 20 and 60 s, leading to average particle sizes of 0.8 and 0.6 mm, respectively. In addition, the grinding of cryogenically frozen seeds for 60 s led to a particle size of 0.4 mm.

Crushing – Seeds were mechanically crushed for 5 min using a pestle and mortar. The average particle sizes obtained were 0.6 mm and 0.5 mm for non-frozen and cryogenically frozen seeds, respectively.

Cryogenic freezing – Seeds were frozen under liquid nitrogen for a 10 min period before applying the mechanical treatments.

Fast decompression – Seeds were subjected to compressed CO<sub>2</sub> at 300 bar and 25 °C for 60 min, after which the bed was suddenly expanded to atmosphere. The decompression rate, measured as the rate of CO<sub>2</sub> density drop in the bed, was 4 kg.m<sup>-3</sup>.s<sup>-1</sup>. The technique employed during the fast decompression treatment is described elsewhere [1].

### Extraction Equipment

The CO<sub>2</sub> extraction equipment is shown in Figure 1.

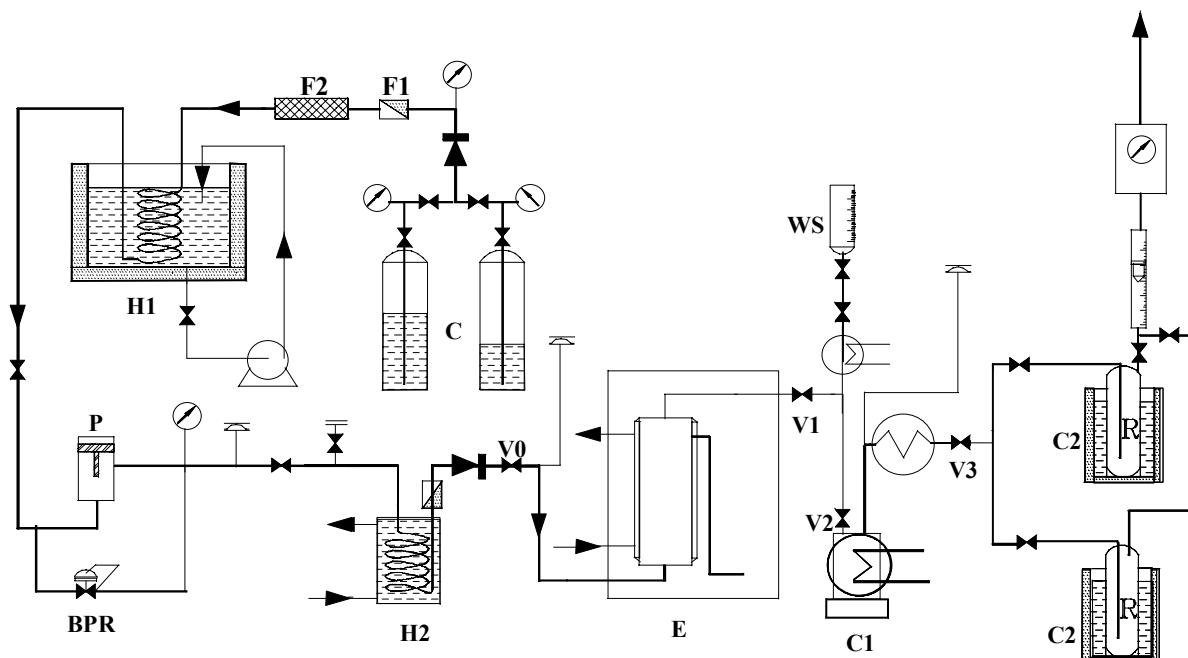

Figure 1. CO<sub>2</sub> extraction apparatus.

A bed of seed material was charged into extractor E. Carbon dioxide (industrial grade) was supplied from the storage cylinders (C) and was cooled in a refrigerator (H1) before pressurisation by a liquid pump (P). A backpressure regulator (BPR) and a heat exchanger (H2) controlled solvent pressure and temperature. The solvent, fed at the bottom of the extractor, passed through the bed of seed material. The stream containing dissolved material from the bed left E and was decompressed in two stages at valves V2 and V3. Expansion at V2 to 8-10 bar deposited most of the extract in the first collector (C1). The outlet stream of

C1 was heated to 40–45 °C before expansion to atmosphere at V3 and entered one of the two collectors in parallel (C2). These collectors were immersed in a mixture of acetone/dry-ice (-85 °C) and retained the water and any volatile components that may have escaped from C1. Valve V3 was adjusted to the desired flow rate that was monitored by a rotameter and a gas flow meter before the CO<sub>2</sub> discharged.

The mass of sample used in each test was 20 g and the diameter and height of the bed were 25 mm and 95 mm, respectively. The extract was collected at intervals as extraction proceeded. For each collection, valve V1 was closed and the downstream pipe to C1 was quickly washed with hot acetone from burette WS. The dissolved extract from C1 was mixed with that from C2 in a given volume of acetone and retained so that the oils contained in it could subsequently be analysed. The extract collectors at C1 and C2 were then replaced and the extraction resumed within 2 to 3 min.

After the dynamic extraction was completed, the extractor was slowly depressurised and the residue from the compressed CO<sub>2</sub> extraction was extracted by hexane in a Soxhlet apparatus in order to estimate the residual oil in the sample. This procedure allows the evaluation of the CO<sub>2</sub> extraction curves to be made in terms of degree of extraction, minimising errors from deviations in sample mass and in oil content. The mean oil content in the borage seeds was 26.7% with a standard deviation of 0.8%.

## RESULTS AND DISCUSSION

### Effect of Seed Pre-Treatment

The aim of the pre-treatment of seeds is to reduce the intraparticle resistance, invoked by the closed structure of the seeds (see Figure 2). A more ‘open’ structure would provide easier ‘access’ for CO<sub>2</sub> to diffuse within the pores and dissolve the oil entrapped in the cells.

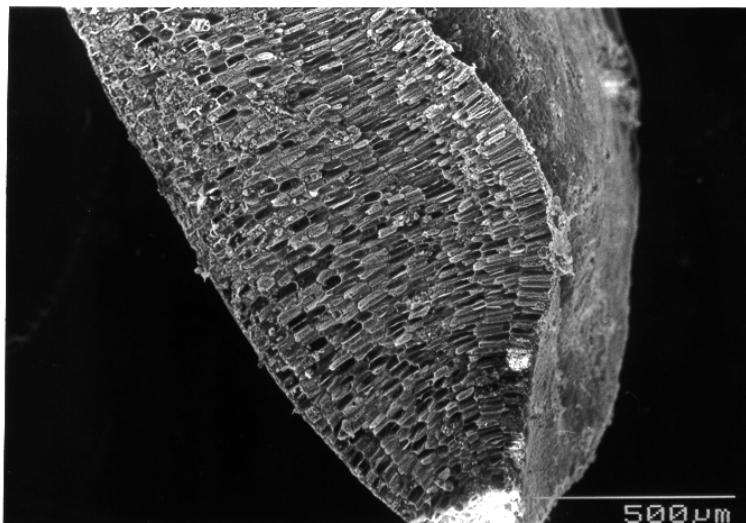

Figure 2. Scanning electron micrograph of a borage seed kernel (longitudinal cut).

The pre-treatment study was performed by extracting seeds, which have been pre-treated by different techniques, with compressed CO<sub>2</sub> at standard conditions (300 bar, 25 °C, 0.5 kg/h). The effect of seed pre-treatment on the extraction curves is shown in Figure 3. It can be seen that a remarkable increase on the rate of extraction and final yields was obtained when the seeds were either ground or crushed. Among the ground seeds it is noticeable that the rate and yields of extraction increased with the decrease of the particle size. Both crushed and

ground seeds to 0.6 mm yielded very high extraction rates and yields. On the other hand the effect of the fast decompression treatment (FD treatment) on the extraction curve was small but noticeable. The compact structure of the oil cells within the seed must have been able to withstand the pressure gradient formed during the decompression without disrupting the majority of the cells.

Figure 4 shows the effect of freezing the seeds cryogenically prior to grinding and crushing. In previous literature, cryogenic grinding has shown significant advantages over ambient milling for the extraction of volatile and/or thermal sensitive compounds [2]. This is due to lower grinding temperatures and smaller particle size. In the case of oil from borage seeds, however, and despite the leading to smaller particle sizes, there was no improvement on the extraction of oil from such material. In fact, the rate and yield of extraction from previously frozen seeds was lower. This is likely to result from the brittle state of the seeds after freezing; the smaller particles obtained contained most likely a higher fraction of intact oil cells.

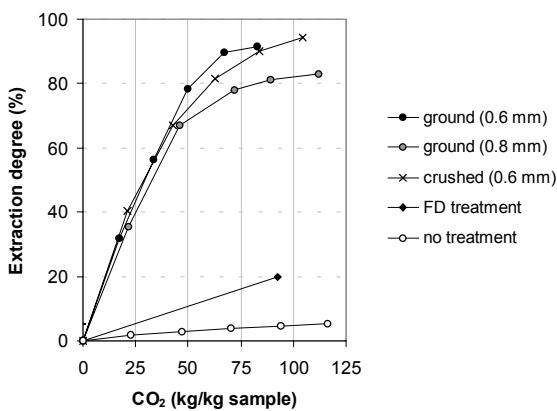

Figure 3. Effect of seed pre-treatment on the extraction curves.

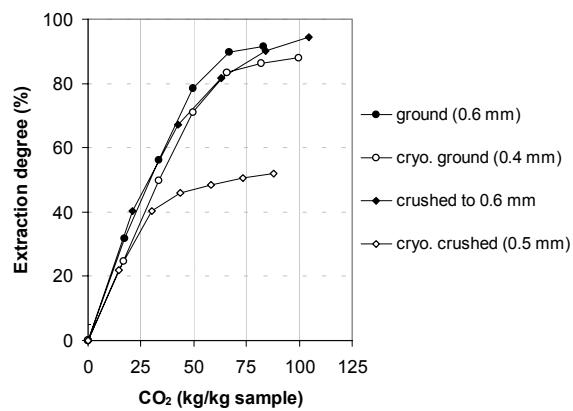

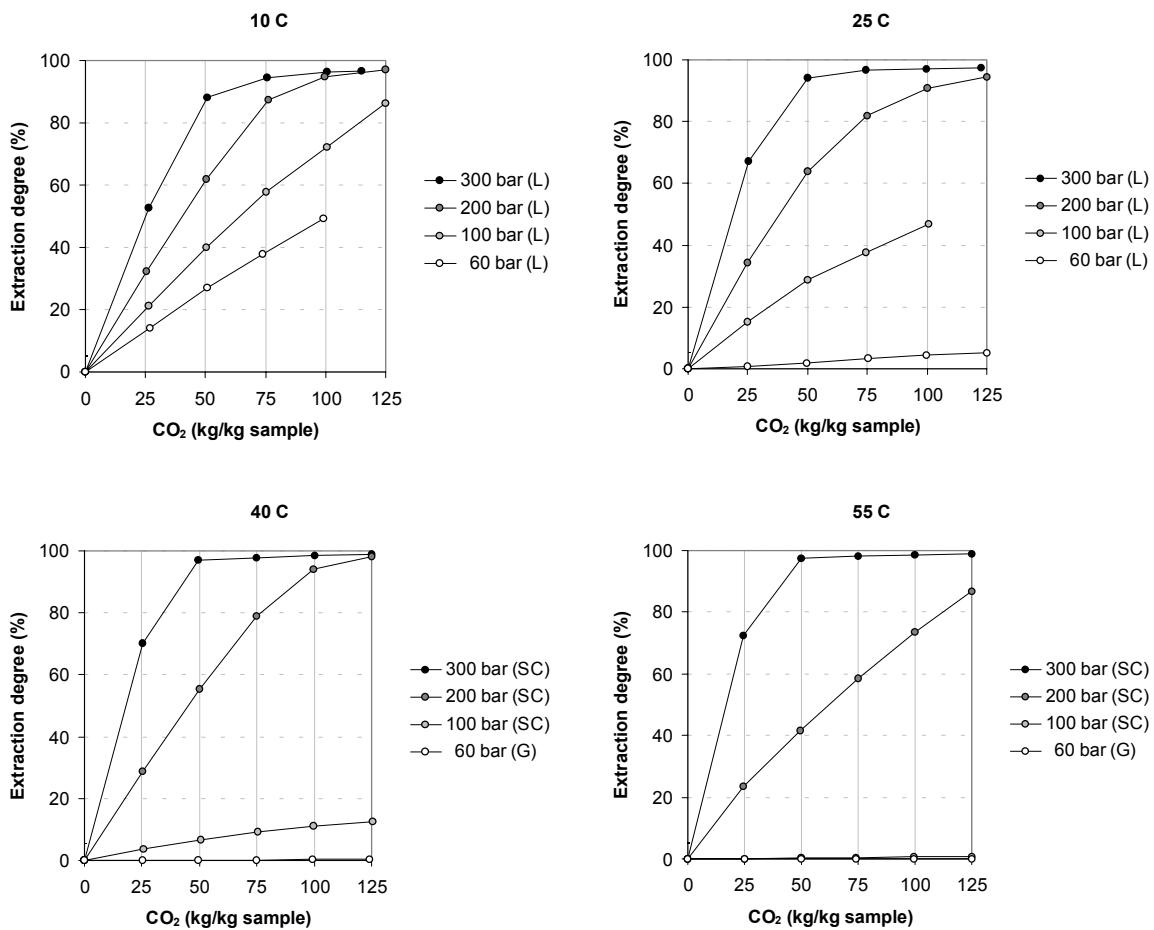

Figure 4. Effect of cryogenic freezing prior to comminution of the seeds on the extraction curves.

### Effect of Extraction Pressure and Temperature

The extraction pressure and temperature were varied from 60 to 300 bar and from 10 to 55 °C, respectively, covering within these ranges gas (G), liquid (L) and supercritical (SC) carbon dioxide. The extraction curves are illustrated in Figure 5. It can be seen that for all temperatures there was a clear improvement of the extraction rate with the increase of pressure. The effect of temperature, however, has shown two distinct behaviours. For pressures lower than 200 bar an increase of temperature lead to a decrease on the extraction rate but the inverse was observed at higher pressures. For pressures lower than 200 bar, the effect observed may be attributed to the reduction in density associated with the increase of temperature and consequently to decrease of oil solubility in CO<sub>2</sub>. For higher pressures the increase of oil volatility with the increase of temperature must have compensated the reduction in solvent density and consequently led to a higher solubility. The fastest extractions were consequently obtained with high pressure and high temperature supercritical CO<sub>2</sub>.

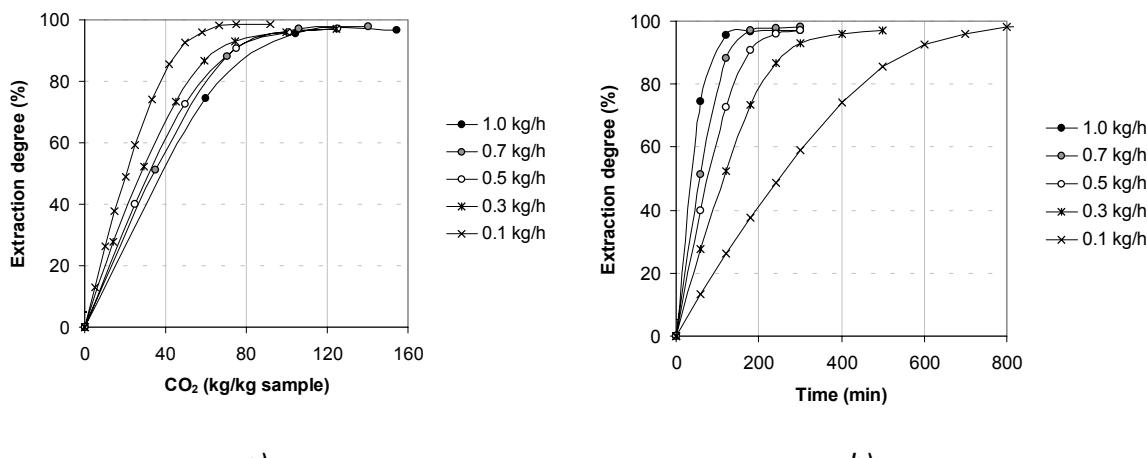

*Figure 5. Effect of pressure and temperature on the extraction curves (seeds ground to 0.5 mm).*

### Effect of Solvent Flow Rate

The effect of solvent flow rate can be used to determine whether the extraction is limited primarily by solubility and chromatographic retention or by the rate of transport of solutes from the matrix to the bulk of the extraction fluid [3]. In the first case increase of the flow rate results in a clear increase in the extraction rate. Moreover if the extraction is controlled only by solubility, the rate of extraction is directly proportional to the solvent flow rate. On the other extreme, if intraparticle is the only restriction, the rate of extraction is only dependent on the kinetics of the intraparticle transport and consequently little or not dependent on the solvent flow rate.

In our tests, performed using liquid CO<sub>2</sub> at 200 bar and 25 °C, the solvent flow rate was varied from 0.1 to 1.0 kg/h. The experimental extraction curves, presented in Figure 6, show that the rate of extraction is both dependent on the extraction time and amount of solvent used. This is an indication that extraction is not only controlled by solubility but also by mass transfer resistance. The film resistance is likely to predominate in the earlier stages of extraction whereas internal diffusion controls the extraction of the last fraction of oil.

**Figure 6. Effect of solvent flow rate on the extraction curves (seeds ground to 0.5 mm)**  
**a) In terms of mass of solvent, (b) in terms of extraction time.**

## CONCLUSIONS

The extraction of oil from borage seeds using compressed  $\text{CO}_2$  greatly depends on seed pre-treatment, extraction pressure and temperature and on solvent flow rate. Pre-treatments leading to extensive disruption of the oil cells within the seed, such as grinding and crushing, were found to yield remarkable improvements on the extraction rates and ultimate yields of extraction. In preliminary tests grinding and crushing under atmospheric conditions to a particle size of 0.6 mm yielded the best results. Freezing the seeds cryogenically prior to comminution resulted in lower extraction rates and yields.

The use of supercritical  $\text{CO}_2$  at high pressures and high temperatures yielded the best extraction rates, most likely due to a greater solubility of the oils at such conditions.

The extraction rate was also found to be affected by both extraction time and mass of solvent used. This indicates that film resistance plays a role in the extraction process.

## LIQUID-LIQUID EQUILIBRIUM DATA FOR THE CORN OIL / OLEIC ACID / AQUEOUS ETHANOL SYSTEM

Cintia B. Gonçalves and Antonio J. A. Meirelles

Faculty of Food Engineering, State University of Campinas, Campinas, Brazil

Deacidification of vegetable oils can be performed by liquid-liquid extraction. The present paper reports data for the system corn oil + oleic acid + ethanol + water at 298.15 K and different water contents. The addition of water to the solvent reduces the loss of neutral oil in the alcoholic phase and improves the solvent selectivity. The experimental data were correlated by the UNIQUAC model with a global deviation of 0.92%.

### INTRODUCTION

Crude vegetable oils consist predominantly of triacylglycerols and free fatty acids, with mono and diacylglycerols also present in lower level. The removal of free fatty acids (deacidification) is the most important stage of the purification process of oils, mainly because the yield of neutral oil in this operation has a significant effect in the cost of refining [1]. Besides, the presence of these compounds can adversely affect oil quality and stability to oxidation.

Deacidification of oils is usually performed by chemical or physical refining. However, for oils with high acidity, chemical refining causes high losses of neutral oil due to saponification and emulsification. Physical refining is also a feasible process for deacidification of highly acidic oils, since it results in less loss of neutral oil than the traditional process, but more energy is consumed. Moreover, in some cases, the refined oil is subject to undesirable alterations in color and a reduction of stability to oxidation [2]. Thus, it is important to develop alternative processes for the deacidification of edible oils.

The deacidification of oils by liquid-liquid extraction using an appropriate solvent has been receiving attention due to its advantages in comparison to the physical and chemical refining. Kale *et al.* [3] studied the deacidification of crude rice bran oil by extraction with methanol. Turkay and Civelekoglu [4] investigated the liquid-liquid extraction of sulfur olive oil miscella in hexane with aqueous ethanol solutions. As this process is carried out at room temperature and atmospheric pressure, less energy is consumed and the oil is subjected to milder treatments. Besides, liquid-liquid extraction has the advantages of avoiding the formation of waste products and reducing the loss of neutral oil. Furthermore, solvent stripping from refined oil and solvent recovery from the extract stream can be easily carried out, because of the high difference between the boiling points of the solvent, fatty acids, and triacylglycerols. In fact, these operations can be accomplished by evaporation or distillation at relatively low temperatures, in most cases lower than 80°C [5].

Liquid-liquid equilibrium data for systems containing vegetable oils and fatty acids are relatively scarce in the literature, yet such information is essential for studying the deacidification of edible oils by solvent extraction. The present paper reports liquid-liquid equilibrium data for the system corn oil + oleic acid + ethanol + water at 298.15 K and different water contents. The addition of water to the solvent reduces the loss of neutral oil and improves the solvent selectivity [5]. The experimental data set was used for adjusting the parameters of the UNIQUAC model.

## MATERIALS

Refined corn oil of the Mazzola brand (Brazil) was utilized as a source of triacylglycerols, and commercial oleic acid of Riedel de Haen as the source of fatty acids. The chemical composition of these reagents was determined by gas chromatography of fatty acid methyl esters (these data are published in Batista *et al.* [6]). Corn oil contains 12 different isomer sets with molecular weights varying in the range 831.35 - 887.46 g/mol. The commercial oleic acid contains 83.13 mass% oleic acid, 5.82 mass% palmitoleic acid, 5.05 mass% linoleic acid, 4.05 mass% palmitic acid and linolenic, stearic and myristic acids as minor components. The average molecular weight was 872.6131 g/mol for the corn oil, and 278.5868 g/mol for the oleic acid.

The solvent used was ethanol, from Merck, with purity greater than 99.5%. Distilled water was used to obtain the aqueous solvent at different water contents (5, 8, 12, 18 wt%).

## EXPERIMENTAL PROCEDURE

Equilibrium cells similar to those of Silva *et al.* [7] were used for the determination of liquid-liquid equilibrium data. The cell temperature was controlled with a thermostatic bath (Cole-Parmer, Model 12101-15, accurate to 0.1 °C). Thermometers (Cole-Parmer Instrument Co) with subdivisions of 0.1°C were used for monitoring the cell temperature. The component quantity was determined by weighing on a Sartorius analytical balance (Model A200 S, accurate to 0.0001 g). The mixture was stirred vigorously with a magnetic stirrer (FISATOM, Model 752A) for 20 min and left to rest for 12 h at least. This led to the formation of two clear and transparent phases, with a well-defined interface.

The oleic acid concentration in each phase was determined using potentiometric titration (Modified AOCS Method Ca 5a-40) [8] with an automatic burette (METROHM, Model Dosimat 715); the solvent was determined by evaporation in an EDG vacuum oven (Model EIV-1). The water concentration was determined by Karl Fisher titration, according to AOCS method Ca 23-55 [9]. Having determined the fatty acids concentration, solvent and water, the tryacylglycerols concentration was obtained by difference. The uncertainties of the concentrations varied within the following ranges: 0.06 – 0.24% for oleic acid, 0.02 – 0.11 % for ethanol, 0.02 – 0.18% for water and 0.06 – 0.26% for corn oil, being the lowest figures obtained for the lowest concentrations.

## MODELLING

The experimental equilibrium data determined in this work and the data for corn oil + oleic acid + anhydrous ethanol reported by Batista *et al.* [6] were used together to adjust the parameters of the UNIQUAC model [10]. Due to the large difference in molecular weights of the components, mass fractions were used as unity of concentration in the UNIQUAC model [11].

The adjustments were made by treating the system as a pseudoquaternary one, composed by a single triacylglycerol having the corn oil average molecular weight, a representative fatty acid with the molecular weight of the commercial oleic acid, ethanol and water. The values of  $r'_i$  and  $q'_i$  for the UNIQUAC model were calculated via Equation 1, which considers the composition of the oil and the commercial oleic acid.

$$r'_i = \frac{1}{\bar{M}_i} \sum_j^C x_j \sum_k^G \tilde{\iota}_k^{(i)} R_k; \quad q'_i = \frac{1}{\bar{M}_i} \sum_j^C x_j \sum_k^G \tilde{\iota}_k^{(i)} Q_k \quad (1)$$

where  $x_j$  is the molar fraction of the triacylglycerols of the corn oil or the fatty acids of the commercial oleic acid and  $\bar{M}_i$  is the average molecular weight of the corn oil or the commercial fatty acid. C is the number of compounds in the oil or in the commercial fatty acid and G the number of groups. As already mentioned, the compositions of the corn oil and the commercial oleic acid used in the present paper are reported by Batista *et al.*[6]. The values for  $r'_i$  and  $q'_i$  are furnished in Table 1. The parameters  $R_i$  and  $Q_i$  were obtained from Magnussen *et al.* [12].

*Table 1. Parameters  $r'_i$  and  $q'_i$  for corn oil, Riedel de Haen oleic acid, ethanol and water.*

Compound	$r'_i$	$q'_i$
corn oil (1)	0.044023	0.035675
commercial oleic acid (2)	0.045142	0.037157
ethanol (3)	0.055905	0.056177
water (4)	0.051069	0.077713

The parameter estimation procedure was based on the minimization of the objective function of composition, following the procedure developed by Stragevitch and d'Avila [13].

$$S = \sum_m^D \sum_n^N \sum_i^{C-1} \left[ \left( \frac{w_{inm}^{I,ex} - w_{inm}^{I,calc}}{\sigma_{w_{inm}^I}} \right)^2 + \left( \frac{w_{inm}^{II,ex} - w_{inm}^{II,calc}}{\sigma_{w_{inm}^{II}}} \right)^2 \right] \quad (2)$$

where D is the total number of groups of data, N is the total number of tie lines, and C is the total number of components in the group of data  $m$ .  $w$  is the mass fraction, the subscripts  $i$ ,  $n$  and  $m$  are component, tie line and group number, respectively, and the superscripts I and II are the phases; ex and calc refer to experimental and calculated concentrations.  $\sigma_{w_{inm}^I}$  and  $\sigma_{w_{inm}^{II}}$  are the standard deviations observed in the compositions of the two liquid phases.

Adjusted parameters are shown in Table 2.

*Table 2. UNIQUAC parameters for the systems corn oil (1) + commercial oleic acid (2) + ethanol (3) + water (4) at 25 °C.*

Pair $ij$	$A_{ij}/K$	$A_{ji}/K$
12	273.64	-212.27
13	246.94	-54.214
14	3032.0	-148.81
23	56.468	-80.240
24	235.76	49.931
34	337.46	-279.92

The deviations between experimental and calculated compositions in both phases for each system can be found in Table 3. These deviations are calculated according to Equation 3:

$$\Delta w = 100 \sqrt{\frac{\sum_{n=1}^N \sum_{i=1}^C \left[ (w_{i,n}^{I,ex} - w_{i,n}^{I,calc})^2 + (w_{i,n}^{II,ex} - w_{i,n}^{II,calc})^2 \right]}{2NC}} \quad (3)$$

Table 3. Mean deviations in phase compositions.

System	$\Delta w$ (%)
corn oil + oleic acid + anhydrous ethanol	0.84
corn oil + oleic acid + 5% aqueous ethanol	1.39
corn oil + oleic acid + 8% aqueous ethanol	0.79
corn oil + oleic acid + 12% aqueous ethanol	0.79
corn oil + oleic acid + 18% aqueous ethanol	0.79
Global deviation	0.92

Figures 1 shows the experimental points and calculated tie-lines for the system corn oil/ oleic acid/ 5% aqueous ethanol. The equilibrium diagram was plotted in triangular coordinates. For representing the pseudoquaternary system in triangular coordinates, ethanol + water was admitted as a mixed solvent. The middle points represent the overall compositions, while the extreme points represent the phases composition in the equilibrium.

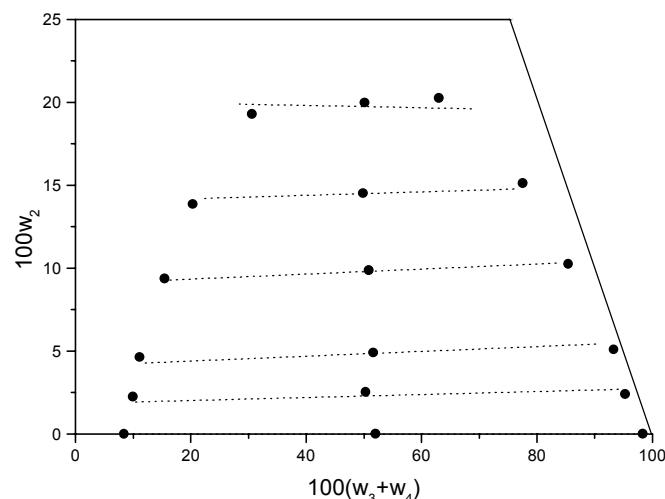

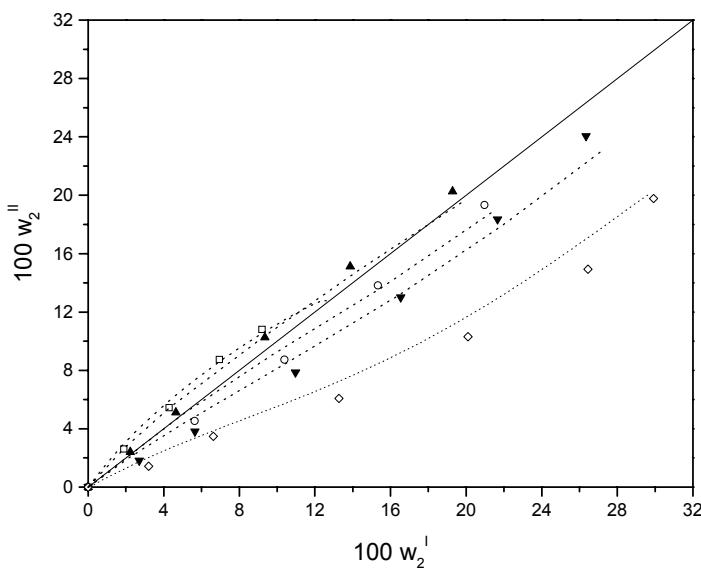

Figure 1. System of corn oil (1) + oleic acid (2) + 5% aqueous solvent [ethanol (3) + water (4)] at 298.15 K: experimental (●); (---) UNIQUAC.

Figure 2 presents the distribution of oleic acid between the phases at 298.15 K for the systems studied. As can be observed, the addition of water in the solvent decreases the fatty acid distribution coefficient, which is calculated according to Equation 4. These results indicate that aqueous ethanol has a lower capacity for extraction of fatty acids. Otherwise, the addition of water increases the solvent selectivity and consequently reduces the loss of neutral oil in solvent extraction. Solvent selectivity is calculated by Equation 5.

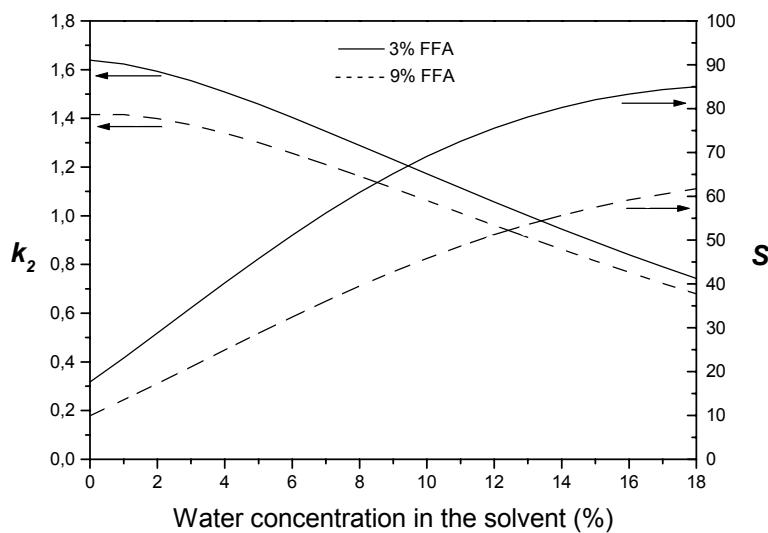

$$k_i = \frac{w_i''}{w_i'} \quad (4)$$

$$S = \frac{k_2}{k_1} \quad (5)$$

*Figure 2. Distribution diagram at 298.15 K for oleic acid ( $w_2$  = acid mass fraction):  
 (□) anhydrous ethanol; (▲) 5% aqueous ethanol; (○) 8% aqueous ethanol;  
 (▼) 12% aqueous ethanol; (◊) 18% aqueous ethanol; (- - -) UNIQUAC.*

In order to have a better insight about the influence of the water content on the performance of the solvent, flash calculations using the UNIQUAC model were performed for two levels of free fatty acids in the crude oil and different water concentrations in the solvent. The mass ratio between crude oil and aqueous solvent was fixed at the value 1:1. The results are given in Figure 3. As can be seen, the distribution coefficients exhibit a relatively slight decrease with the water content until values in the range 4-7 wt% of water in the aqueous ethanol, but the solvent selectivity shows a very significant increase.

*Figure 3. Fatty acid distribution coefficient and selectivities for systems of corn oil (1) + oleic acid (2) + ethanol (3) + water (4): (—) 3 wt% free fatty acid in crude oil;  
 (---) 9 wt% free fatty acid in crude oil.*

## CONCLUSION

Liquid-liquid equilibrium data for systems containing corn oil + oleic acid + ethanol + water were experimentally determined at 298.15 K. The addition of water in the solvent causes a decrease in the fatty acid distribution coefficient and an increase in the selectivity.

Despite the complexity of the studied systems, the estimated parameters for the UNIQUAC model are representative, since the description of the liquid-liquid equilibrium for all the systems had presented mean deviations lower than 1.39% in relation to experimental data. These parameters enable the modeling and simulation of liquid-liquid extractors using the proposed solvents.

Moreover, the results obtained allow one to conclude that a water content in the range of 4-7 wt% in the aqueous ethanol is appropriate for deacidification by solvent extraction, as it still provides high values of fatty acid distribution coefficient (larger than 1), and very significant values for the solvent selectivity (larger than 40).

## LIQUID-LIQUID EXTRACTION FOR DEACIDIFICATION OF VEGETABLE OILS

Eduardo Batista, Rosemar Antoniassi\*, Maria Regina Wolf Maciel\*\*  
and Antonio J. A. Meirelles

Faculty of Food Engineering, State University of Campinas, Campinas, Brazil

\*EMBRAPA, Rio de Janeiro, Brazil

\*\*Faculty of Chemical Engineering, State University of Campinas, Campinas, Brazil

Crude vegetable oils contain undesirable components, such as free fatty acids. They can be removed by alkali refining as well as physical refining. Liquid-liquid extraction is an alternative process that reduces the energy consumption for the oil refining without losses of natural components. This work aims to study the simulation of corn oil deacidification by liquid-liquid extraction using aqueous ethanol as the solvent. The results obtained indicate the best conditions for the deacidification by solvent extraction. The solvent to crude oil flow ratio, the number of stages and the water percent in ethanol could be selected to guarantee the minimum free fatty acids content in the refined oil with a minimum loss of neutral oil.

### INTRODUCTION

In the food and pharmaceutical industries, liquid-liquid extraction can be used in the recovery of vitamins, in the separation of caffeine, penicillin, aromas and fragrances, in the separation of lecithin, in the deterpenation of orange essential oil and in the deacidification of vegetable oils [1,2]. In the conventional refining process of edible oils, the deacidification is conducted by neutralization of free fatty acids with alkali. This process is applied to any vegetable oil, but high concentrations of free fatty acids cause a high loss of neutral oil. Leibovitz and Ruckenstein [3] reported losses of neutral oil in the range 15 to 25 % for the neutralization of crude corn oil containing 8-14 % of free fatty acids. In the Brazilian edible oil refining industry, the losses of neutral oil are proportionally higher, 14 % for crude corn oil with only 4 % of free fatty acids [4].

The deacidification of vegetable oils using solvents is based on the difference of the solubility of free fatty acids and neutral triglycerides in the solvent and on the difference of the boiling points of the solvent and fatty acids [5]. This process can be performed using several solvents: acetone, ethyl acetate, furfural, propanol, isopropanol, butanol, ethanol, methanol, ethyl methyl ketone, etc. Batista *et al.* [6] tested different solvents (methanol, ethanol, *n*-propanol, isopropanol, aqueous ethanol) for deacidification of canola oil. They verified that ethanol and aqueous ethanol were the best solvents for the deacidification process. The presence of water in ethanol increases the solvent selectivity, decreases the mutual solubility of the oil/ethanol mixture and reduces the loss of neutral oil in the final extract. This work is focused on the simulation of the deacidification process by solvent extraction and its optimization using surface response analysis. Batista *et al.* [7] used surface response analysis for optimizing a SRV distillation process and concluded that the factorial design is a powerful tool for analyzing the effects of the selected variables. For this reason this technique was employed in the present work to analyze the variables used in liquid-liquid extraction.

## CHARACTERIZATION OF VEGETABLE OILS

The first step in the chemical characterization of a edible oil is to determine its fatty acid composition by gas chromatography of fatty acid methyl esters. The fatty acid composition of corn oil is presented in Table 1.

*Table 1. Fatty acid composition of refined corn oil.*

n	Symbol	Fatty Acid	M (g.mol <sup>-1</sup> )	% molar	% mass
1	M	Miristic	C14:0 <sup>(1)</sup>	228.38	0.0365
2	P	Palmitic	C16:0	256.43	13.7943
3	Po	Palmitoleic	C16:1	254.41	0.0874
4	S	Stearic	C18:0	284.48	2.0333
5	O	Oleic	C18:1	282.47	32.6848
6	Li	Linoleic	C18:2	280.45	49.2415
7	Le	Linolenic	C18:3	278.44	1.3782
8	A	Arachidic	C20:0	312.54	0.6050
9	B	Behenic	C22:0	340.49	0.1388

<sup>(1)</sup> Cx:y - x = number of carbons, y = double bonds      M = molecular weight

From this fatty acid composition it is possible to estimate the triglyceride composition of the oil (Table 2) by using the computational method developed by Antoniosi Filho *et al.* [8]. The main triglyceride (Table 2) represents the component of greatest concentration in the isomer set with x carbons and y double bonds.

*Table 2. Estimated triglyceride composition of corn oil.*

n	Group	Main Triglyceride	M (g.mol <sup>-1</sup> )	% molar	% mass
1	50:1 <sup>(1)</sup>	POP	833.37	1.9072	1.8226
2	50:2	PLiP	831.35	2.9092	2.7735
3	52:1	POS	861.45	0.5616	0.5548
4	52:2	POO	859.40	5.3611	5.2836
5	52:3	POLi	857.39	13.6558	13.4267
6	52:4	PLiLi	855.37	10.7136	10.5090
7	52:5	PLiLe	853.37	0.6435	0.6298
8	54:2	SOO	887.46	0.9815	0.9988
9	54:3	OOO	885.44	5.5765	5.6623
10	54:4	OOLi	883.43	17.6755	17.9068
11	54:5	OLiLi	881.41	24.8117	25.0789
12	54:6	LiLiLi	879.43	13.5542	13.6694
13	54:7	LiLiLe	877.38	1.0442	1.0506
14	56:3	OLiA	913.52	0.6045	0.6333
Total				100.0000	100.0000

<sup>(1)</sup> X:Y - X number of carbons (except carbons of glycerol) and Y double bonds

The diglyceride composition can be estimated taking into account the probability of partial hydrolysis of each triglyceride (Table 2). For example, the partial hydrolysis of POS in the position 1 or 3 produces the diglycerides PO<sub>2</sub> or SO<sub>2</sub> and in position 2, the diglyceride P<sub>2</sub>S, all diglycerides in equal molar proportion. The estimated diglyceride composition for corn oil is presented in Table 3.

*Table 3. Estimated diglyceride composition of corn oil.*

n	Group	Diglyceride	M (g.mol <sup>-1</sup> )	% molar	% mass
1	34:1	PO_ and P_O	595.00	9.5850	8.2143
2	32:0	P_P	568.96	16.0500	13.1528
3	34:2	PLi and P_Li	592.98	13.8490	11.8283

12	38:1	O_A	651.08	0.2020	0.1894
Total			100.0000	100.0000	

## PROCESS SIMULATION

The algorithm developed by Naphtali and Sandholm [9], in the form proposed by Fredenslund *et al.* [10], was adapted for simulating the liquid-liquid extraction. The phase equilibrium estimation in such a complex system, containing 14 triglycerides, 12 diglycerides, 9 fatty acids, a short chain alcohol and water, is a very difficult task. Phase equilibrium was predicted using the new parameters of UNIFAC adjusted by Batista *et al.* [11] for ternary systems composed by a pure triglyceride, a pure fatty acid and anhydrous ethanol.

The extractor feed stream was composed by triglycerides, diglycerides and free fatty acids in a proportion of 92 / 4 / 4, respectively. All triglycerides and diglycerides of corn oil (Tables 2 and 3, respectively) were used in the feed stream. The free fatty acids were composed of the fatty acids presented in Table 1. It was considered that the free fatty acids present in crude corn oil have the same proportion of the fatty acid composition of refined corn oil (Table 1). Aqueous ethanol was used as solvent. A good deacidification by solvent extraction must provide a content of free fatty acids in refined oil lower than 0.3 mass% [12], without a great loss of neutral oil in final extract.

## SURFACE RESPONSE ANALYSIS

The optimization study was carried out by surface response analysis based on the results from factorial design and regression analysis [13]. The experimental design, which requires the use of coded variables (Table 4), was used as a tool to evaluate the influence of the main process variables on the free fatty acids content of refined oil (in a solvent free basis) and on the loss of neutral oil in final extract. Three levels were considered: 15 ( $2^3 + \text{star}$ ) process simulations were necessary for optimizing the liquid-liquid extraction by surface response analysis.

*Table 4. Coded variables.*

	-1.68179	-1	0	+1	+1.68179
Solvent to Crude Oil Ratio (S/O)	0.93182	0.90000	1.00000	1.10000	1.26818
Number of Stage (NS)	4	5	7	9	10
% Water in Solvent (W)	2.477	3.500	5.000	6.500	7.523

From the simulation results in the above-mentioned range, a mathematical model for each type of response was obtained. This permits the formulation of the following models, expressed in terms of coded variables (Table 4):

Free fatty acids in refined oil:

$$\% \text{ FFA} = 0.511081 - 0.187174 (\text{S/O}^*) + 0.028290 (\text{S/O}^*)^2 - 0.140224 (\text{NS}^*) + \\ + 0.034990 (\text{NS}^*)^2 + 0.290702 (\text{W}^*) + 0.046958 (\text{W}^*)^2 - 0.050325 (\text{S/O}^*) (\text{W}^*) \quad (1)$$

Loss of neutral oil:

$$L = 2.51473 + 0.25968 (\text{S/O}^*) + 0.04090 (\text{NS}^*) - 1.18148 (\text{W}^*) + 0.24230 (\text{W}^*)^2 - \\ - 0.08250 (\text{S/O}^*) (\text{W}^*) \quad (2)$$

where superscript \* defines coded variable.

With these models, it is possible to generate surfaces that represent the influence of the specific variables on each response. In the first analysis with the variables S/O and NS, the value for NS that guarantees a fatty acid concentration of 0.3 % and a lower loss of neutral oil was 10. The next step was to generate a surface with NS equal to 10 (Figure 1) for representing the effect of the solvent to crude oil flow ratio (S/O), as well as the water percent in that solvent (W), on the free fatty acid concentration in refined oil and on the loss of neutral oil. The variables, S/O and W, have a significant effect on the responses. The free fatty acids in refined oil decreases with the increase of solvent/oil flow ratio. At high W-values, in this case ethanol with 7.523 % water, the deacidification is affected because the solvent has a lower capacity of extracting free fatty acids, nevertheless the solvent becomes more selective with the water increase, reducing expressively the loss of neutral oil. The effect of W is much more significant than that of S/O. The loss of neutral oil in the final extract decreases as the S/O ratio decreases and also decreases, but much more significantly, with the increase of the water content in solvent. In fact, the addition of water to ethanol has a very significant influence on the mutual solubility of oil and the mixed solvent, reducing its value. When the surfaces are superimposed, the maximum concentration of free fatty acids permitted by legislation (0.3 %), with a minimum loss of neutral oil, is obtained for a S/O-value equal to the maximum one (1.26818).

The surface for NS and W with S/O equal to 1.26818 was then generated (Figure 2). The free fatty acid concentration decreases with the increase in NS and with the decrease of W, but the effect of W is higher than the effect of NS. When these figures are superimposed, the operating condition that permits a minimum loss of neutral oil and assures 0.3 % of free fatty acids in final product is NS = 10 and W = 5.75 %.

Using this procedure the optimal condition for solvent extraction can be found (Table 5). These values guarantee a concentration of free fatty acids in refined oil lower than 0.3 % [12] as well as a minimum loss of neutral oil in final extract. To check these optimal conditions a rigorous simulation was conducted using their values. The simulation results indicate that for these optimal conditions the concentration of free fatty acid in the refined oil is 0.27 %, the loss of neutral oil is equal to 2.40 % and 60.7 % of diglycerides was extracted. This loss of neutral oil is much lower than the loss presented in the literature, 15-25 % [3] and 14 % [4]. Batista *et al.* [14] found 8.11% of neutral oil loss in the deacidification of canola oil with 4 % of free fatty acids. In this case the authors employed anhydrous ethanol as solvent. This result proves that the maximum concentration of free fatty acids in neutral oil, 0.3%, can be obtained with a significant decrease in the loss of neutral oil in the final extract using aqueous ethanol as solvent.

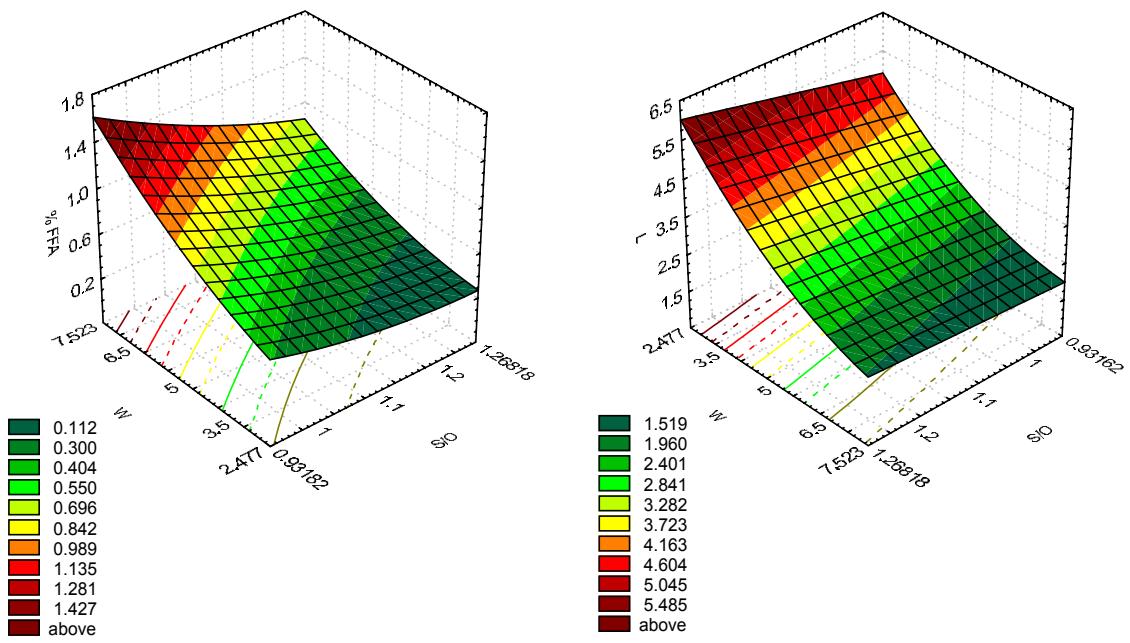

Figure 1. Effect of S/O and W on % FFA and on L (NS = 10).

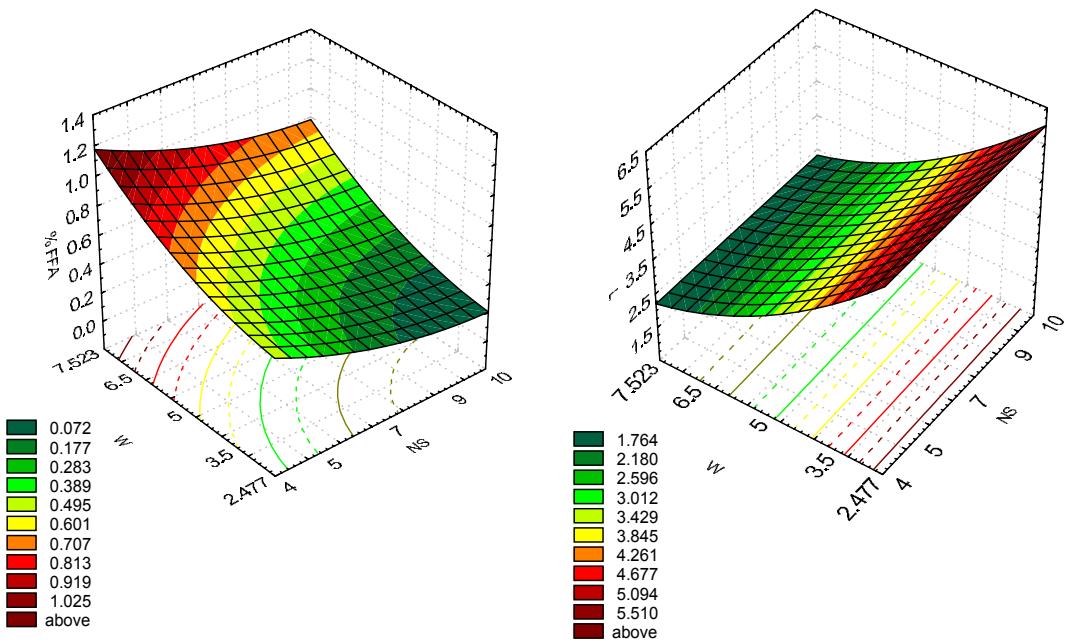

Figure 2. Effect of NS and W on % FFA and on L (S/O = 1.26818).

It should also be noted that experimental results reported in the literature [2] indicated that mechanically agitated extractors could be employed in oil deacidification using relatively high solvent to crude oil ratios without hydrodynamic problems, such as phase inversion.

*Table 5. Optimal conditions for deacidification by solvent extraction.*

Solvent to Oil Ratio (S/O) 1.26818	Number of Stages (NS) 10	Water Percent in Solvent (W) 5.75 %
---------------------------------------	-----------------------------	--

## CONCLUSION

The new parameters of the modified UNIFAC as well as the program developed allows to simulate liquid-liquid extraction of a complex multicomponent system. All components of corn oil (Tables 1, 2 and 3) were considered in the extractor feed stream without compromising the program convergence. The surface response analysis help us to find the optimal condition to operate the extractor with a concentration of free fatty acids in the refined oil lower than 0.3 % and a minimum loss of neutral oil. The presence of water in ethanol guarantees losses of neutral oil substantially lower.

## INFLUENCE OF OPERATING FACTORS ON THE RHUBARB EXTRACTION PROCESS

Y. C. Lu, G. S. Luo and Y. Y. Dai

Tsinghua University, Beijing, China

Chinese traditional medicines are commonly produced from active ingredients extracted from herbs using solid-in-liquid extraction processes. These are often inefficiently operated and are poorly researched. The rhubarb extraction system has been used in this study to investigate various factors that influence the extraction process. These include choice of solvent, temperature, phase ratio and particle size. Based on the experimental findings and on an investigation of various modes of operation an improved extraction process is proposed.

### INTRODUCTION

Local Chinese herbs are commonly treated to provide the active ingredients that are used in the production of traditional medicines. Normally a solid-in-solvent extraction process is employed. These processes are in general inefficient and are not well researched [1].

For this study rhubarb extraction was chosen as the experimental system to investigate factors that influence the extraction process [2]. Rhubarb, the rootstock of the species *polygonaceae*, has highly compacted tissue that makes the extraction of active compounds difficult. In addition the presence of the suite of active ingredients provided by this system enabled the issues relating to complex extraction systems to be addressed. Factors investigated include solvent choice, temperature, phase ratio and particle size. Co-current and counter-current modes of operation were also investigated and a multiple extraction series was tested.

### EXPERIMENTAL PROCEDURES

#### Materials

All the chemicals (NaOH, ammonia, FeCl<sub>3</sub>, ethyl ester, 1,8-dioxyanthraquinone) were of analytical grade purity and used without any further purification.

Rhubarb slices, purchased from Beijing medical material service station, were pulverized with pulverizer, then classified by a series of screens (20, 40, 80 mesh/inch). Particle sizes were defined in following way: particles remaining between 40 mesh and 80 mesh screens were said to belong to 40 mesh size fraction, the rest might be deduced in the same way. All the particles in the same fraction were mixed well before use.

#### Equipment and Procedure

Except for soxhlet extractions, all experiments were done in a batch extractor with a water jacket and magnetic stirrer. The extraction chamber was a cylinder with height of 4 cm and 3 cm in diameter. For all the experiments a fixed stirring speed was used. Initial solvent volume was 20 ml. Before experiments, solvents were infused into the extractor first and pre-heated to the required temperature. The extract was separated from solid residues immediately by filtration when experiments finished. In multi-staged extraction, residues were returned to the extractor for next operation cycle. The pre-experimental results showed that the extract concentration tended to be constant after three hours of extraction in batch extractor. Three hours was therefore chosen as the time for each experiment.

### **Analytical Procedure**

The concentration of total anthraquinone in solution was determined using a HP8452 UV-vis spectrophotometer at wavelength of 512 nm. A standard curve was plotted using 1,8-dioxyanthraquinone as standard [3]. The anthraquinone compounds extracted are composed of a number of individual compounds (such as emodin and rheinic acids) that were determined using HPLC when required.

Phase ratio, denoted with S, is defined as proportion of the mass of initial medicine material and added solvent volume. The extraction ratio is defined as the mass ratio of the extracted anthraquinone and raw material.

## **RESULTS AND DISCUSSION**

### **Effect of Temperature**

Figure 1 gives final extraction ratio of total anthraquinone at a certain phase ratio for various extraction temperatures. It was clear that temperature had prominent effect on final extraction ratio. This effect was more pronounced for higher phase ratios. The variation of temperature changed the reaction environment and thus affected the equilibrium dissolution and adsorption/desorption conditions. A higher temperature was favorable for dissolution and desorption. From an extraction temperature of 60°C, there was no further benefit to extraction with an increase of temperature. Overly high temperature may in fact destroy some of the heat sensitive components.

### **Effect of Solvent Mixture**

Figure 2 shows the extraction results for the different solvent mixtures tested. These were water, various water/ethanol mixtures and pure ethanol. All experiments were done at the phase ratio of 1:200 and 60°C. The choice of solvent plays a key role in the technology optimization. Ethanol-containing solvent mixtures were better than pure water. The extraction ratio did not increase linearly with ethanol volume fraction as was expected but declined after 40 vol % ethanol. The results indicated that solvent mixtures from 40 to 60 vol % ethanol would be adequate. The concentrations of specific components of the extracts, emodin and rheinic acid, were determined by HPLC, the results are shown in Table 1.

*Table 1. Extraction ratio of emodin or rheinic acid with various solvents.  
(0.4 g medicine material, 20 mesh size fraction, 20 ml solvent).*

Solvent	Temperature (°C)	Extraction Ratio	
		Emodin	Rheinic acid
Water	60	0.06	0.38
25% Ethanol	40	0.13	0.32
50% Ethanol	40	0.36	0.59
Ethanol	40	0.29	0.25

It was found that the extraction behaviour of the various solvent mixtures with respect to the two components differed, even though both were anthraquinonic compounds. Solvent mixtures with higher content of water favored the extraction rheinic acid, while those with higher content of ethanol favored the extraction of Emodin. Solvent selection should therefore be based on the target component.

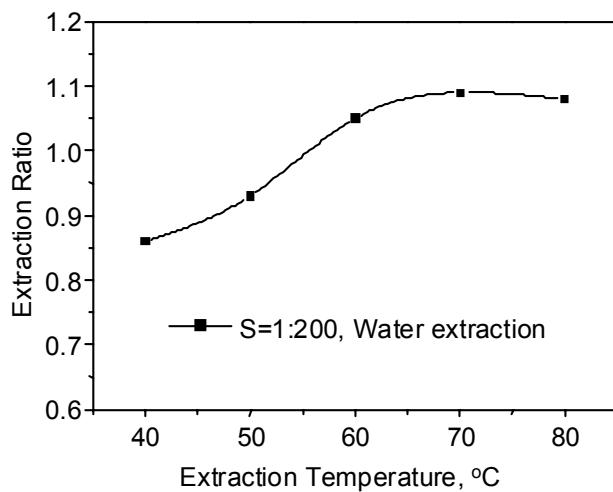

Figure 1. Influence of temperature on extraction ratio.

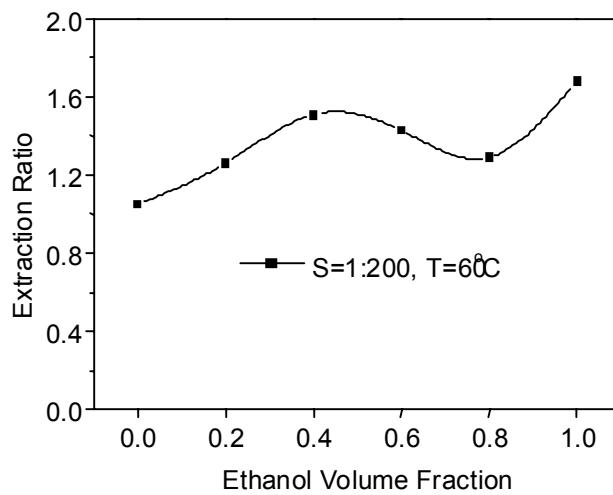

Figure 2. Influence of solvent on extraction ratio.

### Effect of Particle Size

Particles in various size fractions were treated in the batch extractor and a soxhlet extractor (for 8 hours), and the results are given in Tables 2 and 3, respectively.

Table 2. Single stage extraction ratios for various size fractions.  
(0.4 g medicine material, 20 ml solvent, 60°C).

Solvent	Size Fraction (mesh)	Extraction Ratio
Water	40	0.82
Water	80	0.85
Water	160	0.64

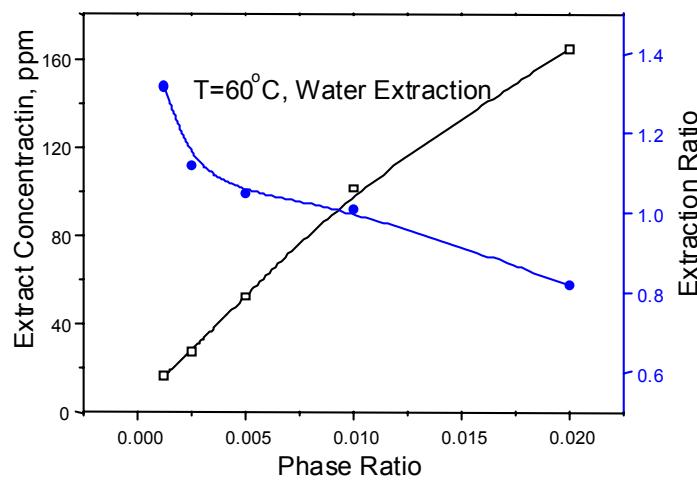

**Table 3. Soxhlet extraction ratios for various size fractions.  
(3 g medicine material, 150 ml solvent).**

Solvent	Size Fraction (mesh)	Extraction Ratio
Water	40	0.44
Water	80	0.68
Water	120	0.44
Water	160	0.39

Lower extraction ratios were obtained in the soxhlet extraction experiments, even when the same size fractions were compared. In soxhlet extraction, there is no stirring and the actual phase ratio varies, deviating from the nominal value. This could account for poor mass transfer from the surface of the particles to the bulk solution. These dynamic effects meant that equilibrium conditions had not been achieved by the interruption of the experiment. The optimal extraction was obtained for the 80-mesh size fraction. Commonly, smaller particle size implies larger specific area. While this will favor mass transfer it will also favor granular adsorption, with the net effect that lower extraction efficiencies would be obtained for both oversize and undersize particles. The extraction ratios observed for the various particle sizes could be related to the method of preparation. The tissue or structures of the plant vary with respect to the concentration of active components. Under specific pulverizing conditions, the degree of pulverization could differ with the degree of compactness of the plant tissue and thus account for the differences observed for the extraction ratios.

### Phase Ratio

Figure 3 shows the relationship of the extraction ratio and extract concentration with the phase ratio. The extract concentration increased with an increase in phase ratio. All of active compounds come from the raw material, and are conserved in the system. The slightly downward curve trend observed for the extraction ratio shows that the fraction of the active components in the bulk solution went down. This could be due to the effects of entrainment in the residue that are in turn related to the swelling characteristics of the tissue. The extraction ratio decreases with an increase of the phase ratio but this effect is less pronounced for  $S > 0.005$ . It is better to optimize the phase ratio to reduce solvent consumption and at the same time to assure an acceptable extraction ratio.

**Figure 3. Influence of phase ratio on extraction ratio and extract concentration.**

### **Co-current and Counter-current Extraction**

As we know, the maximum extraction ratio in any stage is limited by its thermodynamic properties. A three-stage co-current extraction process is usually adopted to assure high extraction ratios in traditional production. This process was simulated and the results are given in Table 4. For comparison a three-stage counter-current process was simulated and the results are given in Table 5. For the co-current extraction the per-stage extraction ratio decreases rapidly with progress to successive steps in the series for each experimental phase ratio. It is therefore important to select a suitable series by considering both total solvent consumption and accumulative extraction ratio.

*Table 4. Extraction ratio for co-current extraction.*

Solvent	Per Stage Solvent volume(ml)	Mass of medicine material (g)	Temperature (°C)	Size Fraction (mesh)	Serie s no.	Extraction Ratio
Water	20	0.4	60	20	1	0.60
					2	0.22
					3	0.08
					4	0.06
					Σ	0.97
Water	20	0.1	60	20	1	1.19
					2	0.22
					3	0.10
					Σ	1.51

*Table 5. Extraction ratio for counter-current extraction.*

Solvent	Solvent volume (ml)	Mass of medicine material (g)	Temperature (°C)	Size Fraction (mesh)	Extraction ratio
Water	20	0.4	60	20	1.06
	20	0.4	60	40	0.97

For the same solvent consumption the extraction ratio was observed to be some 20% greater for counter-current than co-current extraction.

### **Extraction with Different Solvents in Series**

Since the results shown in Table 1 indicated that the extraction of the different active components varied with solvent mixture an experiment was performed using different solvent mixtures in series. The results are given in Table 6. Compared with the extraction obtained with any single solvent, the extraction ratios were much higher. It is also found that the solvent order in the series had a distinct effect. Extraction with ethanol followed by water was best. The affinity of ethanol with the matrix material is better than for water, and this could therefore provide a better environment for the following extraction step.

*Table 6. Results of extraction with different solvent mixtures in series.*

Solvent	Per stage solvent volume (ml)	Mass of medicine material (g)	Size Fraction (mesh)	Extraction Ratio
Water first, then ethanol	20	0.4	20	1.79
Ethanol first, then water	20	0.4	20	2.05

## **CONCLUSIONS**

The experimental results indicated that solvent, temperature and raw material dimension were significant factors that affected the dynamic and thermodynamic performance of the rhubarb extraction system. Solvent and temperature should be chosen according to the active component targeted. Pulverizing raw material properly could decrease extraction time greatly. Increasing the series in co-current extraction to improve recovery ratio is not feasible. To maximize extraction of all of the active components a multiple solvent series is proposed. Multi stage counter-current extraction and extraction with different solvents in series achieved higher extraction ratios than for single-stage extraction, with less solvent consuming relatively. It is proposed that to extract target components more efficiently and to thus improve the utilization of resources and equipment a continuous counter-current extraction process be employed with solvent shifting.

## EXTRACTION OF LYSOZYME WITH REVERSE MICELLES USING A CONTACTOR AGITATED BY AUTOMATIC SUCTION OF LIQUID TYPE STIRRER

W. Zhang, H. Z. Liu, and J. Y. Chen

Young Scientist Laboratory of Separation Science and Engineering,  
State Key Laboratory of Biochemical Engineering, Institute of Chemical Metallurgy,  
Chinese Academy of Sciences, Beijing, China

Although the extraction and purification of proteins using reverse micelles has received wide attention in recent years, this method is not used in commercial practice. One major problem is the difficulty of phase separation because of easy emulsification owing to the presence of surfactant, especially using surfactants with a high hydrophile/lipophile balance value or dealing with intracellular proteins. In this paper, a novel contactor agitated with automatic suction of liquid type stirrer was used to disperse the aqueous phase or organic phase into another phase. Lysozyme was extracted to the reversed micellar phase with high extraction efficiency without emulsification even at low ionic strength (0.02 M KCl). The novel contactor can be used for a continuous process with integration of the mixer-settler contactor. The fixed and operating costs of the contactor are low and it can be used for reverse micelle extraction.

### INTRODUCTION

The extraction and purification of proteins using reverse micelles is a liquid-liquid extraction operation that has received wide attention. Most work has focused on the distribution of proteins and has been performed in a batch mode with little consideration given to the process itself or to the selection of equipment. The continuous extraction of protein using reversed micellar systems has been limited to a few examples, namely, the extraction of  $\alpha$ -amylase using two mixer-settler units [1], the extraction of a recombinant cutinase with a perforated rotating disc contactor [2,3], the recovery of intracellular proteins from *Candida utilis* in a spray column [4], the extraction of BSA using a centrifugal extractor [5] and the extraction of  $\alpha$ -amylase using two centrifugal extractors [6].

One major problem in the application of this method is the difficulty of phase separation owing to emulsification in the presence of surfactant, especially using surfactants with a high hydrophile/lipophile balance (HLB) value, such as AOT (sodium bis (2-ethylhexyl) sulfo-succinate) and SDS (sodium dodecyl sulphate) or dealing with intracellular proteins. It seems that static mixer-settler units and rotating disc contactor cannot be used to solve this problem [4]. Although spray column and centrifugal extractors can decrease the degree of emulsification during the extraction process, the extraction efficiency of the spray column is too low, while the fixed and operating costs of centrifugal contactors are too high. Therefore, a novel contactor that allows the efficient separation of the two phases with low cost and high extraction efficiency needs to be developed. In this study, we designed a novel contactor stirred by an automatic suction type stirrer at low speed, which can disperse an aqueous phase or organic phase into another phase. It was used to extract lysozyme from an aqueous phase to an AOT/ petroleum ether reverse micellar phase without emulsification.

## EXPERIMENTAL

### Experimental Apparatus

Two kinds of contactor stirred by automatic suction type stirrer were provided, as shown in Figure 1(a) and (b). The contactor consists of a cylindrical vessel and an automatic suction type stirrer. The vessel with four vertical baffles is 80 mm in inner diameter and 120 mm in height. As shown in Figure 1(c) and (d), the suction type stirrer consists of a hollow shaft, a hollow cylinder and a disc. The hollow shaft is 8.0 mm in inner diameter with four holes of 5.0 mm diameter drilled in the middle part. The hollow cylinder is 40 mm in diameter and 10 mm in height with 12 holes of 3.0 mm diameter on the wall. The function of the hollow shaft is to transport the solution. The disc is 40 mm in diameter and 5 mm in height. The function of the hollow cylinder is to stir the aqueous or organic phase and disperse the solution into small drops. The function of the disc is to stir the aqueous or organic phase.

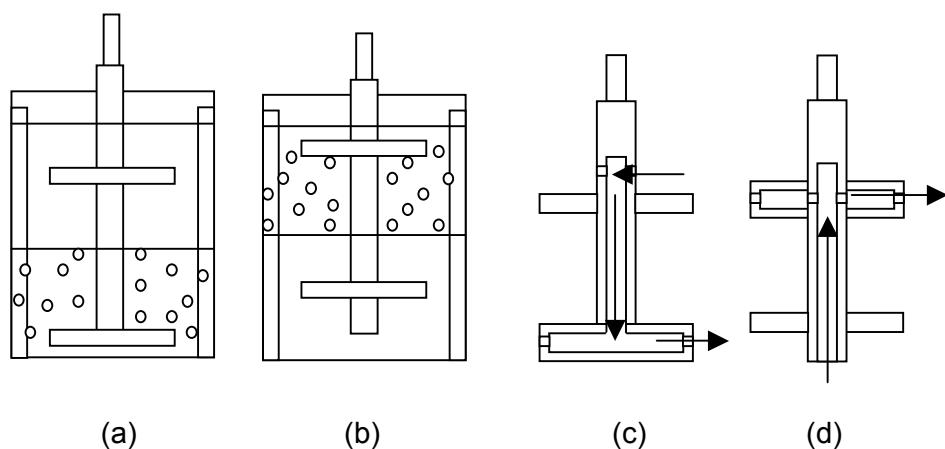

Figure 1. Experimental apparatus.

(a) contactor of light phase dispersed; (b) contactor of heavy phase dispersed; (c) stirrer of light phase dispersed; (d) stirrer of heavy phase dispersed.

### Reverse Micelle Extraction

The organic phase system used was 50 mM AOT/petroleum ether (b.p.: 90-120°C). The aqueous phase was 1.0 mg/ml lysozyme in 0.0125 M borax-HCl buffer at pH 9.0. Potassium chloride was used to control the ionic strength of the aqueous phase. Equal volumes (200 ml each) of aqueous and organic solutions were poured gently into the vessel. The suction stirrer rotated at a speed high enough to suck the dispersed phase and maintain a clear aqueous/organic interface. Samples of equal volumes (3 ml each) of aqueous and organic phase solutions were collected every 2 minutes and the amount of protein in each phase was measured. The protein concentration was determined from the UV absorption at 280 nm (UV-7542 spectrophotometer). Experiments were performed at  $25.0 \pm 0.5^\circ\text{C}$ . The protein mass balance was within the experimental error of  $\pm 5\%$ .

## RESULTS AND DISCUSSION

### The Effect of Rotation Speed

At the proper rotation speed, the aqueous/organic interface remains clear. When using the suction stirrer to disperse the organic phase (Figure 1(c)), the organic solution entered into the holes on the wall of the shaft under the suction pressure, then organic phase drops exited out of the cylinder of suction stirrer. They rose through the aqueous phase and coalesced at the aqueous/organic phase interface (Figure 1(a)).

The effect of rotation speed on lysozyme transfer was investigated using the suction stirrer for dispersion of organic phase (Figure 1(c)), as shown in Figure 2. Lysozyme transfer is relatively slow at low rotation speed such as 350 rpm, while the lysozyme transfer is relatively fast at a high rotation speed such as 580 rpm. For rotation speeds above 600 rpm, the aqueous/organic phase interface was destroyed. Solutions must be settled for a long time to obtain phase separation. For rotation speeds below 300 rpm, the organic solution cannot be dispersed into the aqueous phase due to low suction pressure arising from the rotation.

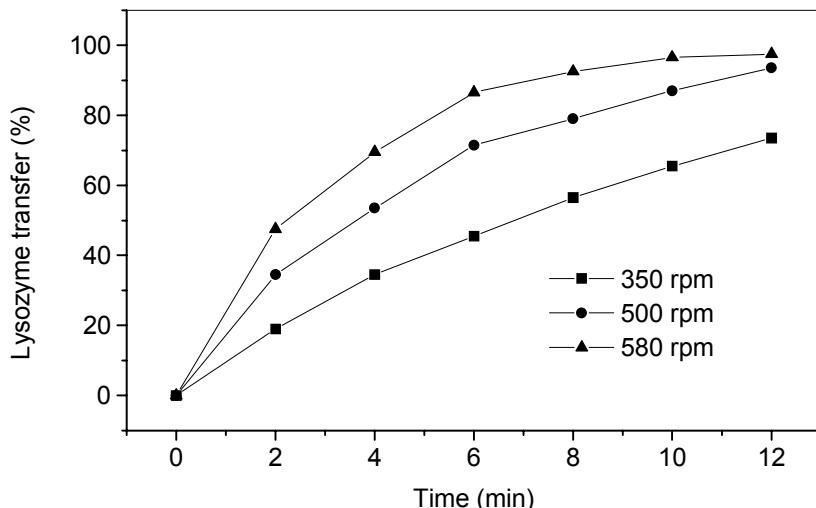

Figure 2. Effect of rotation speeds on lysozyme transfer using automatic suction type stirrer with organic phase dispersed. Aqueous phase: 1.0 mg/ml lysozyme, 0.10 M KCl.

### The Effect of Ionic Strength

The effect of ionic strength of the aqueous phase on the lysozyme transfer was studied using the automatic suction type stirrer to disperse organic phase at 500 rpm, as shown in Figure 3. The balance transfer of lysozyme at 0.02, 0.05 and 0.10 M KCl is close to 60%, 100% and 100%, respectively. Lysozyme transfer could be performed at different low KCl concentrations such as 0.10, 0.05, 0.02 M. The aqueous/organic phase interface remained clear and the organic phase remained transparent. A stable microemulsion was formed when the concentration of KCl in aqueous phase was zero. Lysozyme was extracted to the reverse micellar phase with high extraction efficiency without the emulsification problem of phase separation even with solutions having low ionic strength (0.02 M KCl).

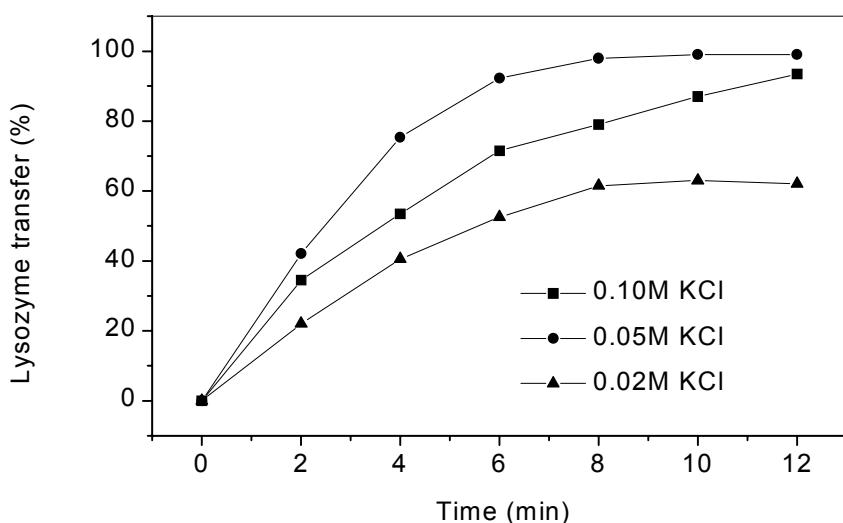

Figure 3. Effect of ionic strength on lysozyme transfer using automatic suction type stirrer with organic phase dispersed at rotation speed of 480 rpm.

### The Direction of Dispersion

The effect of the direction of dispersion on lysozyme transfer was studied, as shown in Figure 4. Mass transfer could be carried out with either phase dispersed. When using suction stirrer dispersing aqueous phase (Figure 1(d)), aqueous solution entered the holes at the bottom of shaft under the suction pressure, then drops of aqueous phase exited out of the cylinder of suction stirrer. They dropped through the organic phase and coalesced at the aqueous/organic phase interface. Finally, they entered into the aqueous phase and mass transfer was performed (Figure 1(b)). The lysozyme transfer for aqueous phase dispersion is faster than for organic phase dispersion. The experimental result could be explained that the reversed micelles were W/O emulsion. However, the highest rotation speed of 500 rpm for dispersion of aqueous phase to maintain a clear aqueous/organic interface is lower than that of 600 rpm required for dispersion of organic phase.

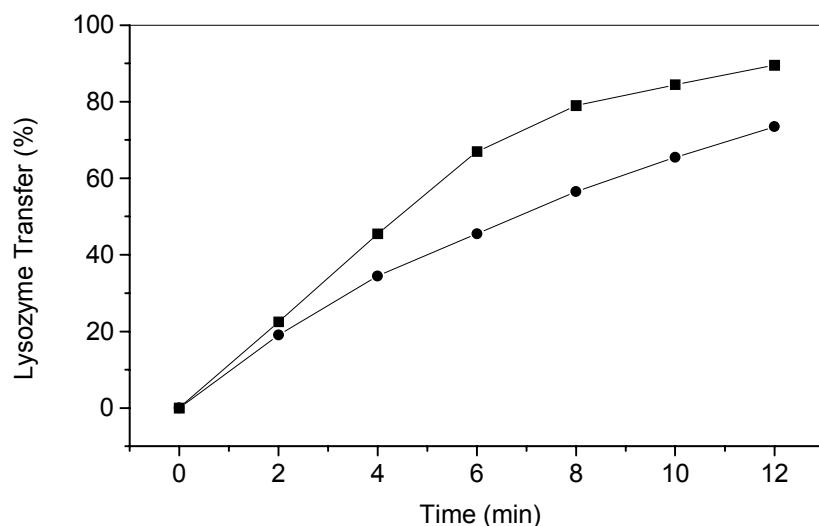

Figure 4. Effect of direction of dispersion on lysozyme transfer at rotation speed of 350 rpm.  
Aqueous phase: 0.10 M KCl, -■- aqueous phase dispersed; -●- organic phase dispersed.

### Comparing with a Traditional Mixer-settler Unit

The efficiency of the contactor agitated by automatic suction of liquid type stirrer was compared with that of a traditional mixer-settler unit. The effect of rotating speed of traditional stirrer on lysozyme transfer is shown in Figure 5. Lysozyme transfer reached 100% when stirred for 1 min and then settled to reach phase separation at relatively high rotating speed such as 580 rpm or 700 rpm. But lysozyme transfer reached 100% when stirred for 4 min and then settled to reach phase separation at relatively low rotating speed such as 480 rpm. The settling times at rotating speed of 480, 580 and 700 rpm were 8.5, 9.5 and 10.8 min, respectively. More than 10 min was needed to reach high efficiency and phase separation when using traditional mixer-settler unit.

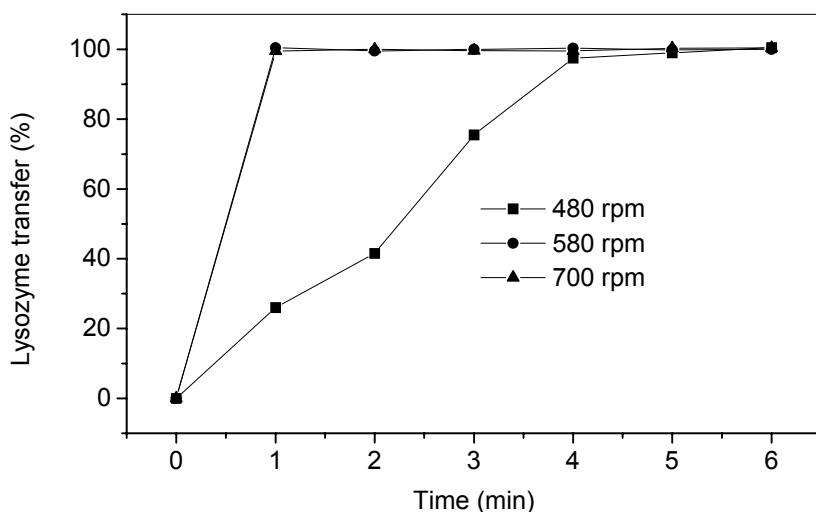

Figure 5. Effect of rotating speed on lysozyme transfer when using mixer-settler unit.

### The Character of the Contactor

The new contactor agitated by automatic suction of liquid type stirrer has several advantages. It can efficiently extract the protein using reverse micelles without emulsification problems even with solutions having low ionic strength (0.02 M KCl). The gentle rotation, which can avoid excessive shear, probably is good for maintaining the activity of proteins, while drastic agitation will cause the denaturation of proteins. The novel contactor can be used for a continuous process with integration of the mixer-settler contactor, as shown in Figure 6. The fixed and operating costs of the contactor may be low and it can be used for either phase dispersed. However, the advantages are not very notable since the total time for 100% extraction plus settling is the same for the new system or a traditional mixed-settler (near 10 min).

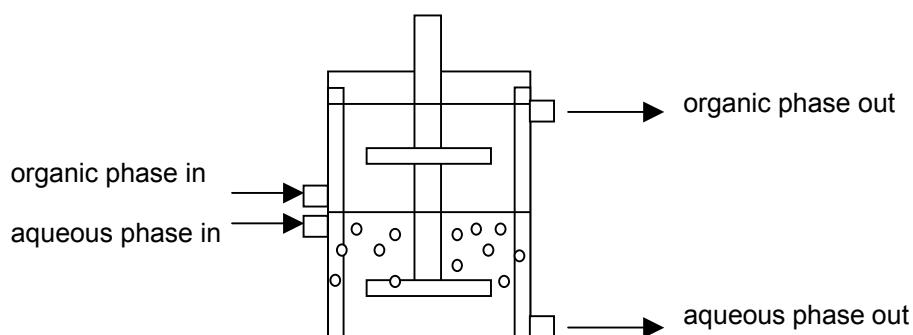

Figure 6. Apparatus for a continuous process when organic phase is dispersed.

### CONCLUSION

A novel contactor agitated with automatic suction type stirrer under low rotation speed to disperse the aqueous phase or organic phase into another phase could be efficiently used for the extraction of proteins using reversed micelles. Lysozyme was extracted to the reversed micellar phase without emulsification even at low ionic strength (0.02 M KCl).

## EXTRACTION OF LYSOZYME BY REVERSED MICELLAR SOLUTION IN A SIEVE-TRAY COLUMN

Yasuhiro Nishii, Chiemi Hara, Takumi Kinugasa,  
Susumu Nii\* and Katsuroku Takahashi\*

Niihama National College of Technology, Niihama, Japan  
\*Nagoya University, Nagoya, Japan

A sieve-tray column was designed and applied for reversed micellar extraction of lysozyme. Two-phase flow and mass-transfer characteristics were studied under various operating conditions. No effect of flow velocities was found on both overall mass-transfer coefficient and droplet diameter. Dispersed phase holdup increased with increasing velocity of continuous and dispersed phase. The column performance was compared with that of a spray and a packed column of similar size in terms of height equivalent per a theoretical stage. The sieve-tray column worked better at high throughput conditions. No significant activity change was observed for lysozyme in feed solution and that in raffinate or extract.

### INTRODUCTION

Reversed micellar extraction has attracted our attention as an emerging technology of bioseparation from 1980s. After the pioneering works by Luisi *et. al.* [1], Goklen and Hatton [2] and Dekker *et. al.* [3], research has been actively carried out to clarify the separation mechanism, equilibrium and kinetics of protein inclusion and release. With a rapid growth of pharmaceutical industries, efficient processes are eagerly desired for bioseparations. The technique of reversed micellar extraction is potentially applicable to a large-scale operation. Because of differences in properties between reverse-micellar solution systems and conventional liquid-liquid systems, special considerations are required for designing equipments for reversed micellar extraction. Only limited research has been carried out on column-type contacting devices.

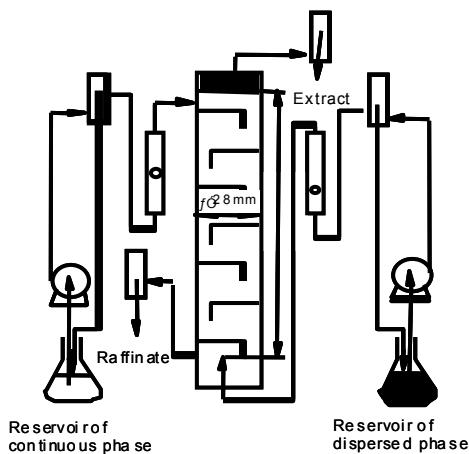

Lye *et. al.* [4] reported individual mass-transfer coefficients in a spray column operation. The present authors conducted experiments on reversed micellar extraction of lysozyme with a packed column and found that the organic phase flows in the form of droplets even for PTFE packing which is highly wettable for organic phase [5]. This flow behavior was specifically observed for reversed micellar systems. Furthermore, the activity of lysozyme was successfully kept at high value during the operation. When a rotating disc contactor was used, sufficiently large holdup of dispersed phase could be attained. However at the same time, a large shear stress caused a loss of protein activity [6]. The present study focuses on a sieve-tray column which is typically used in various extraction processes for large scale operations. Flow and mass-transfer characteristics were examined in a laboratory scale apparatus and the performance was compared with other columns.

## EXPERIMENTAL

Aerosol-OT (bis (2-ethylhexyl) sodium sulfosuccinate, AOT) was supplied from Nacalai Tesque, Inc. and used without further purification. Organic solution as dispersed phase was prepared by dissolving AOT into 2-2-4 trimethylpentane at 0.05 kmol/m<sup>3</sup>. Lysozyme (M.W.14300, pI=11) was dissolved into 0.3 kmol/m<sup>3</sup> KCl aqueous solution and used as a feed solution of continuous phase. Concentration of lysozyme in feed solution was 0.1 kg/m<sup>3</sup>. It was adjusted to pH 7 with aqueous solutions of KOH and HCl. Prior to the experiment, the organic solution was saturated with protein-free feed solution for further use. Physical properties of both phases are listed in Table 1. Lysozyme was obtained from Sigma Chemical Co. and other chemicals from Wako Pure Chemical Industries, Ltd. or Katayama Chemical. Extraction equilibrium of the solution system was reported by Kinugasa *et al.* [7]. Within the range of operational condition of this work, linear equilibrium relation between  $C_d$  and  $C_c$  was obtained. Distribution ratio of lysozyme, which is defined as  $C_d / C_c$ , is as high as about 50.

*Table 1. Physical properties.*

	Density (kg/m <sup>3</sup> )	Viscosity (Pa.s)	Interfacial tension (mN/m)
Continuous phase	998	$0.90 \times 10^{-3}$	2
Dispersed phase	692	$0.47 \times 10^{-3}$	

*Figure 1. Schematic diagram of experimental setup.*

Figure 1 shows a schematic diagram of the sieve-tray extraction column. Within a glass tube of 28 mm in i.d. and 210 mm long, 7 plates of PTFE were mounted at 25 mm clearance. PTFE was chosen as a tray material to provide a surface that is preferentially wetted by organic solvents. Such a surface can work twofold: one is to enhance the coalescence of organic phase droplets and the other is to enhance the droplet formation. The tray was fabricated from a circle plate. A part of the plate was bended down along with a chord to make an opening space for downcomer. Holes formed are on horizontal part of the plate. Detailed specification of the tray is given in Table 2.

The column operation was started with supplying both solutions slowly. After finding the continuous phase reaches a level, flow rates of both phases were adjusted at respective values to keep a constant level of water/oil interface. Samples of both solutions were taken out from the outlet after reaching steady state. Concentrations of lysozyme in each phase were determined with UV-Visible spectrophotometer (Shimadzu UV-1600) from an absorption at 280 nm. Sizes of dispersed droplets were measured from close-up images taken by a digital video camera. Behavior of two-phase flow above a tray was also monitored by the camera. Activity of lysozyme in extract and raffinate was measured by the method developed by Imoto and Yagishita [8].

Change in rising velocity of droplet,  $U_d$ , with  $V_d$  for various  $V_c$  is presented in Figure 5. Because of a constant drop size for any flow velocities examined (referred in Figure 7), the  $U_d$  can be interpreted as the velocity of circulation flow. Obviously, the increase of  $V_d$  leads to an increase of circulation flow velocity and a decrease of  $V_c$  causes an increase of  $U_d$ .

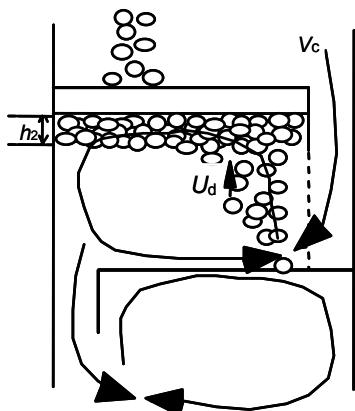

Figure 4. Flow pattern above a tray.

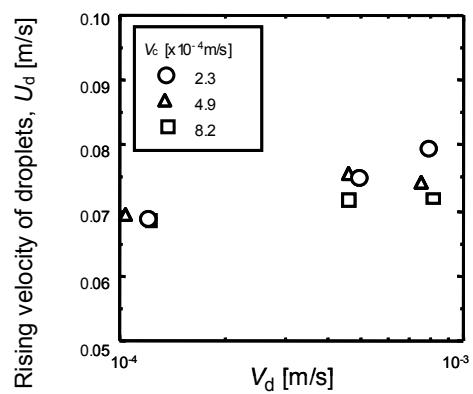

Figure 5. Rising velocity of droplets.

Figure 6 shows the effect of  $V_c$  on thickness of accumulated drop layer,  $h_2$ . The balance of rates between droplet supply and coalescence determines the thickness. Values of  $h_2$  increase with the increase in both  $V_c$  and  $V_d$ . The effect of  $V_d$  on  $h_2$  is straightforward. The increase of  $V_c$  leads to slow down the circulation and to suppress the movement of droplets in the accumulated layer. In such a way, increasing  $V_c$  may result in decreasing the rate of droplet coalescence.

### INTERFACIAL AREA AND MASS-TRANSFER COEFFICIENT

Average diameter of dispersed phase droplets is determined as follows. Since the shape of droplets is ellipse, the size is given as an equivalent diameter of a sphere which has the same volume as the body of ellipse revolution. For more than 100 droplets, the size is measured from their images and the average droplet diameter was determined. Effects of both flow velocities on droplet size are shown in Figure 7. The size is about 3 mm and is independent of both  $V_d$  and  $V_c$ .

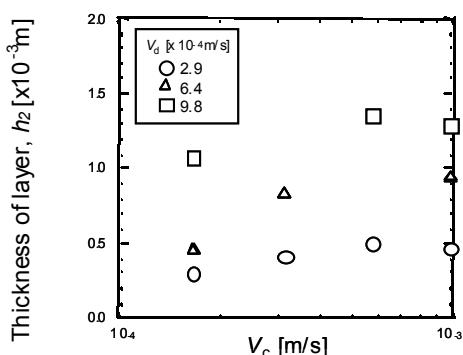

Figure 6. Thickness of layer of accumulated droplets.

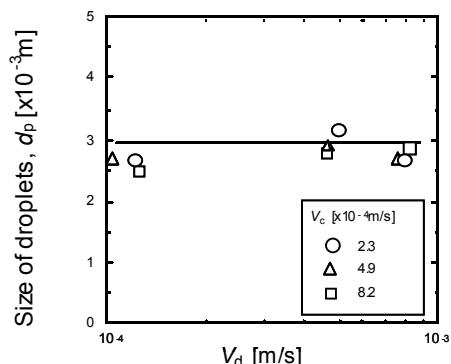

Figure 7. Size of droplets.

Since the organic phase mainly exists as a form of droplet, interfacial area is calculated from the following equation when holdup,  $\phi$ , is known.

Change in rising velocity of droplet,  $U_d$ , with  $V_d$  for various  $V_c$  is presented in Figure 5. Because of a constant drop size for any flow velocities examined (referred in Figure 7), the  $U_d$  can be interpreted as the velocity of circulation flow. Obviously, the increase of  $V_d$  leads to an increase of circulation flow velocity and a decrease of  $V_c$  causes an increase of  $U_d$ .

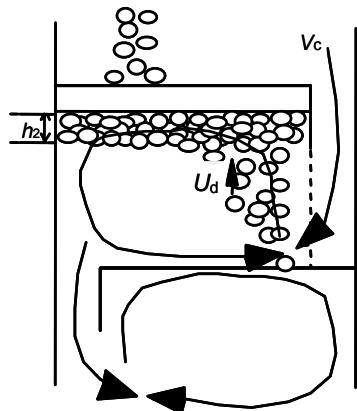

Figure 4. Flow pattern above a tray.

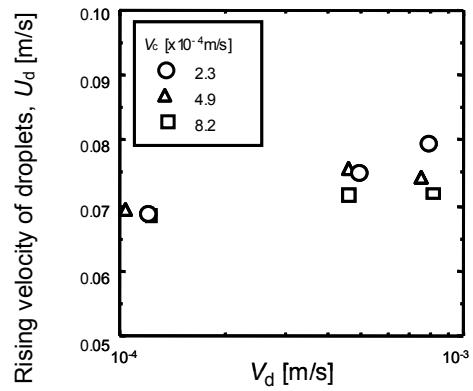

Figure 5. Rising velocity of droplets.

Figure 6 shows the effect of  $V_c$  on thickness of accumulated drop layer,  $h_2$ . The balance of rates between droplet supply and coalescence determines the thickness. Values of  $h_2$  increase with the increase in both  $V_c$  and  $V_d$ . The effect of  $V_d$  on  $h_2$  is straightforward. The increase of  $V_c$  leads to slow down the circulation and to suppress the movement of droplets in the accumulated layer. In such a way, increasing  $V_c$  may result in decreasing the rate of droplet coalescence.

### INTERFACIAL AREA AND MASS-TRANSFER COEFFICIENT

Average diameter of dispersed phase droplets is determined as follows. Since the shape of droplets is ellipse, the size is given as an equivalent diameter of a sphere which has the same volume as the body of ellipse revolution. For more than 100 droplets, the size is measured from their images and the average droplet diameter was determined. Effects of both flow velocities on droplet size are shown in Figure 7. The size is about 3 mm and is independent of both  $V_d$  and  $V_c$ .

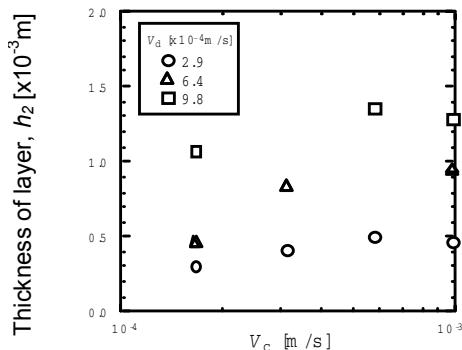

Figure 6. Thickness of layer of accumulated droplets.

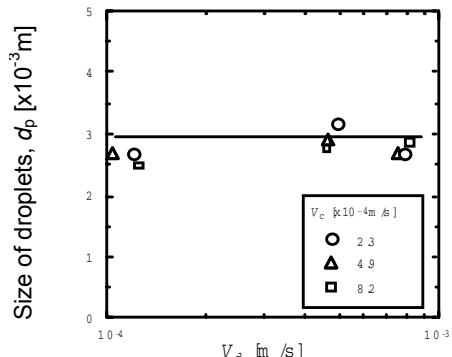

Figure 7. Size of droplets.

Since the organic phase mainly exists as a form of droplet, interfacial area is calculated from the following equation when holdup,  $\phi$ , is known.

$$a = \frac{6\phi}{d_p} \quad (2)$$

In Figure 8, interfacial area,  $a$  is plotted against  $V_d$  and  $V_c$ . Because  $d_p$  is constant under the present condition, interfacial area is proportional to holdup of dispersed phase. As mentioned above, the increase in  $V_c$  leads to the increase in holdup, thus the  $a$  increased with increasing  $V_c$ . Once interfacial area is determined, the overall mass-transfer coefficient,  $K_c$  can be separated from  $K_c a$ .

Overall mass-transfer coefficient,  $K_c$ , is presented in Figure 9. Values of  $K_c$  are constant with varying  $V_d$  and  $V_c$ , which suggests the mass-transfer coefficient of lysozyme is independent of flow conditions. Interestingly, values of  $K_c$  are in the same order of those values obtained for metal ion extraction in a mixer-settler column. Furthermore, those values are almost constant for the change of flow velocities under strong agitation [9]. This fact implies that a change of interfacial area predominates the extraction rate in column operations rather than a change of mass-transfer coefficient.

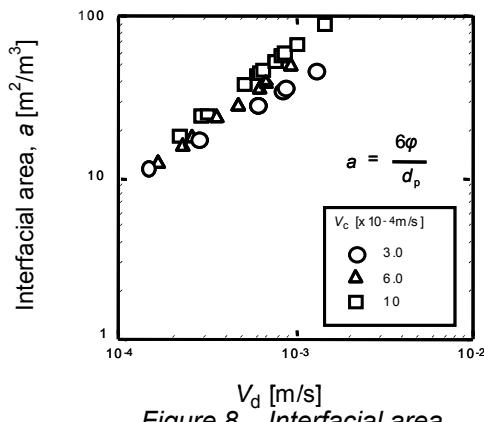

Figure 8. Interfacial area.

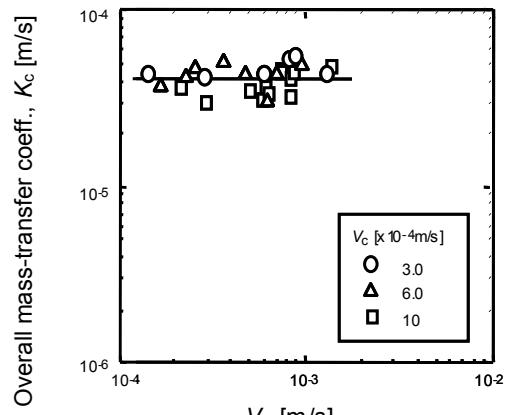

Figure 9. Overall mass-transfer coefficient.

## COMPARISON WITH OTHER COLUMNS

Performance of the sieve-tray column is compared with that of a spray or a packed column in terms of height equivalent per a theoretical stage (HETS). These three columns have similar height and diameter. Size of the spray column is the same as the sieve-tray column, and the packed column is of 35 mm i.d. and the height of packing is 200 mm.

Figure 10 represents values of HETS against total throughput,  $V_t$  which is defined as  $V_c + V_d$ . Better performance of the sieve-tray column is found at large  $V_t$ . Although the packed column gives the best HETS in the range of small  $V_t$ , the performance becomes worse with increasing the throughput. The use of sieve-tray column is recommended for the operation at a large throughput condition.

## ACTIVITY CHANGE OF LYSOZYME

Relative activity of lysozyme in the extract and the raffinate is given in Table 3. No significant change was observed for the activity during the experiment. Under a mild mixing condition in the sieve-tray column, lysozyme was extracted into reversed micelles without denaturation. Repeating of droplet coalescence and re-dispersion give no effect on the protein activity.

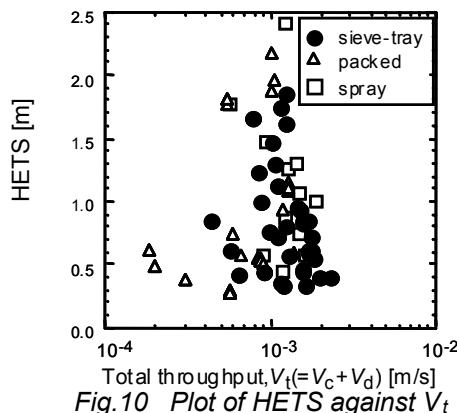

Fig. 10 Plot of HETS against  $V_t$

Table 3. Relative activity of lysozyme.

	$V_c$ (m/s)	$V_d$ (m/s)	Relative activity (%)
Extract *	$5.8 \times 10^{-4}$	$9.4 \times 10^{-4}$	99
Raffinate	$5.7 \times 10^{-4}$	$2.6 \times 10^{-4}$	108

\* Lysozyme was back-extracted from extract into aqueous solution.

## CONCLUSION

Extraction of lysozyme in a sieve-tray column was studied under various operating conditions and the column performance was compared with other columns. Droplet size was independent of flow velocities. A large circulation flow of continuous phase was observed above the tray and the effects of  $V_c$  and  $V_d$  on the circulation velocity was discussed. The holdup of dispersed phase, which is closely related to the interfacial area, changed with the circulation velocity. No effect of flow velocities was found on the overall mass-transfer coefficient. Performance of the sieve-tray column was compared with that of a spray and a packed column of similar size in terms of HETS. The sieve-tray column had an advantage of the operation at high throughput conditions. Activity of lysozyme was perfectly kept during the experiment.

## NOMENCLATURE

$a$ = interfacial area per unit volume	[ $m^2/m^3$ ]	$z$ = stage clearance	[m]
$C$ = lysozyme concentration	[ $kg/m^3$ ]	$\phi$ = holdup of dispersed phase	[-]
$E_{oc}$ = overall stage efficiency	[-]		
$d_p$ = drop diameter	[m]	<Subscripts>	
$h_2$ = thickness of accumulated layer	[m]	c = continuous phase	
$K$ = overall mass-transfer coefficient	[ $m/s$ ]	d = dispersed phase	
$U_d$ = rising velocity of droplets	[ $m/s$ ]	t = total	
$V$ = superficial velocity of phases	[ $m/s$ ]

## MODELING OF SOLUBILITIES OF ESSENTIAL OILS IN LIQUID CARBON DIOXIDE PRESENT IN THREE ODORIFEROUS PLANTS

E. M. B. D. Sousa, D. N. Silva, O. Chiavone-Filho and M. A. A. Meireles\*

UFRN, Dept. de Engenharia Química, Natal, Brazil

\*UNICAMP, Faculdade de Engenharia de Alimentos, Campinas, Brazil

This work discusses a methodology to estimate the solubility for systems formed of an odoriferous plant + CO<sub>2</sub>. To develop the estimation method, experimental solubility data for three different odoriferous plants, whose volatile oils have several pharmacological applications, are used. The estimation method proposed uses the volatile oil composition obtained by supercritical fluid extraction. Based on the chemical composition of the volatile oil and the use of a group contribution method, a pseudo pure component is defined. The solubilities of the volatile oils for the systems are calculated using the Peng-Robinson equation of state with one adjustable parameter. The results demonstrate that, in spite of the simplifying assumptions, the method quantitatively describes the experimental data.

### INTRODUCTION

The worldwide energy crises and the consumer's choice for products made from natural resources have stimulated the search for new technologies. Supercritical fluid extraction (SFE) is known as a clean technology because it presents no harm to either man or the environment. SFE using CO<sub>2</sub> requires no additional treatment of the product and of the residues since the solvent (CO<sub>2</sub>) is not toxic. In addition, due to the use of relatively low temperatures, the solute maintains its original characteristics.

For the process design of SFE systems, reliable methods to calculate the phase equilibrium parameters of the extraction step (odoriferous plant + CO<sub>2</sub>) and the separation step (volatile oil + CO<sub>2</sub>) must be available. The multicomponent mixture that forms the volatile oil is generally composed of substances from different chemical classes such as aldehydes, alcohols, terpenes, sesquiterpenes, oxygenated and phenolic compounds, etc. Such systems have a behavior that is appreciably far from the ideal, to make thermodynamic modeling difficult. In addition, the strong asymmetry of the system, due to differences of size and polarity of the substances, and the proximity of the solvent critical point would require thermodynamic modeling using a complex equation of state. This would need a considerable amount of experimental data, not yet available. Therefore, simplified models are presently used to assess some of the information of the system. This work proposes a model for the measured solubilities of the, odoriferous plant + CO<sub>2</sub>, system using the chemical compositions of the volatile oils and the Peng-Robinson equation of state with one adjustable parameter for the attractive term.

The following odoriferous plants were selected for this work: Clove buds (*Eugenia caryophyllus*), Eucalyptus-NE (*Eucalyptus tereticornis* Smith), and *Lippia sidoides* Cham. The solubility data for the system odoriferous plant + CO<sub>2</sub> were obtained using the dynamic method [1].

## CHARACTERIZATION OF THE VOLATILE OIL

Volatile oils are multicomponent mixtures composed of substances from several chemical classes, for which the thermophysical properties are mostly unknown. For the solubility modeling, the volatile oil was considered a pseudo-component formed by the multicomponent mixture. The compositions of the multicomponent mixtures were determined by gas chromatography coupled to mass spectrometry [2, 3]. Although the response factor of the various substances for the GCMS analysis may not be the same, the area percent was used directly as a mass fraction. This information was used to obtain the mixture composition in terms of molar fractions. The thermophysical properties of CO<sub>2</sub> and of some volatile oil components were obtained from AIChE-DIPPR [4]. When the thermophysical properties of the substances were missing, their values were estimated using the group contribution method of Joback [5]. The needed vapor pressures  $P$  were estimated using the Wagner equation as modified by Vetere [6]:

$$A = -\alpha_c ; \quad \alpha_c = -0.294 + 1.1708 \frac{T_{br} \ln P_c}{1 - T_{br}} ; \quad (1)$$

$$\frac{\alpha_b}{\alpha_c} = 3.0042 - 2.4211 T_{br} ; \quad B = \frac{\alpha_b + 2\alpha_c - 3H - \ln P_c}{1.5(1 - T_{br})^{0.5}} ; \quad (2)$$

$$C = \frac{\alpha_c - H - B(1 - T_{br})^{0.5}}{(1 - T_{br})^{0.5}} ; \quad H = \frac{T_{br} \ln P_c}{1 - T_{br}} \quad (3)$$

where  $A$ ,  $B$ ,  $C$ ,  $\alpha$  and  $H$  are constants evaluated from the reduced ( $r$ ) and critical ( $c$ ) and boiling ( $b$ ) properties. The acentric factor  $\omega$  was determined using the Edmister [7] expression:

$$\omega = \frac{3}{7} \left( \frac{T_b}{T_b - T_c} \right) \log \left( \frac{1.01325}{P_c} \right) - 1 \quad (4)$$

Once the thermophysical properties of each compound were known, the Kay rule [8] was used to calculate the pseudo-component properties ( $M$ ):

$$M = \sum x_i M_i \quad (5)$$

The molar volume of each volatile oil ( $V_1^{sat}$ ) was experimentally determined using a digital densimeter (DMA 602 ANTON PAAR, Austria) for temperatures from 283.15 to 298.15 K, with a 5 K interval. The volatile oil densities varied linearly with the temperature, and this information was used to evaluate the Poynting correction.

## THERMODYNAMIC MODEL

The solubility was modeled using the following isofugacity criterion:

$$\hat{f}_i^S(T, P, X_i) = \hat{f}_i^F(T, P, Y_i) \quad (i = 1, N) \quad (6)$$

where the superscripts  $S$  and  $F$  refer to the solid (odoriferous plant) and the fluid (liquid, gas, or supercritical), respectively.  $X_i$  and  $Y_i$  correspond to the solid and fluid phase composition, respectively.

If the solid phase is said to be formed by a cellulosic structure (inert to the action of the solvent) and a solute, *i.e.*, the volatile oil, then we have  $\hat{f}_1^s(T, P, X_1) = f_1^s(T, P)$ . Recalling that the volatile oil is treated as a pseudo-component, designated by the subscript 1, the fluid phase can also be treated as a binary mixture, where the molar fraction of component 1 is the volatile oil solubility ( $Y_1$ ), so that equation (6) may be re-written as:

$$f_1^S(T, P) = \hat{f}_1^F(T, P, Y_1) \quad (7)$$

Therefore, the fugacities ( $\hat{f}_i^F$  and  $f_i^S$ ) of the volatile oil in the fluid and in the solid phases are given, in terms of the pseudo-component, by:

$$\hat{f}_1^F = Y_1 \hat{\phi}_1^F P \quad (8)$$

$$f_1^S = P_1^{sat} \phi_1^{sat} \exp \left[ \frac{V_1^{sat} (P - P_1^{sat})}{RT} \right] \quad (9)$$

Combining equations (8) and (9) and remembering that the vapor pressure values are low ( $\phi_1^{sat} \approx 1$  and  $P - P_1^{sat} \approx P$ ) and that so are the oil concentration ( $\hat{\phi}_1^F \approx \hat{\phi}_1^{F,\infty}$ ), the solubility can be evaluated from:

$$Y_1 = \frac{P_1^{sat} \exp \left( \frac{V_1^{sat} P}{RT} \right)}{\hat{\phi}_1^{F,\infty} P} \quad (10)$$

The fugacity coefficient at infinite dilution was calculated using the Peng-Robinson equation [9] and the computer routines from Sandler [10]. The values of  $K_{12}$  were estimated for every pair of temperature and pressure, considering that the solute is at infinite dilution in the solvent phase, i.e.,  $Y_{oil} = Y_1 = 10^{-6}$ , and using the experimental value of the solubility to establish the optimum value of the interaction parameter. Next, the average with respect to temperature and pressure of  $K_{12}$  for each oil or system was evaluated. These values were used to estimate the solubility and compared to the experimental value. Therefore, the procedure just described makes the parameter  $K_{12}$  correct both the non-ideal behavior of the fluid phase and the interaction between the oil components and the cellulosic structure. Actually, the parameter  $K_{12}$  is defined as a correction of the geometric average for the attractive term (a), using the quadratic mixing rule. For the repulsive term (b), the linear mixing rule was used, without additional parameter.

$$a = \sum \sum x_i x_j a_{ij} \quad (11)$$

when  $i$  is different to  $j$ , for instance  $i = 1$  and  $j = 2$ :

$$a_{12} = \sqrt{a_{11} a_{22}} (1 - K_{12}) \quad (12)$$

## RESULTS AND DISCUSSION

The thermophysical properties of the volatile oils are given in Table 1. Although the volatile oils compositions are very different from each other [1-3] their thermophysical properties are similar. For instance, clove oil contains 79.7% of eugenol, 10.1% of  $\beta$ -caryophyllene, 9.40% of Eugenyl acetate, and 0.80% of humulene. These values were obtained by averaging the composition of clove oil given in literature [1, 2]. The *L. sidoides* oil contains 24 compounds, the major ones being thymol (48.3 %), trans-caryophyllene (13.8%), 1,8-cineole (8.6%),  $\alpha$ -terpineol (2.3%) [3]. The eucalyptus-NE oil contains 26 substances [3], the major ones being aromadendrene (21.1%), globulol (13.8%), 1,8 cineole (11.0%), and 4-terpineol (4.4%). The volatile oils compositions given above are expressed in area percentage. Nonetheless, as previously discussed, they were directly used as a mass fraction in order to express the oils compositions in terms of molar fraction. The other substances found in the volatile oil of these three odoriferous species were polar, thus adding to the difficulties of characterizing and modeling the phase equilibria.

*Table 1. Thermophysical properties of clove oil, eucalyptus oil, and L. sidoides oil.*

Volatile oil	<i>MW</i> (g/mol)	<i>T<sub>b</sub></i> (K)	<i>T<sub>c</sub></i> (K)	<i>P<sub>c</sub></i> (bar)	$\omega$	<i>A<sub>p</sub></i> *	<i>B<sub>p</sub></i> *

*Table 4. Solubilities of Eucalyptus-NE oil [1] in CO<sub>2</sub> [2] as a function of temperature and pressure. Solubility values were calculated using  $K_{12} = 0.296$ .*

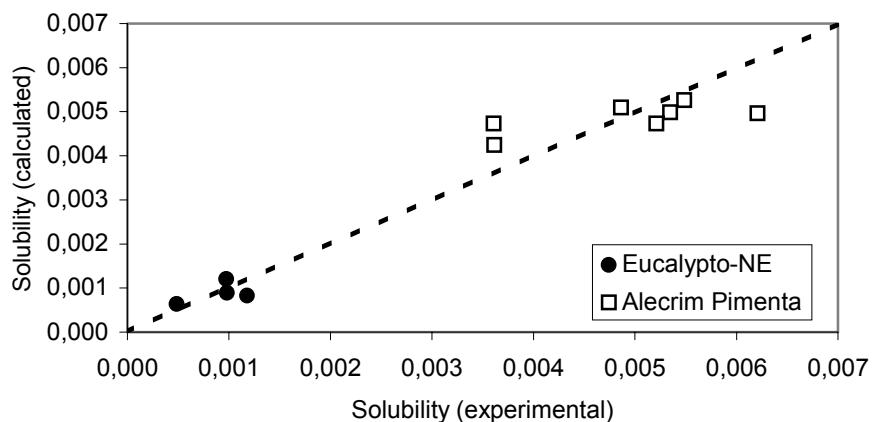

Experimental data Ref.	Pressure (bar)	Temperature (K)	Calculated solubility	Experimental solubility	Relative deviation (%)
[2]	66.7	288.15	0.00089	0.00094	5.1
	66.7	288.15	0.00089	0.00098	8.7
	66.7	283.15	0.00064	0.00049	32.0
	66.7	293.15	0.00120	0.00097	23.8
	78.5	288.15	0.00082	0.00118	30.0
Mean deviation					19.9

The mean deviations in Tables 2 to 4 are relatively large, but we should recall that several simplifications were made in order to treat a very complex system as a two-phase binary system. In addition, the majority of the experimental data used were taken close to the solvent critical point, thus making modeling even harder. Notwithstanding, from the designing point of view the calculated solubility can be satisfactorily used for initial scale-up calculations. In addition, the results can be used as a guide to experimental design for solubility isotherms determinations.

Figures 1 and 2 show the dispersion between calculated and experimental values of the solubility. The spread of the values observed for the system clove + CO<sub>2</sub> is partially due to the fact that two independent data sets were used. Nevertheless, for the other two systems (eucalyptus + CO<sub>2</sub> and *L. sidoides* + CO<sub>2</sub>) the deviations were even higher, although in both cases the experimental data came from a unique data set.

*Figure 1. Solubility of clove oil in CO<sub>2</sub> in mole fraction.*

*Figure 2. Solubilities of Eucalyptus-NE and *L. sidoides* oils in CO<sub>2</sub> in mole fraction.*

## CONCLUSIONS

The methodology employed to estimate the solubility for systems containing odoriferous plant + CO<sub>2</sub> provided satisfactory results. They were satisfactory if we consider both the simplifications made to treat the multicomponent mixture that forms the volatile oil as a pseudo-component and the need to assess the thermophysical properties using a group contribution method, which was developed with information for substances that belongs to other chemical classes.

The parameter  $K_{12}$  embodies both the non-ideal behavior of the fluid phase and the interaction of the volatile oil with the cellulosic structure. Nevertheless, in order to obtain a quantitative description of the system, the cubic equation of state that was used would have to be substituted by relations that are more accurate, so that the polarity of the substances are better considered [11]. However, we should keep in mind that the phase equilibrium of the major volatile oil compounds with CO<sub>2</sub> has to be studied in order to understand the true nature of the interaction between the various substances. Another suggestion, is to optimize  $K_{12}$  with a least square procedure, instead of using the average value.

It must be added that for the scale up of processes the results are very important and satisfactory, since up to now scaling up is performed using the overall extraction curves, thus treating the SFE extracts as a pseudo-component.

## EVALUATION OF IMPROVED SOLVENTS FOR CAPROLACTAM EXTRACTION

Mathijs L. van Delden, Norbert J.M. Kuipers, André B. de Haan and Oded Lerner\*

University of Twente, Enschede, The Netherlands  
 \*Bateman Advanced Technologies Ltd., Yokneam, Israel

For environmental reasons conventional solvents such as benzene and chlorinated hydrocarbons are not desired for the industrial extraction of caprolactam. Therefore, alternative solvents and solvent mixtures have been investigated. Based on solvent design calculations using an extended UNIFAC group contribution model, mixtures of organic alkanes (hexane) with small amounts of alcohols (hexanol) as a co-solvent show caprolactam partition ratios equal or better than with benzene. These and other solvent mixtures will be tested on pilot plant scale in the Bateman Pulsed Column (BPC) and other types of columns.

### INTRODUCTION

Caprolactam, C<sub>6</sub>H<sub>11</sub>NO, the monomer of nylon 6, is produced in a multi-step process, shown schematically in Figure 1. More detailed descriptions of the available commercial processes are available elsewhere [1-4].

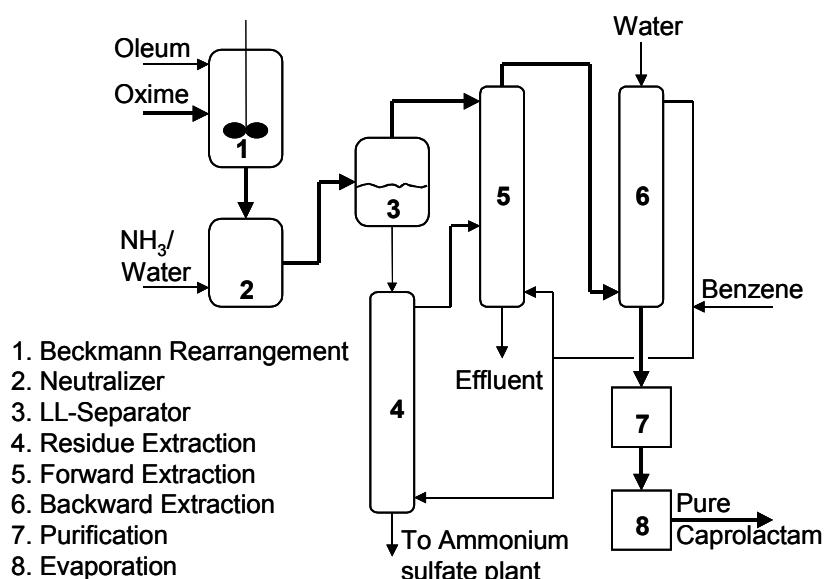

Figure 1. Schematic representation of the caprolactam process.

Crude caprolactam is first obtained by neutralizing the sulphuric acid containing reaction mixture from the Beckman rearrangement with aqueous ammonia. The neutralization results in the formation of two immiscible phases consisting of a highly concentrated, 65-70 wt%, crude aqueous caprolactam phase in equilibrium with a nearly saturated ( $\pm$  40 wt%) aqueous ammonium sulphate solution. After separating the two phases the caprolactam from both streams is recovered and purified by solvent extraction. Finally the crude caprolactam is re-extracted with water followed by chemical treatment and vacuum distillation. The extraction of caprolactam is commonly carried out with solvents such as benzene, toluene, nitrobenzene and various chlorinated hydrocarbons [1-8] in rotating disc contactors and pulsed packed columns.

Problems associated with equipment inefficiencies and toxicity of the solvents used have lead to the development of several options to improve existing caprolactam extraction technology by different process layouts [9, 10] or by a more accurate description of the effect of high ammonium sulphate concentrations on the phase behaviour in the caprolactam/water/ benzene system [11,12]. A possible option is the replacement of currently used contactors by the Bateman Pulsed Column technology. Other significant technology breakthroughs concern the development of new extraction schemes. Essential for the success of creating new extraction processes is the availability of suitable solvents. Introduction of alternative solvents can offer the opportunity of the development of environmentally benign caprolactam extraction technology in combination with enhanced selectivity's and capacities.

Evaluation of solvents can be based on predictive calculations using the UNIFAC group contribution approach, as presented in [13]. In this study an extended UNIFAC model was used to first verify it's applicability to predicting the effect of solvent structure on caprolactam distribution and then to evaluate solvent mixtures. It is intended that in future studies the most suitable solvent mixtures will be evaluated in pilot-plant investigations where the performance of various columns will be compared to that of the Bateman Pulsed Column.

## **DESIGN OF CAPROLACTAM SOLVENTS USING EXTENDED UNIFAC MODEL**

A study on the design of alternative, environmentally benign solvents for caprolactum extraction was performed. The UNIFAC group contribution model with linearly temperature dependent interaction parameters [14-17] was used to evaluate the effect of solvent structure on the selectivity as well as the capacity. Before this was possible the UNIFAC parameter matrix had to be extended to include more specific amide groups such as those present in caprolactam. According to the division used to characterize amine groups, the original, single UNIFAC amide group (-CO-NH-) was split up into 3 formamide and 3 new amide groups. An extensive amount of new vapour-liquid equilibrium and excess enthalpy data, using n-methylacetamide as the model component, was measured [18-22] and combined with data available in literature to determine interaction parameters for the amide group (-CH<sub>n</sub>-CO-NH-).

After demonstrating that the extended UNIFAC model was able to predict the effect of solvent structure on the distribution of caprolactam, the next step was to evaluate possible solvents and solvent mixtures that might be suitable for the extraction of caprolactam. For this evaluation two techniques were used. Firstly a pre-selection of potential solvent classes (alkanes, aromatics, ketones, alcohols, amines) was made using the principle component method [23]. Secondly, use was made of the knowledge that aromatics, chlorinated hydrocarbons and nitrobenzene were suitable solvents with respect to their capability of extracting caprolactam from an aqueous solution.

Combining this information leads to the following preliminary directions to find suitable alternative pure solvents.

1. Non-polar solvents such as alkanes and cycloalkanes are not suitable for the extraction of caprolactam because of their unfavourable caprolactam partition ratio. Other non-polar solvents such as secondary amines are also expected to be unsuitable.
2. Polar solvents, such as ketones, ethers, alcohols (see Figure 2), phenols, acids and amines exhibit strong and specific interactions with caprolactam. This results in a much more favourable caprolactam partition ratio compared to non-polar solvents. The main disadvantage of polar solvents is their relatively high solubility in the aqueous phase. Using polar solvents with a long hydrocarbon tail can counteract this. However, in that case solvent recovery is difficult because of the high boiling point. Another disadvantage of polar solvents is that a large fraction of polar impurities will be co-extracted resulting in a decreasing product quality.

Both polar and non-polar pure solvents are not suitable for the extractive recovery of caprolactam. However, by using tailor-made mixtures of polar and non-polar solvents the positive properties of both solvent classes can be combined to produce suitable solvents.

### **Experimental Procedure**

To obtain experimental data the following procedure was followed. A stirred glass equilibrium cell, controlled by thermostat to maintain the temperature within  $\pm 0.1$  K, was used. For each experiment an aqueous feed mixture, consisting of the desired amount of caprolactam in water, was prepared. After adding the organic solvent(s) and obtaining the desired temperature, the cell was stirred continuously for 30 minutes to ensure that equilibrium was attained. The stirring was stopped and the mixture was allowed to settle for the required time, generally 2 or more hours, to obtain full separation into two completely clear liquid phases. Samples were taken from both phases and analysed. Liquid chromatography was used to measure the caprolactam concentration, Karl-Fisher titration for the water concentration, and gas chromatography for the organic solvent concentration. The concentrations of caprolactam, water and organic solvent were obtained with a relative accuracy of  $\pm 1\%$ .

## **RESULTS**

### **Results For Pure Solvents**

In the caprolactam recovery processes one of the most important parameters is the distribution of the caprolactam between the solvent and aqueous phase. Figure 2 shows a comparison of the extended UNIFAC predictions with experimental data for the distribution of caprolactam between benzene and the aqueous phase. Considering the fact that the predicted distribution curves shown were produced using no information on caprolactam containing systems, their agreement with the quantitative results was quite good. The figure also illustrates that the predictions agreed quite well with the experimentally observed trend that at equal concentrations in the aqueous phase the solubility of caprolactam decreases in the order: benzene > toluene > cyclohexane. Further a solvent with strong specific interactions such as cyclohexanol shifts the caprolactam partition ratio (wt% in solvent phase / wt% in aqueous phase) by 1 to 2 orders of magnitude.

### **Results For Solvent Mixtures**

Instead of replacing benzene with a pure solvent, an environmentally benign solvent mixture can be used to modify the solvent character to such an extent that a more favourable caprolactam partition ratio is combined with minimal changes in the impurity partition ratios. Figure 3 illustrates that by adding small amounts of polar co-solvents, such as 1-hexanol to toluene, the caprolactam partition ratio became more favourable than for pure benzene.

Furthermore even for poor solvents, such as cycloalkanes and alkanes, the partition ratio was shown to increase rapidly to values comparable with those for pure benzene. Experimental results for hexane confirmed the increase of the partition ratio caused by adding 1-hexanol. However, deviations from the model predictions occurred, even for pure hexane. Figure 2 shows that such a deviation was also observed for cyclohexane.

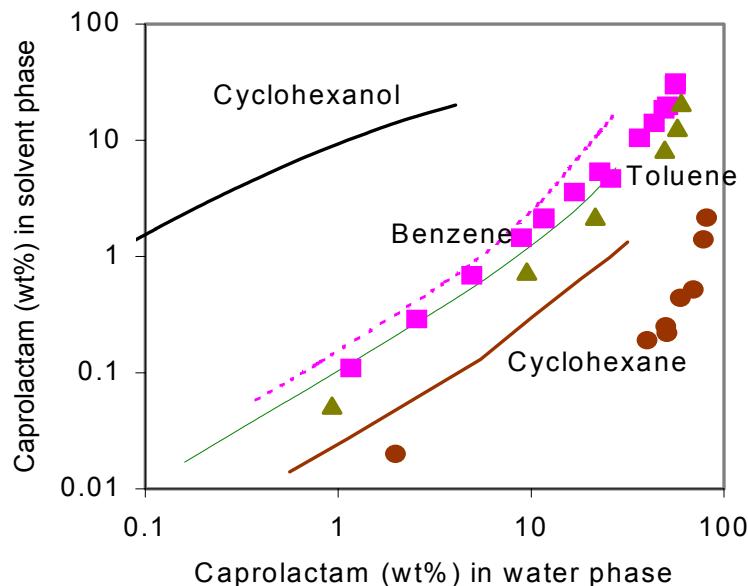

Figure 2. Distribution of caprolactam between various solvents and water at 20 °C.

■ = benzene; ▲ = toluene and ● = cyclohexane.

The curves are predicted with the extended UNIFAC group contribution model.

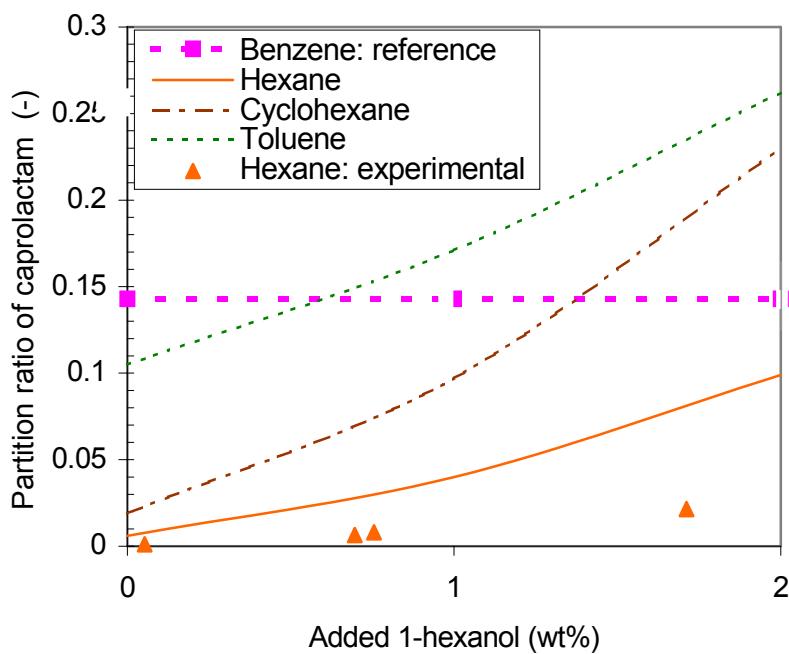

Figure 3. Calculated (lines) and experimental (for hexane) effect of adding 1-hexanol as a co-solvent to various solvents on the caprolactam partition ratio between the solvent and aqueous phase at 20 °C.

## INTENDED PILOTING WORK

Pilot plant trials are necessary to establish operating parameters, to obtain data for risk free scale-up and provide process guarantees. In the near future we want to be able to run various pilot plant scale extraction columns (Rotating Disc Contactor, Centrifugal Extractor, Membrane Extractor, Pulsed Packed Column) simultaneously using the same feed solutions. This enables direct comparisons between the various contactors. A recently erected contactor is a 40 mm diameter Bateman Pulsed Column with its characteristic alternating disks and doughnut-shaped baffles. This column promises to have improved extraction efficiency relative to other types of pulsed solvent extractors. Other advantages are the high mass transfer rates, the ease of operation with any desired phase continuity, and a closely controlled energy of mixing by varying the pulse intensity.

## CONCLUSIONS

For environmental reasons conventional solvents such as benzene and chlorinated hydrocarbons are not desired for the industrial extraction of caprolactam. Therefore, alternative solvents and solvent mixtures have been investigated. Both polar and non-polar pure solvents are not suitable for the extractive recovery of caprolactam due to an unfavourable caprolactam partition ratio and a high solubility in the aqueous phase, respectively. Based on solvent design calculations using an extended UNIFAC group contribution model, mixtures of organic non-polar alkanes (hexane) with small amounts of alcohol (hexanol) as a polar co-solvent show caprolactam partition ratios to be equal or better than with benzene. Experiments for the hexanol/hexane system confirm an increase in the caprolactam partition ratio by hexanol addition, though its absolute value is less than predicted. Promising types of solvent mixtures will be tested on pilot plant scale in the Bateman Pulsed Column and other types of extraction columns.

# EXTRACTION AND ENRICHMENT OF PHYSIOLOGICALLY ACTIVE LIPIDS AND NUTRIENTS FROM PLANT MATERIALS USING SUPERCRITICAL FLUID EXTRACTION

Darren Westerman, Bushra Al-Duri, Regina Santos, and John Bosley\*

Supercritical Fluids Group, School of Chemical Engineering,  
University of Birmingham, Birmingham, England  
\*Unilever Research, Bedford, England

Supercritical carbon dioxide solvent extractions were carried out on whole grain seed material over the range of temperatures 313K – 323K and pressures 100 barg – 300 barg. The aim was to isolate in an enriched fraction the commercially valuable compound squalene.

Milling of the seed was found to be the most effective sample pre-treatment as the physical nature of the seed was such that crushing and flaking were ineffective to complete commutation. Extraction yields were determined gravimetrically as a percentage of exhaustive Soxhlet hexane extraction.

Solubility studies of squalene were performed over the temperature and pressure range of interest with good agreement to predictions from the Adachi-Lu modification of the Chrastil Equation and Empirical Equations.

## INTRODUCTION

The properties of compressed gases as solvents and reaction mediums have been reported for over 100 years [1]. Intensified research into the solvating powers of compressed gases in the supercritical (sc) region, most notably carbon dioxide, has been undertaken since the mid 1970s, and is gaining favour as an alternative to processes requiring traditional organic solvents. The high initial capital investments required for the use of highly compressed gases have been difficult to justify in many cases. However, as environmental restraints continue to become more stringent, the commercial viability of the process is becoming more appealing.

The aim of this work is to investigate the extraction of essential oils from seed material (subject to confidentiality agreement) with a squalene, C<sub>30</sub>H<sub>50</sub>, as a major component whilst leaving the extracted seed material as a saleable food product.

The therapeutic properties of the squalene stem from its antioxidant nature, oxidative cell damage being a major cause for the development and spread of certain types of tumours. The natural presence of squalene in human skin tissue promotes cell oxygenation and so has both prophylactic and anti-oxidant anti-carcinogenic properties. It is also used in the cosmetic industry as a carrier for lipid soluble components through the skin. Since the principal uses of squalene are in the food, cosmetic and pharmaceutical industries, the use of organic solvents for its extraction must be avoided. Traditional steam distillation techniques are also unfavourable, as thermal degradation occurs.

## **Selection of Carbon Dioxide as Solvent**

From a material standpoint, CO<sub>2</sub> is a cheap, inert, non-flammable, non-corrosive, non-toxic by-product of many natural and industrial processes. It is intrinsically safe in use, has no residual taste, odour, colour or toxicity and is easily recycled and purified with minimal capital expenditure. As a solvent scCO<sub>2</sub> is non-polar and will therefore solubilise other non-polar molecules (oils, waxes etc.), however, the addition of small amounts of modifiers, entrainers or co-solvents such as water have a dramatic effect on the ability of the fluid to selectively solubilise more polar molecules. Patents exist for the extraction of compounds from acid hydrolysed plant materials using SCFs and co-solvents [2]. In addition to these benefits, the thermodynamic properties of CO<sub>2</sub> are such that the T<sub>c</sub> (31.1°C) and P<sub>c</sub> (73.8 bar) are sufficiently low and easily achieved compared to other SCFs as to make it the ideal sc solvent for the extraction of thermally labile molecules. Finally, since CO<sub>2</sub> is gaseous at atmospheric conditions the solute product is easily isolated upon venting and is completely free from solvent contamination.

## **Limitations of Distillation Techniques**

Distillation techniques are among the oldest methods for the extraction of oils. They rely on the relative volatility and hydrophilicity of the extracts and can be sub-divided into four main categories, each having its own specific advantages and disadvantages.

### ***Steam distillation***

Steam is applied at atmospheric pressure to the sample, the compounds extractable by this process are carried up with the steam flow to a condenser where the steam condenses to a liquid and the extracted components are collected. The major disadvantages to this process are that the superheated water vapour destroys thermo labile components in the extract (with associated thermal artefact production), also the extract requires further separation from the aqueous phase collected in the condenser.

### ***Hydrodistillation***

This process is similar to steam distillation except that the material to be extracted is immersed in water to which heat is applied. The extract is collected as a condensate as before but the process carries with it the same problems with regard to thermal decomposition and product separation. A small advantage over steam distillation is gained however as the material to be extracted is in continual motion within the extractor, thereby presenting a greater surface area to the 'solvent'.

### ***Steam injection***

This little-used technique is in principle identical to steam distillation except that high pressure steam is injected into the base of the material bed. The advantage of particle motion within the extractor gained by hydrodistillation is present with this technique, but the same disadvantages apply.

### ***Vacuum distillation***

This process is analogous to all the above processes with the advantage of lower temperatures being required. The boiling point of a liquid decreases with pressure and so the relative volatility increases. This is exploited where thermal degradation of extract is problematic with ambient pressure techniques. The advantage of this process is offset however by the higher capital and running cost of a vacuum system. The problem of extract separation in the condenser still applies however.

## **Limitation of Organic Solvents**

Organic solvent extraction techniques rely on a chemical affinity of the solute to the solvent. The selection of solvent for a specific component is not always possible and so oleoresin extracts typically contain both volatile and non-volatile components. The problem of solvent

removal from the extract persists (as in distillation techniques) however the more volatile components extracted can be lost due to entrainment during solvent evaporation. As mentioned elsewhere in the text the residual organic solvent traces permitted in the extract are typically <1 ppm for food and pharmaceutical use.

## EXPERIMENTAL

### Brief Discussion of Continuous Extraction Rig Capabilities

An extraction rig was constructed that was capable of extracting natural oils from solid materials. The rig was capable of obtaining a working pressure of 300 barg and a working temperature of 343 K, with carbon dioxide solvent flow rates ranging from 1 l/min to 5 l/min for extraction experiments and collection of the solute product by a two-stage decompression.

The basic principle of the 'once through' continuous extraction process involves the compressing of liquid carbon dioxide beyond its  $P_c$  (73.78 bar) and then heating this compressed liquid beyond its  $T_c$  (304.04K). At the cp the fluid departs from liquid or gas like properties and above this point becomes supercritical, the solvent used in this work. For  $\text{CO}_2$  a density of 0.47 g  $\text{cm}^{-3}$  is attained at this point.

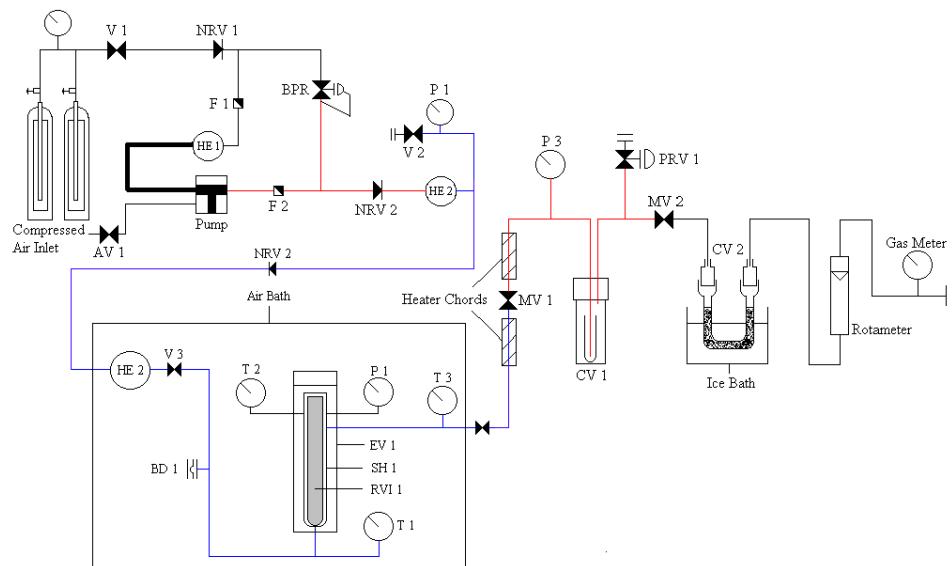

Figure 1. Schematic diagram of extraction rig.

The fluid, now in a supercritical state, entered an extraction vessel and contacted the material to be extracted. After passing through the material bed the extract loaded sc $\text{CO}_2$  stream left the extraction vessel and was slowly depressurised across a throttling device to 10 barg where the bulk of the extract was collected. The sub-critical  $\text{CO}_2$  stream, though still above the triple point ( $tp$ ) of  $\text{CO}_2$ , was then reduced to atmospheric pressure across a second throttling device where the more volatile components were collected in a chilled receptacle.

The prepared sample was loaded into the sample holder in such a way that the  $\text{CO}_2$  stream contacted the entire surface of the sample bed. This was accomplished by the insertion of a diffuser frit set into a hollow machined into the base of the sample holder. The loaded sample was also tamped down slightly to ensure the maximum  $\text{CO}_2$  contact through the sample bed.

The intact shell of the seed was impervious to SCF extraction, therefore, prior disruption of the shell was necessary. Flouring of the seeds in a Tema Mill (Siebtechnik) for 1 minute was selected as both crushing and blending proved less effective due to the physical nature of the seeds.

### **Solid seed material**

Solubility determinations enabled the solvent to be repeatedly re-circulated through the material bed at a known flow rate (~2 l/h) until saturation of the vapour was attained. A sample size of 250 ml was used to ensure it was always in excess. Make-up carbon dioxide was supplied as required from the solvent delivery section to maintain pressure during the experiment. Appreciable make-up was necessary in the early stages of the experiment to replace carbon dioxide lost to absorption into the material bed. Initial experiments were 12 hours in duration to ensure complete saturation of the solvent. After 4 hours the re-circulation pump was stopped and a measured volume of solvent (~10 l STP) was depressurised from the equilibrium cell through a throttling device, the solute was collected and weighed. The precipitated solute was left to stand in order to allow any absorbed CO<sub>2</sub> to desorb until a constant weight was achieved. The re-circulation was resumed and collections were repeated at 2 hour intervals. When the mass of successive solute collections ceased to increase the solvent was deemed saturated. The mass of the solute was then determined and used to calculate its solubility in scCO<sub>2</sub> at a given temperature and pressure.

### **Squalene liquid**

Liquid solubility experiments were essentially the same as for those of solid material using the same apparatus and duration. An excess sample volume of 100 ml was used as literature values of between approximately 0.3 g kg<sup>-1</sup> and 48 g kg<sup>-1</sup> have been reported over the range of temperatures and pressures used in this study [3]. Pure standard oil was used (Sigma 98% pure) and each fraction tested for molecular degradation by Infra-red Spectroscopy (Perkin Elmer 1600 series FTIR). No decomposition was observed from that of the pure standard.

## **RESULTS AND DISCUSSION**

Squalene solubilities in scCO<sub>2</sub> compare favourably to predictions from the 2 equations tested [4], these were:

### *Adachi-Lu Modification of the Chrastil Equation*

$$c = \rho^e \exp(a / T + b) \quad (\text{where the exponent } e = e_0 + e_1\rho + e_2\rho^2)$$
$$a(K) = -4545 \quad b = 39345, e_1 = -6.224, e_2 = 5.421 \times 10^3(\text{kg}^{-1}\text{m}^3), e_3 = -2.20 \times 10^{-6}(\text{kg}^{-2}\text{m}^6)$$

### *Catchpole Empirical Equation*

$$\ln(S_o) = K_s \ln(\rho_v) + A - B / T \quad (\text{where } K_s = 6.54, A = -28.24, B = 3936.6)$$

The Adachi-Lu modification of the Chrastil equation and Catchpole empirical equations adequately show the predicted vapour phase solubility concentration of squalene as a pure component in scCO<sub>2</sub> with good agreement (Figure 2). The experimental results follow the predicted solubility curve trend however there is a closer correlation to the Adachi-Lu equation at lower temperatures. It is assumed that the slight reduction in solute concentration experimentally observed was due to insufficient time between sample collections not allowing total re-saturation of the solvent.

Results of initial extraction experiments on milled seed material show that for a given temperature the rate of extraction increases with pressure. It can also be seen that the effect of pressure on the rate of extraction is more enhanced at higher temperatures as the result of

the combined effect of solvent density and vapour pressure of the extract. At low pressures, the increase on temperature leads to a significant decrease of solvent density and consequently on its dissolving power. However, at high pressure, the decrease in solvent density due to the increase of temperature is much less dramatic and is compensated for by the increase in the volatility of the extract, justifying the stronger dissolving power.

Figure 3 shows the four isobaric seed extraction curves at three temperatures. The rate of extraction increases with an increase of temperature for extraction pressures of 300 barg, this trend is reversed for pressures below 200 barg. This indicates that the cross-over pressure from density to volatility dependency of the total extract is between 200 and 300 barg.

## FUTURE WORK

The ultimate commercial goal of the project is to produce a squalene rich extract while leaving a saleable product in the flour. It is necessary therefore to extract only that component fraction to the exclusion of the majority of extractable matter, mainly diglycerides, triglycerides and fatty acids. To this end it is necessary to investigate the fractionation of squalene and the effect of co-solvent from the solute firstly:- directly from the seed matrix and secondly:- from the extracted material with a view to re-infusion of the flour with the residue.

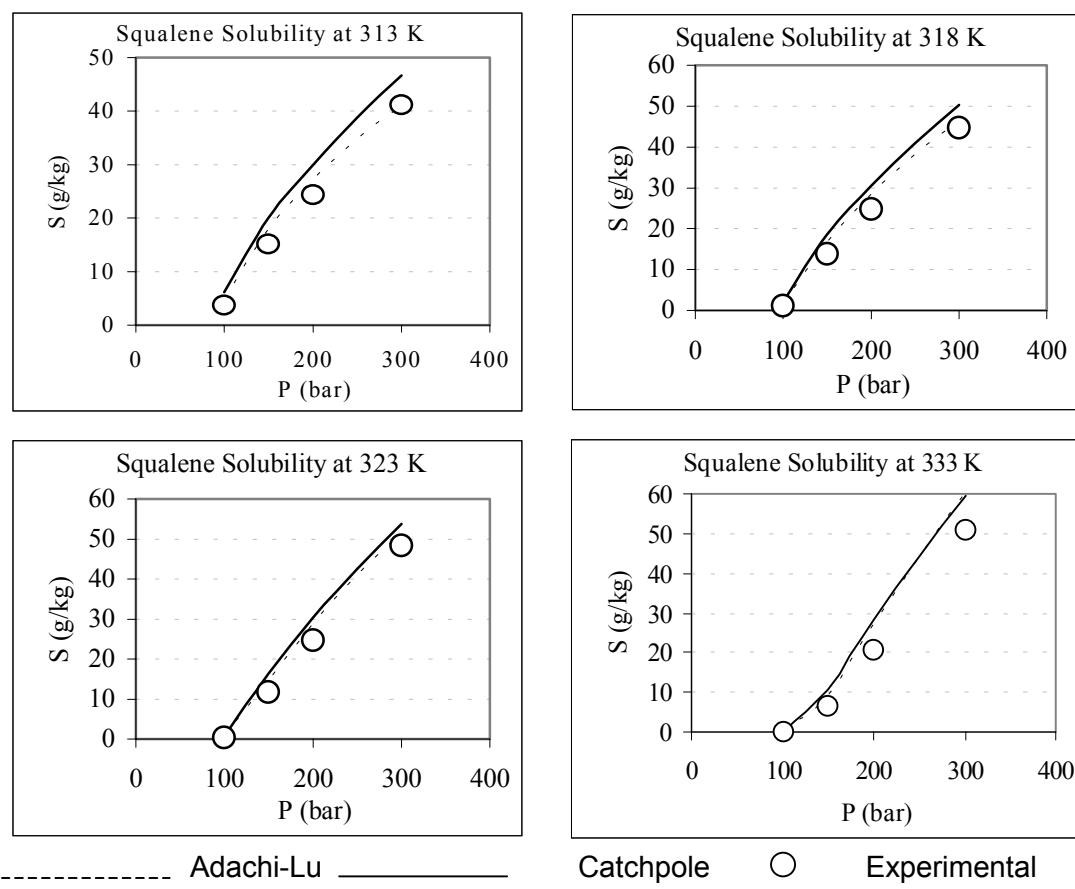

Figure 2. Experimental and empirical solubilities of squalene in  $\text{scCO}_2$ .

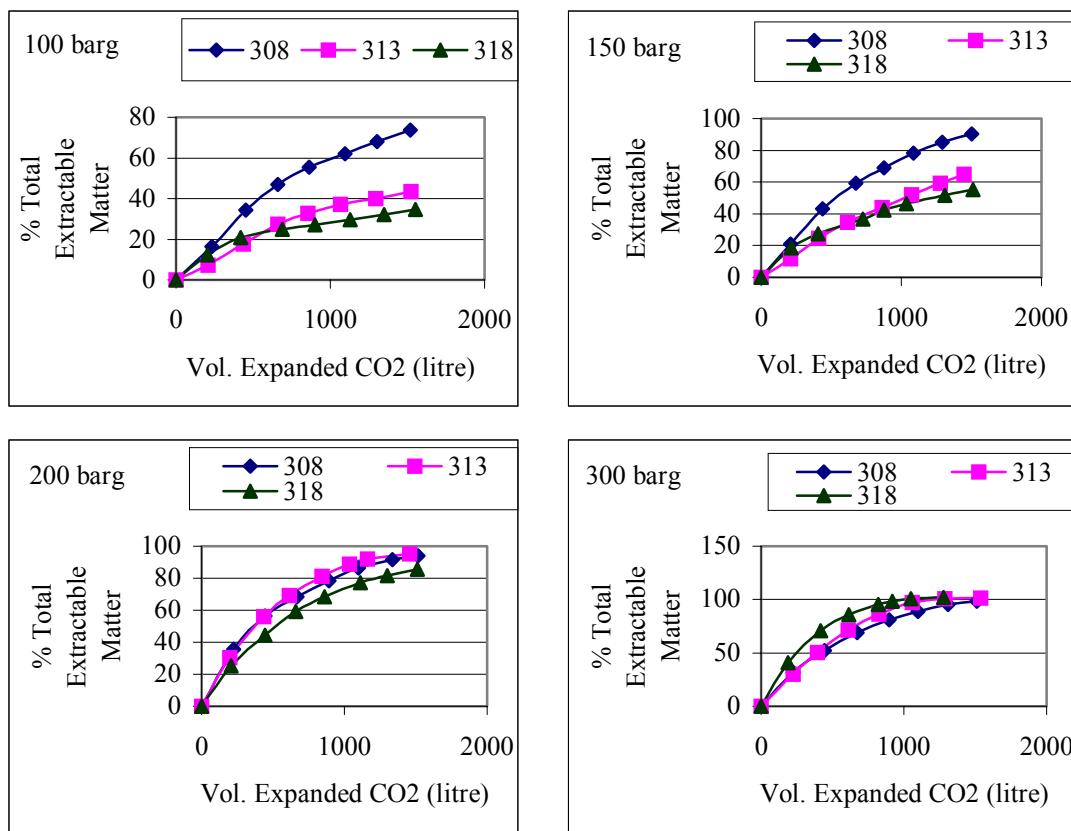

Figure 3. Experimental seed extraction curves at different temperatures.

Modification of the extraction rig to incorporate a temperature gradient controlled oven has been completed. The oven houses a 50 ml pressure vessel so that extractions can be performed over a solvent density gradient with controlled addition of co-solvents via a HPLC pump. The extract will be monitored on-line in the SCF phase by a Milton Roy UV detector fitted with a supercritical pressure cell. This system is similar in design and operation to a Supercritical Chromatography Instrument.

## ACKNOWLEDGEMENTS

This work was co-sponsored by The University of Birmingham School of Chemical Engineering and Unilever Research, Colworth.

I would like to thank my supervisors Dr. Bushra Al-Duri and Dr. Regina Santos (University of Birmingham), Dr. John Bosley, Dr. Scott Barclay and Mr. Gary Sassano (Unilever Research, Colworth) for their help and support throughout this work. I would also like to acknowledge the support of the staff of the Supercritical Fluids Technology Group, Birmingham for their technical expertise in the field.

## FORWARD AND BACKWARD EXTRACTION OF BSA USING MIXED REVERSE MICELLAR SYSTEM OF CTAB AND 4-METHYL-2-PENTANONE

W. Zhang, H. Z. Liu and J. Y. Chen

Young Scientist Laboratory of Separation Science and Engineering,  
State Key Laboratory of Biochemical Engineering, Institute of Chemical Metallurgy,  
Chinese Academy of Sciences, Beijing, P. R. China

The forward and backward extraction of bovine serum albumin (BSA) has been studied using the mixed reverse micellar system of cetyl trimethyl ammonium bromide (CTAB) and 4-methyl-2-pentanone (methyl isobutyl ketone, MIBK). The addition of 4-methyl-2-pentanone to 50 mmol/L CTAB/20%(v/v) hexanol/ petroleum ether reversed micellar system can significantly improve the BSA transfer into the reverse micelles. The mixed reverse micellar system formed with CTAB and 4-methyl-2-pentanone exhibits excellent backward extraction behavior for BSA. The mixed reverse micelles can obviously enhance the recovery of BSA under conditions such as in a wide pH range and low salt concentration of backward aqueous phase. The mixed reverse micellar system requires much less time to achieve higher BSA recovery in comparison with reverse micellar systems with CTAB only. It was deduced that the addition of 4-methyl-2-pentanone to CTAB reversed micellar system could decrease the hydrophobic interaction between protein molecules and surfactants. Petroleum ether, which is much cheaper than pure straight chain hydrocarbons such as iso-octane and hexane, could be used as solvent in protein extraction with reverse micelles.

### INTRODUCTION

The separation and recovery of proteins using reverse micelles is one type of liquid-liquid extraction operation which may keep the activity of proteins in the organic continuous phase [1]. The separation using reverse micelles is easy to scale up and operate continuously [2].

Recently, the application of a synergistic effect by adding a secondary surfactant for protein extraction has been reported. Kinugasa has reported that mixed reverse micelles formed with AOT (sodium bis(2-ethylhexyl)sulfosuccinate) and DEHPA (di(2-ethylhexyl)phosphoric acid) could be used to extract hemoglobin with transfer yield about 80% [3]. Goto has reported that the AOT and DOLPA (dioleylphosphoric acid) mixed reversed micelles showed a high selectivity between the active  $\alpha$ -chymotrypsin and denatured proteins [4]. Yan [5] and Zhang [6] reported that mixed reversed micelles formed with AOT or CTAB and TBP (tributyl phosphate) or TRPO (trialkylphosphine oxide) exhibited obvious advantage over the reversed micelles formed with AOT or CTAB only. Spirovská (1998) reported that the addition of sucrose in forward aqueous phase increased both protein recovery and activity of the protein [7]. It is clear that mixed reverse micelles exhibited some advantages over reverse micelles formed with one surfactant only.

In order to improve the forward and backward extraction behavior of CTAB reverse micelles, we studied the extraction of model protein BSA using the mixed reverse micellar system formed with CTAB and 4-methyl-2-pentanone (MIBK). The extraction of BSA using mixed reverse micellar systems formed with CTAB and heptylaldehyde or *n*-butyl acetate was carried out, which will be reported in another article.

## MATERIALS AND METHODS

### Materials

BSA (molecular weight 68,000, isoelectric point pl 4.8) was purchased from Beijing Baitai Biochemical Reagents Company. CTAB (>99%, analytical grade), hexanol (>98%, chemical grade), petroleum ether (b.p.: 90~120 °C, analytical grade), MIBK (>99%, analytical grade), were purchased from Beijing Chemical Reagents Company. Other reagents used were all commercially available reagents of analytical grade and were used as received.

### Forward Extraction and Backward Extraction Procedures

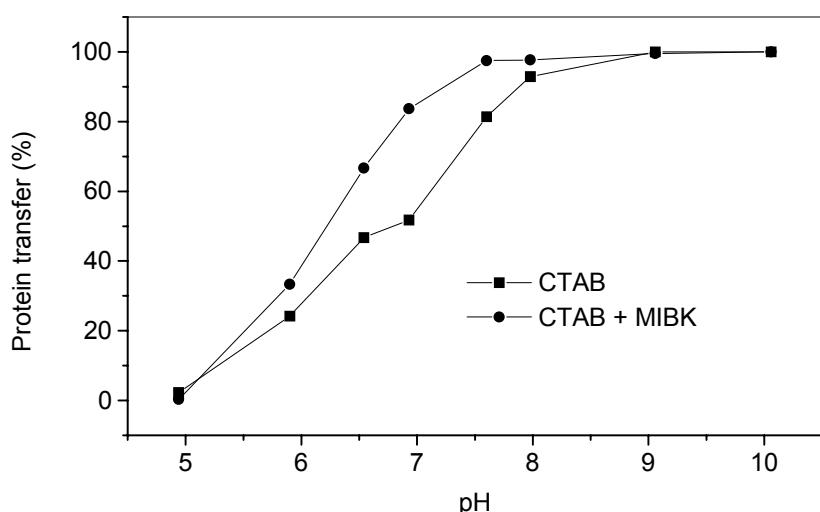

Forward extraction procedures for BSA were conducted by contacting petroleum ether solution containing a weighed amount of CTAB with an aqueous solution containing BSA. Equal volumes (usually 5 ml each) of aqueous and organic solutions were poured gently into a 50-ml flask, which was stoppered to prevent the evaporation of the solution. The flasks were shaken at the rate of agitation of 3.5 s<sup>-1</sup> at room temperature (22.0 ± 0.5 °C) for 20 minutes. After centrifugation (4000 rpm, 5 min), the protein concentration in the reversed micellar phase was determined by spectroscopy at 280 nm (UV-7542 spectrophotometer). The amount of BSA recovered in aqueous phase was determined by the Bradford method [8].

Backward extraction of BSA was conducted by contacting the reverse micellar solution that loaded BSA before with a fresh aqueous phase of desired pH and ionic strength at room temperature (22.0 ± 0.5 °C). Equal volumes (usually 5 ml) of aqueous and organic solutions were poured gently into a 50-ml stoppered flask. The flasks were shaken at the rate of agitation of 4.0 s<sup>-1</sup> at room temperature (22.0 ± 0.5 °C) for 60 minutes. The mixture was then centrifuged (4000 rpm, 5 min), and the protein concentration of the stripped aqueous phase was determined by Bradford method. The yield of the backward transfer of BSA was based on the percentage of BSA recovered from the aqueous phase divided by the amount of BSA extracted into the reverse micellar phase. The protein mass balances for a pair of forward & backward extractions were generally within the experimental error (± 5%).

## RESULTS AND DISCUSSION

### Effect of pH on the Forward Transfer of BSA

BSA with isoelectric point, pl, of 4.8 carries an overall negative charge under the conditions where the aqueous pH is higher than 4.8. Under such conditions, both CTAB and CTAB-MIBK reverse micellar systems could extract BSA completely as shown in Figure 1. The addition of MIBK to CTAB reverse micelles could significantly improve the forward transfer of BSA. On the other hand, with pH below pl of BSA, extraction into the reverse micellar phase was inhibited by the unfavorable electric repulsion. BSA transfer of mixed reversed micelles formed with CTAB and MIBK is higher than that of reverse micelles formed with CTAB only because of the addition of MIBK to CTAB reverse micelles resulted to the increase of the size of CTAB reverse micelles.

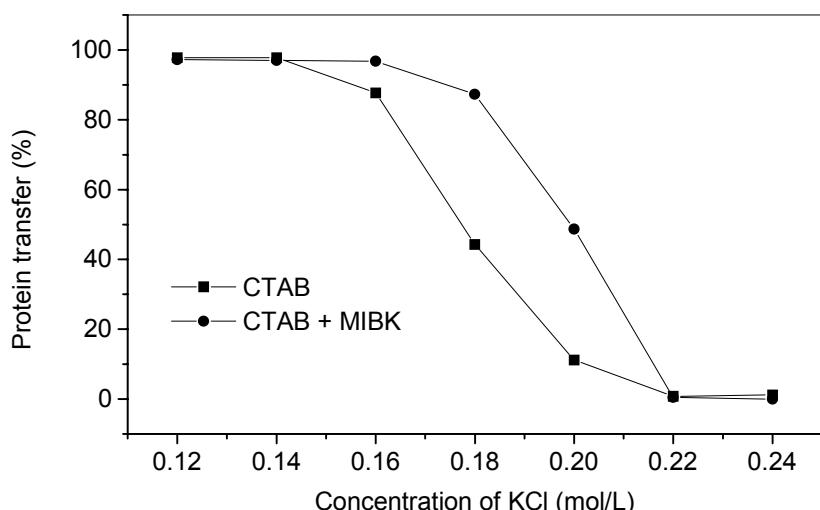

*Figure 1. Effect of aqueous phase pH on BSA transfer.*

Aqueous phase: 1.0 mg/ml BSA, 0.1 mol/L KCl.

Organic phase: 50 mmol/L CTAB/20%(v/v) hexanol/5%(v/v) MIBK/petroleum ether.

### Effect of Ionic Strength on the Forward Transfer of BSA

The ionic strength of the aqueous phase influences the degree of shielding of the electrostatic potential imposed by a charged surface. The effect of salt concentration on BSA transfer was investigated by varying the KCl concentration at pH 9.0, as shown in Figure 2. The BSA transfer to the reversed micellar phase decreased for reverse micellar systems formed by CTAB only or by CTAB and MIBK with increasing KCl concentration. The BSA transfer to the reverse micelles phase with the addition of MIBK is higher than that with CTAB only as surfactant, which indicated the improvement of BSA transfer with the presence of MIBK.

*Figure 2. Effect of concentration of KCl in aqueous phase on BSA transfer.*

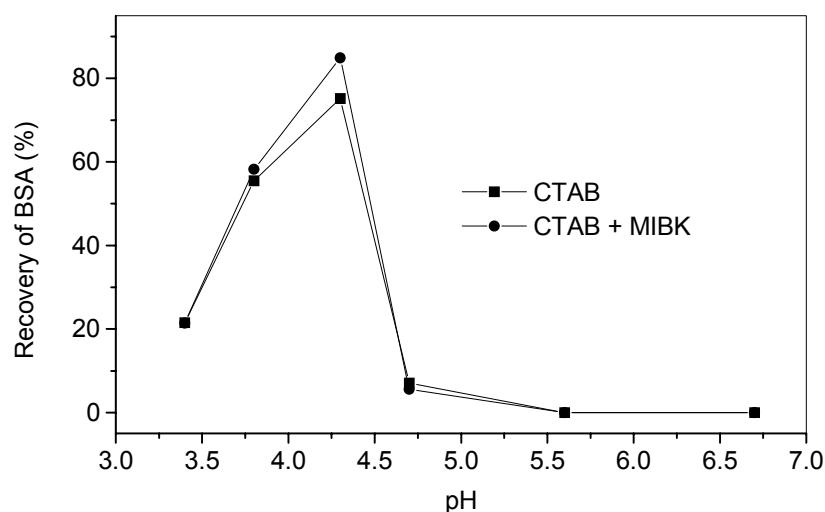

Aqueous phase: 1.0 mg/ml BSA, pH = 9.0.

Organic phase: 50 mmol/L CTAB/20%(v/v) hexanol/5%(v/v) MIBK/petroleum ether.

### Effect of Aqueous Phase pH on the Backward Transfer of BSA

The protein extracted into the reverse micelles can be recovered through backward transfer either as a result of electrostatic repulsion of the surfactant by changing the solution pH, or through size exclusion by increasing the salt concentration in the aqueous phase used for

backward transfer. The recovery of BSA could carry out when using KBr as salt, while the recovery of BSA was difficult when using KCl. This might be due to the effect of different anionic on protein extraction. The effect of aqueous phase pH for backward transfer on BSA recovery was shown in Figure 3. The mass balance of protein was within the experimental error of  $\pm$  5%. BSA could be recovered only under conditions with pH below pI when using CTAB or CTAB-MIBK reverse micelles. The recovery curve of the reverse micelles formed with CTAB and MIBK is higher than that of the reverse micelles formed with CTAB only. Obviously, the addition of MIBK to CTAB reverse micelles improved the backward transfer behavior of CTAB reverse micelles. The result may be explained that the addition of MIBK to CTAB reversed micellar system could decrease the hydrophobic interaction between protein molecules and surfactants. Both of the recovery of BSA from CTAB and CTAB-MIBK reverse micelles shows optimum pH near pI.

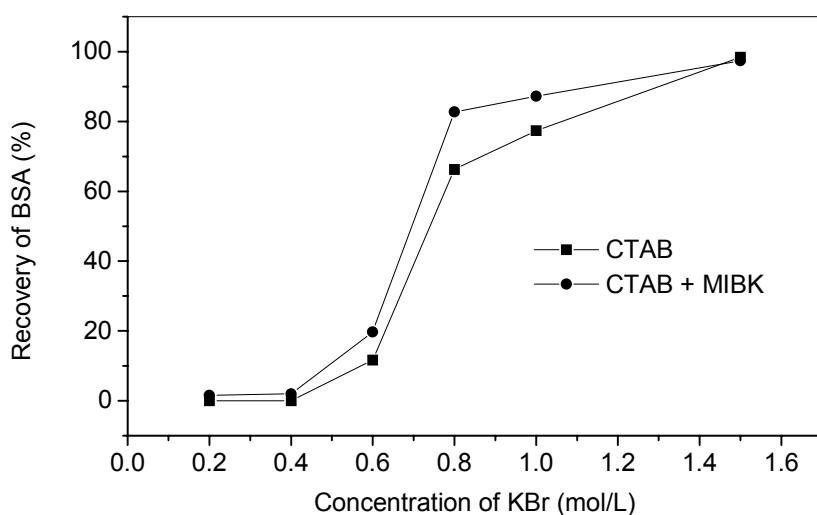

*Figure 3. Effect of aqueous phase pH on backward transfer of BSA recovery.*

Forward transfer aqueous phase: 1.0 mg/ml BSA, 0.1 mol/L KCl, pH = 9.0.  
Organic phase: 50 mmol/L CTAB/20%(v/v) hexanol/5%(v/v) MIBK/petroleum ether.  
Backward transfer aqueous phase: 1.0 mol/L KBr.

#### **Effect of Solution Ionic Strength on the Backward Transfer of BSA**

The salt concentration in the aqueous phase can affect the efficiency of protein transfer through the size exclusion effect. The effect of ionic strength of aqueous phase in backward extraction on BSA back-transfer was shown in Figure 4. The mixed reverse micelles formed by CTAB and MIBK exhibit higher backward transfer behavior for BSA than reverse micelles formed by CTAB only. The mixed reverse micelles formed with CTAB and MIBK obviously improve the BSA back-transfer. The reaction rate is also influenced by the ionic strength, because the extraction contains an electrostatic interaction in the reaction mechanism. However, one hour is long enough to achieve or close to backward extraction balance.

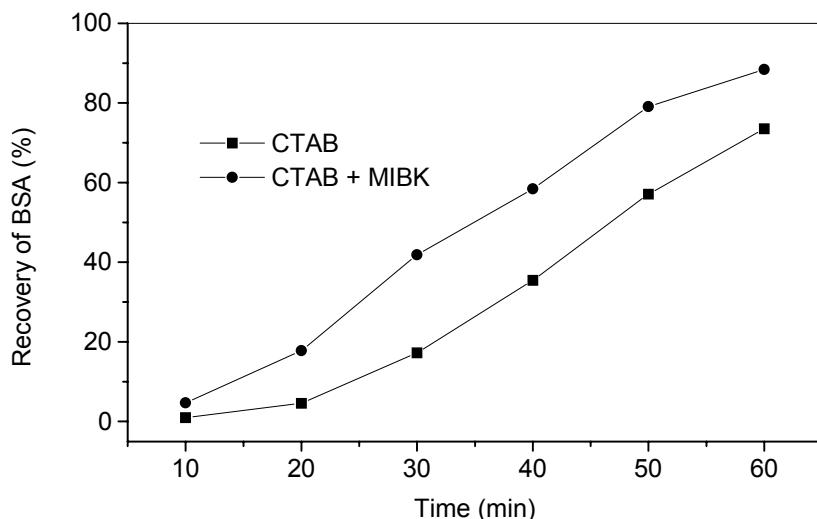

**Figure 4. Effect of concentration of KBr of backward transfer aqueous phase on BSA recovery.**

Forward transfer aqueous phase: 1.0 mg/ml BSA, 0.1 mol/L KCl, pH = 9.0.  
 Organic phase: 50 mmol/L CTAB/ 20%(v/v) hexanol/ 5%(v/v) MIBK/petroleum ether.  
 Backward transfer aqueous phase: pH = 4.3, KBr.

#### Time of Backward Extraction

It is well known that the rate of backward transfer of proteins from reverse micelles to an aqueous phase is relatively slow because of rather strong interaction resistance in mass transfer. The effect of time on BSA recovery when using CTAB or CTAB-MIBK reversed micellar systems was studied as shown in Figure 5. The mixed reverse micellar systems require less time to achieve higher BSA recovery in compare with reverse micellar systems with CTAB only.

**Figure 5. Effect of backward transfer time on BSA recovery.**

Forward transfer aqueous phase: 1.0 mg/ml BSA, 0.1 mol/L KCl, pH = 9.0.  
 Organic phase: 50 mmol/L CTAB/ 20%(v/v) hexanol/ 5%(v/v) MIBK/petroleum ether.  
 Backward transfer aqueous phase: 1.0 mol/L KBr, pH = 4.30.

## CONCLUSIONS

The forward and backward extraction of BSA was investigated using mixed reversed micellar systems formed with CTAB and MIBK. The experimental results indicate that the addition of MIBK to CTAB reversed micelles could improve the extraction behavior of reversed micelles for BSA. The mixed reverse micelles can obviously enhance the recovery of BSA under the conditions such as in a wide pH region, at low salt concentration of backward aqueous phase. The mixed reverse micellar systems formed with CTAB and MIBK require less time to achieve a higher BSA recovery in comparison with reverse micellar systems with CTAB only. It was deduced that the addition of MIBK to CTAB reversed micellar system could decrease the hydrophobic interaction between protein molecules and surfactants.

## OPTICAL SENSOR FOR CHROMIUM(VI) MONITORING: OPTIMISATION OF CHROMIUM(VI) TRANSPORT THROUGH LIQUID MEMBRANES

Elianna Castillo, Mercè Granados and José Luis Cortina\*

Analytical Chemistry Department, Universitat de Barcelona, Barcelona, Spain

\*Chemical Engineering Department, Universitat Politècnica de Catalunya, Barcelona, Spain

Flat-sheet liquid-supported membranes have been evaluated as interface between the sample and the sensor head of an optosensor for chromium(VI). The sensor uses 1,5-diphenylcarbazide as spectrophotometric reagent for optical detection through optical fibers. One of the key parameters for sensor performance is the effective transport of Cr(VI): thus, this is an important issue to optimise. The effect of experimental variables such as nature of solvent, carrier, carrier concentration, pH and concentration of 1,5-diphenylcarbazide on the Cr(VI) transport are presented.

### INTRODUCTION

In the last few years, chromium determination has received considerable attention because of the element's toxicity even at low concentrations. This is highly relevant, as there are a considerable number of pollution sources responsible for the presence, accumulation and mobility of Cr in the different compartments of the environment. The major uses of chromium are metal finishing and corrosion control, pigments and leather tanning. Chromium is found in two oxidation states in natural systems, namely Cr(III) and Cr(VI). Whereas Cr(III) is considered relatively nontoxic, Cr(VI) causes both acute and chronic toxic effects.

Cr(VI) determination is of particular interest in industrial wastewater treatment plants and in environmental compartments, and new trends in Cr(VI) analysis are oriented towards continuous *in situ* monitoring. Optical sensing is an attractive approach to reach these objectives and in particular sensors based on reagent renewal [1,2] seem to fulfil the requirements for continuous monitoring.

The sensor uses a membrane as an interface between the sample and the detection cell. A chemical reaction occurs between the analyte that has diffused through the membrane and a chromogenic or fluorogenic reagent, and a strongly absorbing or fluorescent species is produced and is detected through optical fibers connected to the detector (spectrophotometer or fluorimeter). The reagent is continuously pumped, and the solution inside the detection cell continuously renewed, thus avoiding irreversibility problems, one of the main limitations of sensors based on immobilised reagents. The key parameters for the success of the sensor are the proper selection of the chemical reaction for the optical detection, and the membrane, which should allow an efficient transport of the analyte from the sample to the detection chamber, be not permeable to interferences, and prevent reagent leakage from the chamber to the sample.

In this particular case, 1,5-diphenylcarbazide (DPC) was selected as the chromogenic reagent, because it is a very selective and sensitive reagent for Cr(VI) [3]. On the other hand previous studies on membranes have pointed out that flat-sheet liquid-supported membranes (FSLSM) using Aliquat 336 (ALQ) as a carrier are a good option as sensor interface [4]. In this paper we present the results of the optimisation of transport conditions directed towards Cr(VI) optical sensing.

## SENSOR TRANSDUCTION MECHANISMS

The sensor transduction mechanism of Cr(VI) can be described by the following steps [5,6]:

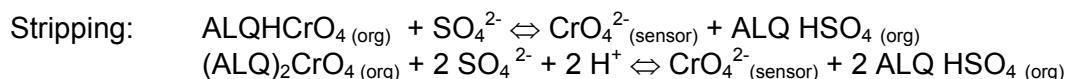

*Transport step I:* Cr(VI) (sample)  $\Rightarrow$  Cr(VI) (membrane).

Cr(VI) anions ( $\text{HCrO}_4^-$  and/or  $\text{CrO}_4^{2-}$ ) are extracted into the anion-exchange liquid supported membrane containing Aliquat 336 (ALQ) by a formation of a Cr(VI)-ALQ complexes.

*Transport step II:* Cr(VI) (membrane)  $\Rightarrow$  Cr(VI) (sensor detection chamber).

This is accomplished by the combination of Cr(VI) stripping and redox and complexation reactions between chromium and DPC. Thus, the stripping process is facilitated by the combination of chemical reactions leading to the formation of the absorbing species.

## EXPERIMENTAL

### Reagents and Solutions

All the chemicals used were A.R grade unless stated otherwise. Hexane (Fluka), kerosene (Fluka), toluene (Merck) and *n*-decanol (Fluka) were used as received. 1 g L<sup>-1</sup> Cr(VI) standard solution was prepared by dissolving sodium chromate (Merck) in water. 0.4 % (w/v) DPC solutions were prepared by dissolving 0.25 g of DPC (Merck) in 10 ml of ethanol and diluting to 100 ml with water. Working DPC solutions were prepared by appropriate dilution of 0.4% solutions with sulfuric acid solutions. ALQ, a quaternary ammonium salt ((CH<sub>3</sub>)R<sub>3</sub>N<sup>+</sup>Cl<sup>-</sup>), from Henkel was used as received.

### Apparatus

A 640 Varian atomic absorption spectrophotometer (AAS) was used for chromium measurements in the source phase and the stripping phase. A Metrohm AG 9100 glass combined electrode connected to a Digilab 517 pH-meter (Crison) was used for pH measurements.

Spectrophotometric measurements in the stripping phase were made with a Hewlett Packard diode array spectrophotometer HP 5483, coupled to a fiber-based transmittance probe from Photonetics.

### **FSSLM Preparation**

Millipore Durapore GVHP 4700  $12.5 \times 10^{-3}$  cm thick, a microporous polyvinylidenefluoride film with a nominal porosity of 75% and effective pore size of 0.22  $\mu\text{m}$ , was used as the polymeric support for the FSLSMs.

The FSLSMs were impregnated with ALQ solutions containing the extractant dissolved in hexane, kerosene, toluene and mixtures with n-decanol by immersion for 48 h, and then leaving it to drip for a few seconds before being placed in the transport cell.

### **Transport Experiments**

The batch transport experiments were carried out in a permeation cell consisting of two compartments made of methacrylate and separated by a FSSLM. The geometrical membrane area was  $19.50 \text{ cm}^2$  and the volume of the feed and stripping solution was 200 ml. The experiments were performed at  $20^\circ\text{C}$  at a mechanical stirring speed of 1300 rpm in the feed and the stripping phase except in the experiments where the stirring speed was varied. The aqueous feed solutions contained different concentrations of Cr(VI) and pH varied between 2 and 12.

The chromium permeation was monitored by periodically sampling the feed and the stripping phase, and chromium was analysed after appropriate dilution by AAS.

Continuous Cr monitoring in the stripping solution was performed using a transmission probe connected *via* optical fiber to the diode array spectrophotometer.

## **RESULTS AND DISCUSSION**

### **Optimisation of Cr(VI) Transport**

Series of experiments were performed in order to find the optimum conditions for chromium transport, which was evaluated in terms of extraction efficiency ( $E$ ),  $E$  being determined as the ratio between [Cr] in the stripping solution and the initial [Cr] in the feed solution. The stirring speed was fixed to 1300 rpm, since preliminary studies pointed out that above 1000 rpm the aqueous resistance to the mass transfer process was minimised.

The selection of the diluent used to prepare the ALQ FSLSMs is an important issue. Initial assays showed that, among the solvents tested to prepare the membranes, kerosene provided the best results. The use of n-decanol as a modifier has been proposed to improve Cr recoveries in liquid-liquid extraction [7]. Thus, n-decanol was added to kerosene to increase the polarity of the organic phase (*i.e.*, the FSSLM) and it was observed that 10% n-decanol in kerosene provided a significative improvement in Cr transport (Figure 1). The effect of the concentration of ALQ in the membrane phase on the extraction efficiency is shown in Figure 2. An increase is observed from 0.1 M to 0.2 M, and above this value  $E$  remains constant. From these results it was decided to prepare FSLSMs with 0.2 M ALQ in kerosene:n-decanol (90:10).

On the other hand it was observed that Cr(VI) transport improves with increases in the pH of the feed phase, which has important implications in Cr(VI) sensing. That is, calibration of the sensor system must be performed with Cr(VI) standards adjusted to the same pH that the sample to be monitored.

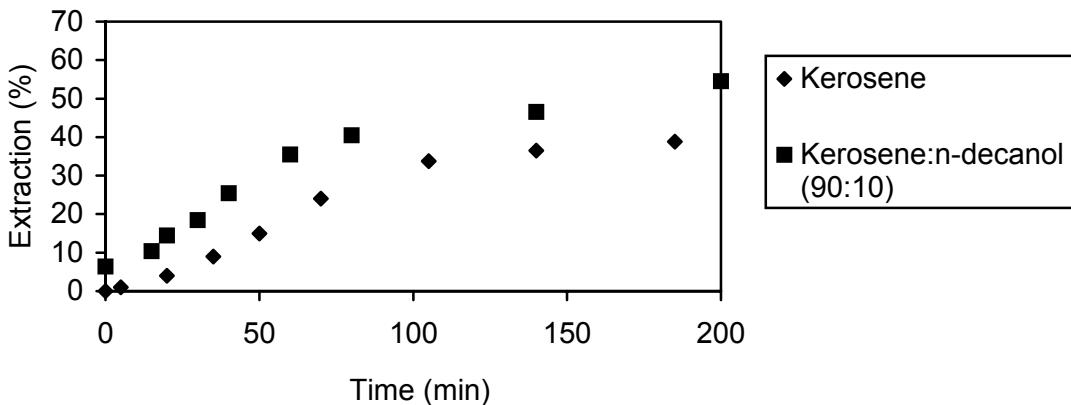

Figure 1. Effect of *n*-decanol. Feed phase:  $[Cr]=20\text{ mg L}^{-1}$ ,  $pH=3.0$ . Stripping phase:  $[DPC]=0.1\%$ ,  $pH=1.0$ . FSLSMs:  $0.1\text{ M ALQ}$  in kerosene.

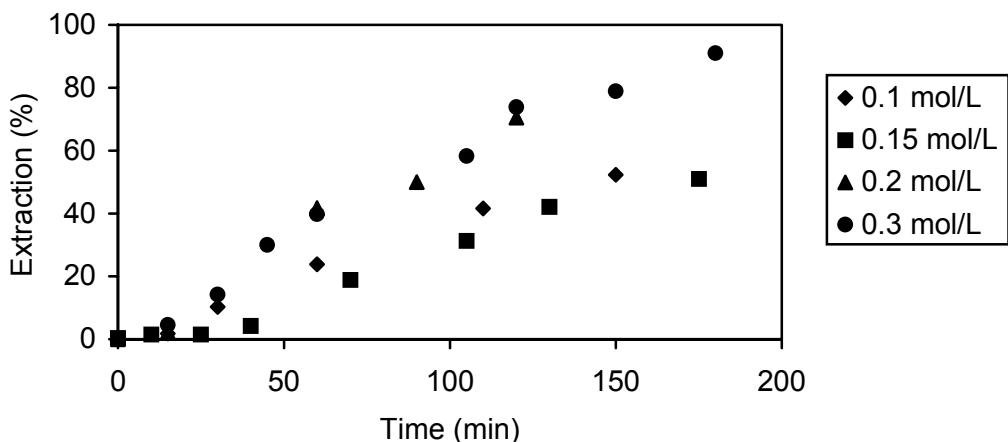

Figure 2. Effect of ALQ concentration. Feed phase:  $[Cr]=20\text{ mg L}^{-1}$ ,  $pH=3.0$ . Stripping phase:  $[DPC]=0.1\%$ ,  $pH=1.0$ . FSLSMs: ALQ in kerosene:*n*-decanol (90:10).

The effect of the stripping phase composition was also considered. It is in the stripping phase solution that optical sensing takes place, and this requires the presence of DPC in  $\text{H}_2\text{SO}_4$  medium. Therefore there are some constraints on the suitable range for the variables. pH of the phase was kept constant at 1. When DPC concentration was varied from 0.05% to 0.1% there was a clear improvement on the Cr(VI) transport, but increasing DPC concentration up to 0.2% did not contribute to any significative raise of transport (Figure 3). Higher DPC concentrations were not suitable because the reaction between Cr(VI) and DPC took place into the membrane, and complex immobilisation occurred. 0.1% was selected as the optimum value to assure the reduction and complexation reactions, which act as driving forces of the Cr transport and lead to the formation of the absorbing species.

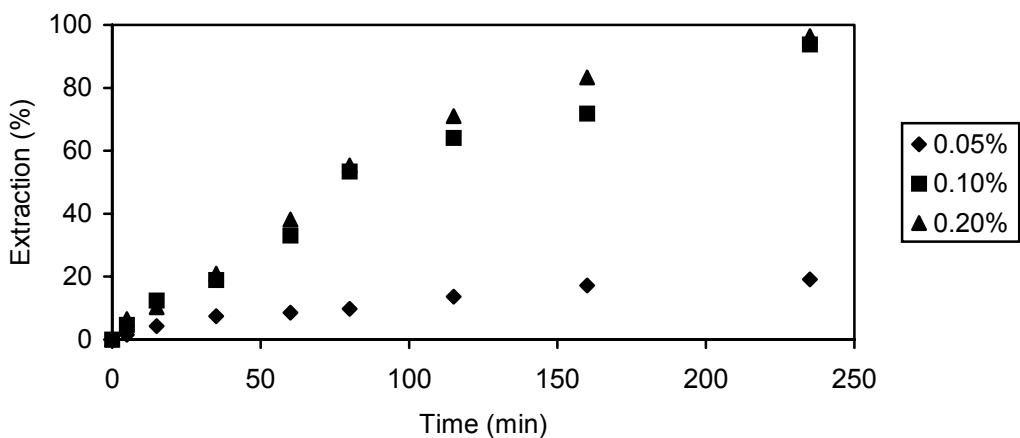

Figure 3. Effect of DPC concentration. Feed phase:  $[Cr] = 20 \text{ mg L}^{-1}$ ,  $pH = 3.0$ . Stripping phase:  $pH = 1.0$ . FSLSMs: 0.2 M ALQ in kerosene:*n*-decanol (90:10).

### Optical Sensing of Cr(VI)

Once the optimum conditions for Cr(VI) transport are established, (*i.e.*, the composition of both the FSLSM and the stripping phase), experiments were performed with a transmittance-based probe to check the feasibility of the *in situ* chromium monitoring with signal transmission through optical fibers. Thus, the probe was immersed into the stripping solution, and connected to a diode array spectrophotometer. Absorption spectra were acquired at elapsed times, and it was observed that light intensity was modulated by absorption changes in the visible range that occur when chromium(VI) diffuses across the FSLSM (Figure 4) and forms the violet Cr-DPC complex. Different Cr(VI) concentrations in the feed phase lead to different absorbance surfaces, indicating that the optical signals can be correlated to Cr(VI) concentration, through a calibration model, which will enable Cr(VI) quantitative monitoring.

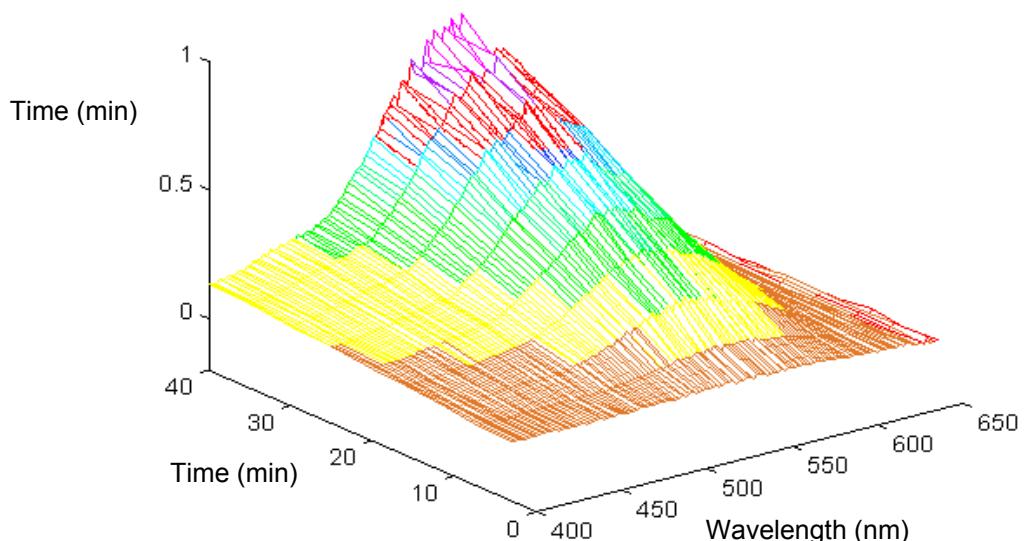

Figure 4. Chromium(III)-DFC<sub>ox</sub> complex spectra collected with a transmission probe in the stripping solution. Feed solution:  $Cr 15 \text{ mg L}^{-1}$ ,  $pH=3$ . FSLSM: ALQ 0.2 M in kerosene-*n*-decanol 90:10. Stripping solution: DPC 0.01%,  $pH 1.0$ .

## CONCLUSIONS

Flat-sheet liquid-supported membranes based on Aliquat 336 have been shown to be appropriate interfaces for a Cr(VI) optical sensor based on the chemical reaction between chromium(VI) and diphenylcarbazide and the spectrophotometric detection of the violet complex obtained. This chemical reaction simultaneously acts as a driving force for Cr(VI) transport. Optimisation of the chemical composition of the liquid membrane as well as that of the stripping solution allows achievement of a satisfactory Cr(VI) diffusion through the membrane.

The nature of the diluent used to prepare the membrane, Aliquat 336 concentration and diphenylcarbazide concentration have been identified as key parameters for successful Cr(VI) transport.

## APPLICATION OF NOVEL EXTRACTANTS FOR ACTINIDE(III)/ LANTHANIDE(III) SEPARATION IN HOLLOW FIBER MODULES

Andreas Geist, Michael Weigl, Udo Müllrich, Klaus Gompper

Forschungszentrum Karlsruhe, Institut für Nukleare Entsorgung, Karlsruhe, Germany

Separation tests in hollow fiber modules were performed regarding the difficult selective extraction of trivalent actinides over fission lanthanides from acidic media. With 2,6-di(5,6-dipropyl-1,2,4-triazin-3-yl)pyridine as extractant, up to 94% americium could be extracted from 1.0 kmol/m<sup>3</sup> HNO<sub>3</sub>, with minimal lanthanide co-extraction. Using a synergistic mixture of bis(chlorophenyl)dithiophosphinic acid and tri-*n*-octyl phosphine oxide, tests were performed on extraction, lanthanide scrubbing and stripping. In the extraction test, up to 99.99% americium could be extracted from 0.5 kmol/m<sup>3</sup> HNO<sub>3</sub>, with approximately one third of the lanthanides being co-extracted. Mass transfer calculations using a consistent set of input data showed good agreement with the experiments.

### INTRODUCTION

The radiotoxicity of spent nuclear fuel is governed by its content of plutonium and the Minor Actinides (neptunium, americium, curium) for several 10<sup>5</sup> years. The *Partitioning and Transmutation* strategy [1] aims at minimizing the long-term radiotoxicity by separating these elements (Partitioning) and fissioning them to short-lived and eventually stable nuclides (Transmutation). The separation of trivalent actinides (americium, curium) from the fission lanthanides is the key step of Minor Actinide Partitioning due to the chemical similarity of the two groups. To make this step process compatible, a feed acidity in the range of 0.1 to 1 kmol/m<sup>3</sup> HNO<sub>3</sub> must be processed.

Two of the most promising extractants for this separation task are:

- A synergistic mixture of bis(chlorophenyl)dithiophosphinic acid and tri-*n*-octyl phosphine oxide (TOPO) [2]. Depending on the diluent used, this mixture extracts actinides(III) from 0.5 kmol/m<sup>3</sup> HNO<sub>3</sub> with an Am(III)/Eu(III) separation factor of approx. 30 [3]. The so called SANEX-/I process (**s**elective **a**ctinide **e**xtraction) [3] is based on this extractant.
- 2,6-di(5,6-dipropyl-1,2,4-triazin-3-yl)pyridine (*n*-Pr-BTP), a solvating extractant which was developed in our laboratory [4]. It is able to extract actinide(III) nitrates from 1-2 kmol/m<sup>3</sup> HNO<sub>3</sub> with usable distribution coefficient and an Am(III)/Eu(III) separation factor of approx. 135. This extractant is used in the SANEX-III process [3].

These extractants have already proven their potential in mixer-settler and centrifugal extractor battery tests performed in other laboratories [3].

Instead of utilizing multistage contactors, we have performed tests on americium(III)/lanthanide(III) separation in hollow fiber modules (HFM) using these extractants. Basically, a HFM is a differential column contactor. Aqueous and organic phases are macroscopically separated by a micro-porous membrane. Phase contact is maintained within the pores by the application of an appropriate pressure difference. This yields a wide flexibility towards hydrodynamic conditions, overcoming restrictions encountered with conventional extractors, e.g., entrainment, flooding [5, 6].

The experiments were accompanied by predictive computer code calculations yielding stationary outlet concentrations. The calculations take into account relevant processes and use a consistent set of input data, making them applicable to scale-up and process design.

## EXPERIMENTAL

### Reagents and Feed Solutions

A solution of 0.5 kmol/m<sup>3</sup> bis(chlorophenyl)dithiophosphinic acid (bought from an external laboratory) + 0.25 kmol/m<sup>3</sup> TOPO in tert.-butylbenzene was used in the SANEX-IV experiments. *n*-Pr-BTP was synthesized according to [4]. A solution of 0.04 kmol/m<sup>3</sup> *n*-Pr-BTP in kerosene/1-octanol (70:30 vol.) was used in the SANEX-III extraction experiment.

Aqueous feed was a solution of inactive trivalent fission lanthanides (La, Ce, Pr, Nd, Sm, Eu, Gd + Y) in either 1.0 kmol/m<sup>3</sup> HNO<sub>3</sub> (SANEX-III) or 0.5 kmol/m<sup>3</sup> HNO<sub>3</sub> (SANEX-IV) tracered with <sup>241</sup>Am(III) (see Table 1). The loaded organic effluent from the SANEX-IV extraction experiment was used as feed in the scrubbing experiment into 1.0 kmol/m<sup>3</sup> HNO<sub>3</sub>, the organic effluent of which was then treated in the stripping experiment into 2.0 kmol/m<sup>3</sup> HNO<sub>3</sub>.

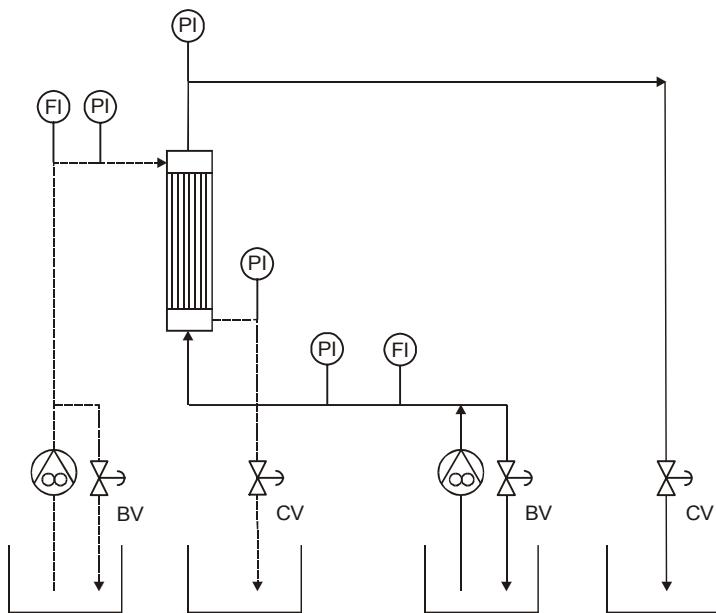

*Table 1. Aqueous feed compositions for the SANEX-III and -IV extraction experiments.*

compound	SANEX-III	SANEX-IV
HNO <sub>3</sub>	1.0 kmol/m <sup>3</sup>	0.5 kmol/m <sup>3</sup>
<sup>241</sup> Am	0.49 MBq/L	0.88 MBq/L
Y	89 mg/L	221 mg/L
La	294 mg/L	756 mg/L
Ce	566 mg/L	1460 mg/L
Pr	264 mg/L	699 mg/L
Nd	998 mg/L	2512 mg/L
Sm	199 mg/L	457 mg/L
Eu	36 mg/L	91 mg/L
Gd	28 mg/L	55 mg/L

### HFM Setup and Procedure

We set up a single HFM extractor inside a glove box. The HFM setup is shown schematically in Figure 1. Both phases were passed through the module in quasi-counter-current, single-pass mode, i.e., phases were not recycled. The modules used were Celgard LiquiCel Extra-Flow type modules (10,000 hollow fibers (HF), membrane material polypropylene, HF inner diameter = 0.24 mm, HF outer diameter = 0.30 mm, average pore size 0.02 µm, porosity 40%, tortuosity 2.6, active length = 0.15 m).

The HFM was filled with aqueous and organic phases and appropriate flow rates and pressures were set up. Static pressure in the aqueous phase was kept approx. 0.5 bar higher than in the organic phase to maintain proper phase separation. Aqueous and organic effluent samples were taken at appropriate intervals until steady state was reached. Then, flow rates were changed and the sampling procedure repeated.

*Figure 1. Single-pass HFM setup (schematic). — organic phase, - - - aqueous phase, PI = pressure gauge, FI = flow meter (rotameter), CV = control valve, BP = bypass valve.*

Americium-241 activity in both effluent phases was measured on a gamma-counter (Packard Cobra Auto-Gamma). Lanthanide concentrations were measured with ICP-AES after appropriate dilution in nitric acid (aqueous samples) or stripping into nitric acid (organic samples). Stationary outlet concentrations were plotted vs. flow rate.

### MASS TRANSFER CALCULATIONS

A modeling was performed to predict experimental data. The calculations take into account fundamental physical and chemical processes (flow of phases, mass exchange according to experimentally determined equilibrium and kinetic data). The nature of the calculations allows to use them for scale-up. The modeling, which is described in detail in [7, 8], was adapted to the extraction systems and HFMs used here [9]. Mass fluxes were calculated from input concentrations, equilibrium and kinetic data, and diffusivities. With a hydrodynamic description of the module and a cell-wise calculation, outlet concentrations were calculated.

Mass transfer rate in the SANEX-IV system (dithiophosphinic acid) is controlled by diffusion in the range of hydrodynamic conditions relevant [9, 10]. Hence, the above mentioned modeling of mass transfer systems controlled by diffusion [7, 8] was adapted by using equilibrium data from [3]. Aqueous diffusion coefficients were taken from the literature, organic diffusion coefficients were estimated using the Wilke-Chang correlation [11].

In the SANEX-III system (n-Pr-BTP), extraction of metal nitrates and nitric acid was taken into account. Corresponding equilibrium data was taken from [3]. Kinetic investigations revealed that the rate of americium mass transfer is controlled by the chemical reaction [10]. A forward reaction rate constant was derived,  $k_{fwd} = 3 \cdot 10^{-5}$ . The additional (and dominating) mass transfer resistance due to the chemical reaction was implemented in the calculations.

## RESULTS

For all experiments performed, operation was stable and dispersion-free. Calculations agreed well with the experimental results. Extraction efficiency is strongly dependent on flow rate,  $Q$ , and hence residence time.

In the SANEX-IV extraction test, the aqueous phase was flowing inside the hollow fibers. Aqueous flow rate was varied,  $Q_{aq} = 300 \text{ mL/h}, 490 \text{ mL/h}, 800 \text{ mL/h}$ . Organic flow rate was kept constant at  $Q_{org} = 300 \text{ mL/h}$ .

Mass balances were 100-103% (americium) and (100±5)% (lanthanides). Aqueous effluent concentrations normalized to aqueous feed concentrations,  $[Me^{3+}]_{out}/[Me^{3+}]_{in}$ , as a function of aqueous flow rate,  $Q_{aq}$ , are shown in Figure 2: At  $Q_{aq} = 300 \text{ mL/h}$ , 99.99% americium could be removed from the feed phase. Approx. 30% of the lanthanide inventory was co-extracted.

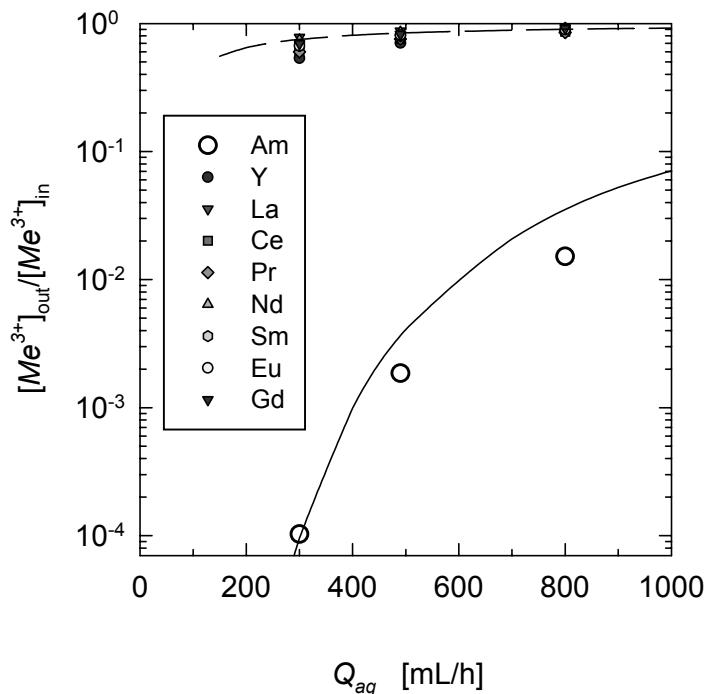

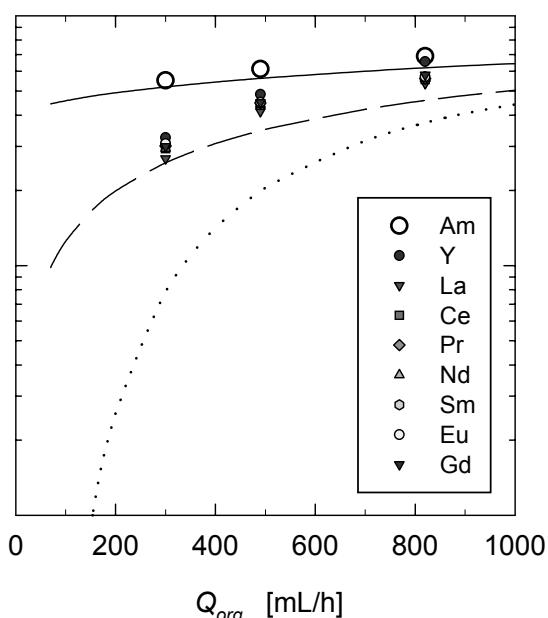

Figure 2. SANEX-IV extraction experiment. Flow rate dependency of extraction efficiency. Aqueous phase, in HF: Am(III) + Ln(III) in  $HNO_3$  0.5 kmol/m<sup>3</sup> (see Table 1). Organic phase, shell-side: Bis(chlorophenyl)dithiophosphinic acid 0.5 kmol/m<sup>3</sup> + TOPO 0.25 kmol/m<sup>3</sup> in tert.-butylbenzene.  $Q_{org} = 300 \text{ mL/h}$ . Symbols: experiment, lines: calculated.

A lanthanide scrubbing experiment was performed, contacting the loaded organic phase from the SANEX-IV extraction test with 1.0 kmol/m<sup>3</sup>  $HNO_3$ . Erroneously, the organic phase was led shell-side. Aqueous and organic flow rates were varied, 300 mL/h, 490 mL/h, 820 mL/h.

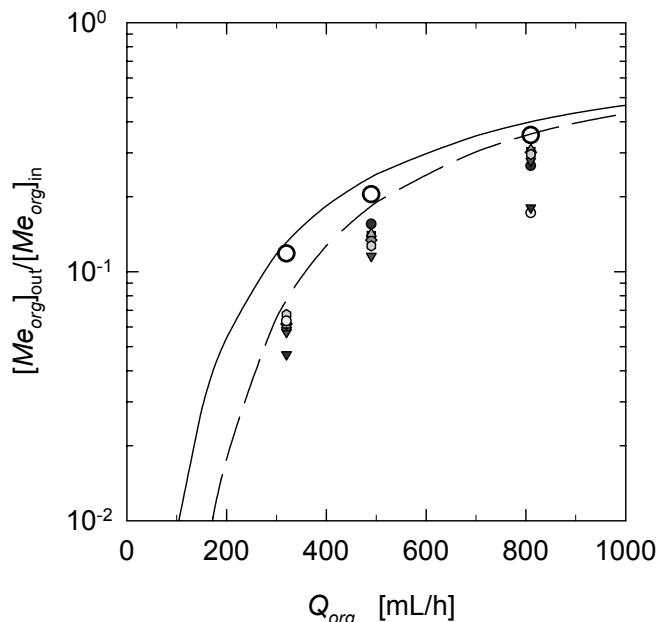

Mass balances were (100±1)% for americium, (100±5)% for yttrium and 89-94% for the other lanthanides. At 300 mL/h, approx. 70% of the lanthanides were scrubbed. 45% of americium was also scrubbed, see Figure 3. The dotted line shows the calculated lanthanide scrubbing efficiency if the organic phase was led inside the hollow fibers (americium scrubbing is not influenced by operating mode). The reason for the improved efficiency is explained in [9].

Finally, the organic effluent from the SANEX-IV scrubbing experiment was stripped into  $2.0 \text{ kmol/m}^3 \text{ HNO}_3$ . The organic phase was led in the lumen of the hollow fibers. Aqueous and organic flow rates were varied, 320 mL/h, 490 mL/h, 810 mL/h, with  $Q_{\text{aq}} = Q_{\text{org}}$ .

Mass balances were 97-99% for americium and  $(100 \pm 5)\%$  for the lanthanides. At 320 mL/h, 88% of americium and 93-95% of the lanthanide inventory could be stripped from the organic phase, see Figure 4. This is an improvement over a stripping experiment performed into  $1.5 \text{ kmol/m}^3 \text{ HNO}_3$  [9]. To reach 99% americium stripping efficiency, stripping would have to be performed at a flow rate of 100 mL/h, as suggested by the calculations.

 $\text{HNO}_3 = 1.0 \text{ kmol/m}^3$ .*

*Figure 4. SANEX-IV stripping experiment,  
organic phase in HF,  
 $\text{HNO}_3 = 2.0 \text{ kmol/m}^3$ .*

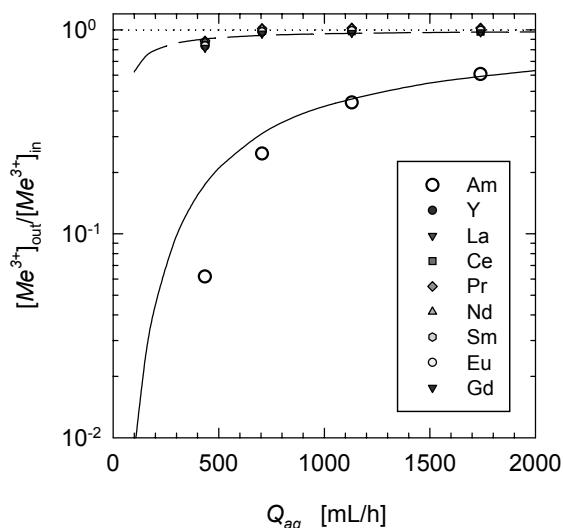

*Loaded organic phase: Bis(chlorophenyl)dithiophosphinic acid  $0.5 \text{ kmol/m}^3$  + TOPO  $0.25 \text{ kmol/m}^3$  in tert.-butylbenzene.  $Q_{\text{org}} = Q_{\text{aq}}$ . Symbols: experiment,  
— americium calculated, - - - lanthanides calculated.*

With the SANEX-III system, we have performed one extraction experiment yet. Aqueous phase was flowing on the shell-side of the HFM. Aqueous flow rate was varied,  $435 \text{ mL/h} \leq Q_{\text{aq}} \leq 1740 \text{ mL/h}$ , organic flow rate was kept constant at  $Q_{\text{org}} = 500 \text{ mL/h}$ . Except with an aqueous flow rate of 435 mL/h, mass balances were  $(100 \pm 2.5)\%$  for lanthanides, and 90-98% for Am(III). With an aqueous flow rate of 435 mL/h, americium mass balance was 66%, lanthanide mass balances were approx. 88%. This is a sign that, at this flow rate, the experiment was not run sufficiently long to reach steady state.

The results are shown in Figure 5. With an aqueous flow rate of 435 mL/h, 94% of americium could be removed from the aqueous phase. Lanthanide co-extraction, determined from the organic phase, was in the range of 1%. This is a result of the very high selectivity of n-Pr-BTP. However, to reach almost quantitative americium extraction, flow rates would have to be significantly lower.

## CONCLUSIONS

The performance of two novel extraction systems for the selective extraction of trivalent actinides over lanthanides was tested in HFM experiments. The SANEX-IV system shows excellent extraction efficiency. On the other hand, the extraction efficiency of the SANEX-III system is impeded by a slow chemical reaction. To achieve comparable Am(III) decontamination, flow rates must be substantially lower. However, the high separation factor of n-Pr-BTP could possibly simplify subsequent lanthanide scrubbing in a coupled extraction-scrubbing-stripping process.

## HOLLOW FIBER MEMBRANE-BASED NON-DISPERSIVE EXTRACTION OF SILVER(I) FROM ALKALINE CYANIDE MEDIA USING LIX 79

Anil Kumar Pabby\*, A. Melgosa, R. Haddad and A. M. Sastre

Department of Chemical Engineering, Universitat Politecnica de Catalunya, Barcelona, Spain

\*PREFRE, Nuclear Recycle Group, Bhabha Atomic Research Center, Tarapur, India

This investigation is concerned with applications of hollow fiber non-dispersive solvent extraction (HFNDSX) of silver(I) from alkaline cyanide media using microporous hydrophobic hollow fiber contactors. LIX79 dissolved in *n*-heptane (Cognis Corporation) has been employed as extractant. The HFNDSX operation was carried out with 12% LIX79/*n*-heptane by passing alkaline feed  $\text{Ag}(\text{CN})_2^-$  through the tube side and organic extractant through the shell side in counter-current mode. The different hydrodynamic and chemical parameters such as linear flow velocity of the feed aqueous phase ( $3.07 \text{ cm/s} \geq v_f \geq 0.39 \text{ cm/s}$ ), linear velocity of organic phase ( $1.18 \text{ cm/s} \geq v_f \geq 0.92 \text{ cm/s}$ ) and pH variation of aqueous feed were evaluated. The mass transfer coefficients were calculated under different hydrodynamic and chemical conditions.

### INTRODUCTION

During the past few years, more attention has been focused on techniques pertaining to the recovery of precious metals [1]. Silver has gained pronounced importance owing to special interest in new technological applications. Moreover, because the market value of precious metals in many cases are very high, their full recovery from hydrometallurgical solutions (primary sources like ores, etc.) and via recycling are justified from an economic point of view. Although several conventional methods are tried for silver recovery no attempt has been made to use the hollow fiber non-dispersive solvent extraction (HFNDSX) technique for silver recovery.

HFNDSX is simply a liquid-liquid extraction in a hollow fiber contactor in which aqueous and organic streams flow through the capillary shell side and contact each other in the pore mouth without dispersion, which minimizes the possibility of forming emulsion/third phase or crud formation with this extractor. Hollow fiber modules may be connected in series or in parallel, and the length and diameters of fibers and modules can be varied to provide the required interfacial area. Such membrane processes not only remove the required compounds from the streams but can also concentrate these species simultaneously on the product side for possible further processing [2-3]. HFNDSX is also characterized by being rapid in separation, high in efficiency, low in power consumption and adaptable to diverse uses, in addition to being suitable for industrial applications due to a large area-to-volume ratio which can approach a value of  $10^4 \text{ m}^2/\text{m}^3$  [2, 4-5]. Furthermore, HFNDSX techniques have been extensively deployed in separation science applications such as metal recovery from leaching and waste waters, extraction of precious and strategic metals from neutral waters, and treatment of large volumes of the effluents including toxic and hazardous wastes generated by industries [2, 6-8].

In order to develop the HFNDSX scheme for silver extraction, LIX79 was selected as extractant based on the previous published work [9]. The aim of this paper is to evaluate design parameters in order to optimize performance of hollow fiber modules for the HFNDSX of Ag(I) from alkaline cyanide media.

## EXPERIMENTAL PROCEDURE

### Reagents

A stock solution of Ag(I) (5 g/L) was prepared from pure solid KAg(CN)<sub>2</sub> [Johnson Matthey Chemicals (Karlsruhe, Germany)] was dissolved in NaCN (Merck). The organic solvent used in HFNDSX studies was *n*-heptane, which is a commercially available solvent. All chemicals were used as received. LIX 79 (N,N'-bis(2-ethylhexyl) guanidine) was kindly provided by Cognis Corp. The HFM is manufactured by Hoechst Celanese, Charlotte, NC (Liqui-Cel, 8x28 cm 5PCG-259 contactor and 5 PCS-1002 Liqui-cel laboratory LLE) and specified as below.

Type of module	Number of fibers	Module diameters (cm)	Module length(cm)	Active interfacial area (m <sup>2</sup> )
5PCG-259 (contactor)	10,000	8	28	1.4

### Hollow Fiber Membrane

Fiber I.D. (cm)	$24.0 \cdot 10^{-3}$	Fiber O.D.(cm)	$30.0 \cdot 10^{-3}$	Fiber wall thickness (cm)	$3.0 \cdot 10^{-3}$
Fiber length (cm)	15	Porosity (%)	30	Pore size ( $\mu\text{m}$ )	0.03
Polymeric Material	polypropylene	Hydraulic diameter (cm)	0.1	Area per unit volume ( $\text{cm}^2/\text{cm}^3$ )	29.3

### Partition Coefficients of Ag(I)

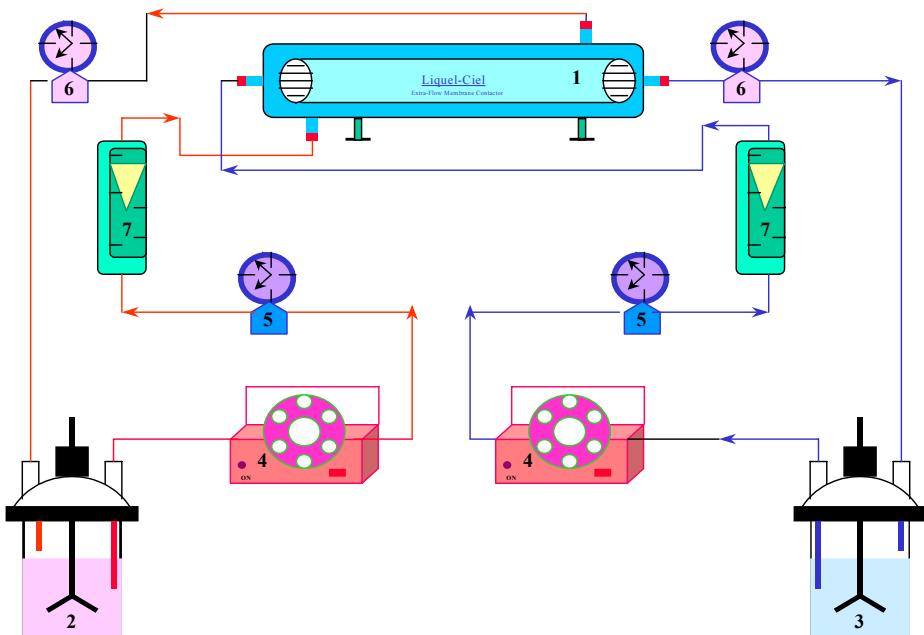

The procedure adopted for determining Ag(I) partition coefficient is described elsewhere [10].

### The Non-Dispersive Membrane Extraction Set-up

A schematic view of the membrane-based extraction process of Ag(I) using a hollow fiber contactor in recirculation mode is shown in Figure 1. Both aqueous and organic phases were contacted counter-currently in a hollow fiber module for carrying out extraction or stripping run under recirculating mode. In the extraction module, the feed aqueous phase flows through the lumen of the fibers, while the organic phase circulates through the shell side, wetting the wall of the hydrophobic fibers. The pressure of the aqueous phase was held at 0.2-0.5 bar higher than the pressure in the organic phase.

In the stripping run, loaded organic extractant (LIX 79 with silver complex) flowed through the shell side, whereas NaOH flowed through the tube side in counter-currently in recirculation mode.

The Ag(I) concentration in the feed varied between  $4.64 \cdot 10^{-4}$  mol/dm<sup>3</sup>. The solution of 0.4 M to 1 M NaOH was used as the stripping phase when back extraction of Ag(I) was carried out in the hollow fiber module. At known times during the procedure, small aliquots of the stripping stream and from organic the solution were taken and analyzed for metal concentration by standard atomic absorption spectrophotometry (2380 Perkin Elmer Absorption Spectrometer).

*Figure 1. A schematic view of the membrane-based extraction process of Ag(I) from cyanide media using hollow fiber contactor. (1) hollow fiber contactor; (2,3) organic extractant and feed; (4) feed and organic pump; (5,6) Inlet and outlet pressure gauge respectively for organic and feed; (7) Flow meters for feed and organic.*

## THEORETICAL BACKGROUND

### Extraction Equilibrium

The extraction mechanism for silver with LIX 79 is based on the ion-pair type. The extraction of Ag(I) from the process stream takes place at the interface of the feed and membrane. The Ag(I) ions in alkaline cyanide media (present as  $\text{Ag}(\text{CN})_2^-$ ) form a complex with the extractant LIX 79 ( $\text{N,N}'\text{-bis}(2\text{-ethylhexyl})\text{ guanidine}$ , R), which is protonated between pH 10.0-10.5, and is expressed as:

and similarly for stripping, the chemical reaction is presented as

The extraction equilibrium can be described by the following reactions and extraction constants:

$$K_{\text{ex}} = \frac{[\text{Ag}(\text{CN})_2(\text{HR}) \bullet 2\text{R}]_{\text{org}}}{[\text{Ag}(\text{CN})_2^-]_{\text{aq}} [\text{H}^+] [\text{R}]_{\text{org}}^3} \quad (3)$$

where R is the organic extractant. The value of  $K_{\text{ex}}$  for Ag(I) with LIX 79 was found to be  $7.41 \pm 0.5 \cdot 10^{+15}$   $\log K_{\text{ext}} = 15.87$  [10] and is related to the partition coefficient (H) through the following expression:

$$\log H = \log K_{\text{ex}} + \log[H^+] + 3\log[R]_{\text{org}} \quad (4)$$

## Mass Transfer Coefficient Evaluation

As derived by Delia *et al.* [11], the equation for the calculation of  $K_{Ag}^E$  for countercurrent flow is

$$\ln \left[ \frac{\left( C_{e/s}^0 / H - C_f^0 \right)}{\left( C_{e/s}^0 / H - C_f^0 \right) + \left( V_f / HV_{e/s} \right) \left( C_f^0 - C_f \right)} \right] = t \frac{\left[ 1 - \exp \left( -4 K_{Au}^E V_m / d \left( 1 / Q_f - 1 / Q_{e/s} H \right) \right) \right] \left[ 1 / V_f + 1 / V_{e/s} H \right]}{\frac{1}{Q_f} - \frac{1}{Q_{e/s}} \exp \left[ -\frac{4 K_{Au}^E V_m}{d} \left( \frac{1}{Q_f} - \frac{1}{Q_{e/s} H} \right) \right]} \quad (5)$$

where  $Q_f$  and  $Q_{e/s}$  are the feed and extract/strip flows;  $V_f$  and  $V_{e/s}$  are the feed and extract/strip volumes;  $C_f^0$  and  $C_{e/s}^0$  are the concentrations of the solute in the feed and in the extract/strip solutions at time zero;  $C_f$  is the concentration of the solute in the feed at time  $t$ ;  $V_m$  is the volume of all the hollow fibers; and  $d$  is the diameter of one fiber.

## RESULTS AND DISCUSSION

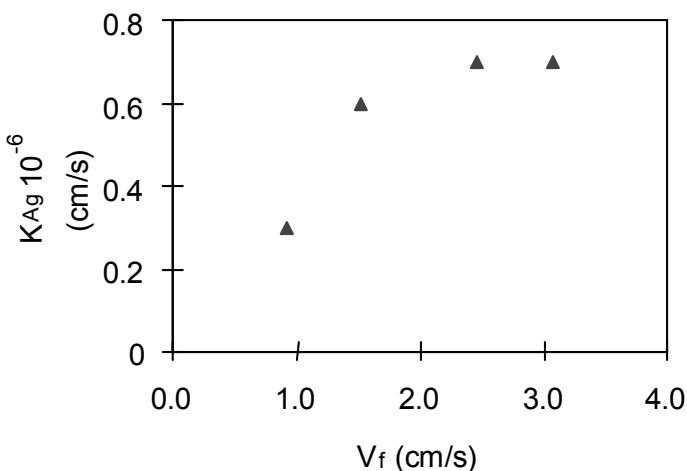

### Optimisation of Hydrodynamics and Chemical Parameters

In the HFNDSX technique, it is well established [2] that, in order to keep the interface within the pores of a hydrophobic membrane, it is necessary to maintain a higher local pressure in the aqueous phase. Figure 2 shows a typical plot of mass transfer coefficient versus aqueous linear flow velocity predicted by Equation 5 for extraction of Ag(I) into LIX 79. The results of these calculations are given in Table 1 which show the mass transfer coefficients  $K_{Ag}^E$  for the extraction varied from  $2.6 \cdot 10^{-7}$  to  $1.7 \cdot 10^{-6}$  cm/s. In extraction module, the Ag(I) extraction ranged from 95 to 100% in around 1-2 h for counter-current contact. As seen in Figure 2, the overall mass transfer coefficient increased with the feed flow rate and its value was maximum at  $13.88 \text{ cm}^3/\text{s}$ . For example, when linear flow velocity ( $v_f$ ) varied by a factor of 3, the overall mass transfer coefficient ( $K_{Ag}^E$ ) increased by 6 times.

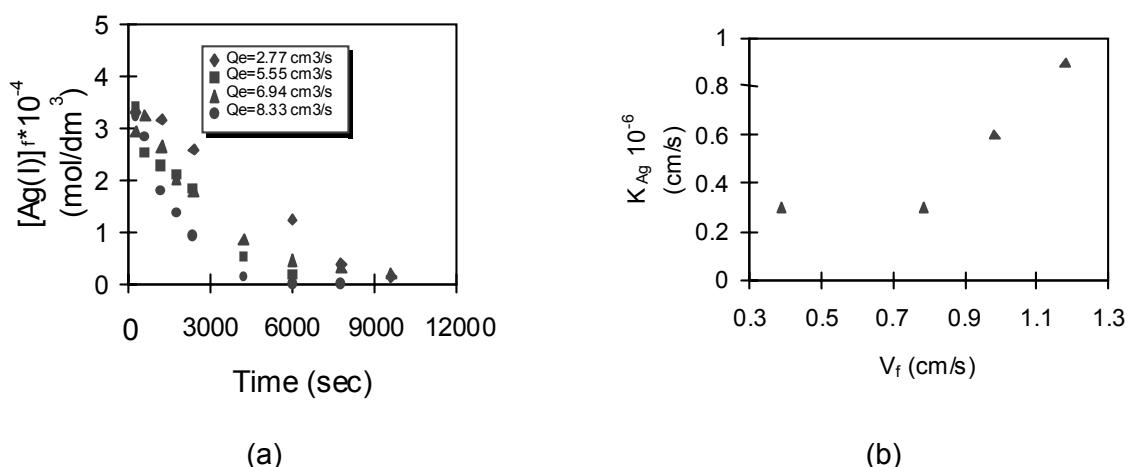

*Table 1. Mass transfer coefficients for extraction of Ag(I) from aqueous alkaline cyanide media (pH=10.3) with 18% LIX 79 in n-heptane using HFNDSX technique in counter-current mode as a function of aqueous flow rates.*

Experiment No.	$Q_e$ ( $\text{cm}^3/\text{s}$ )	$Q_f$ ( $\text{cm}^3/\text{s}$ )	$v_f$ ( $\text{cm}/\text{s}$ )	$K_{Ag}^E \cdot 10^{-6}$ ( $\text{cm}/\text{s}$ )	$r^2$	Extraction (%)
1	4.72	4.16	0.92	0.26	0.99	93
2	4.72	6.94	1.53	0.60	0.97	100
3	4.72	11.11	2.46	0.70	0.99	100
4	4.72	13.88	3.07	1.70	0.99	100

Figure 3 shows the effect of changing the shell side organic-phase flow rate and keeping the aqueous flow rate constant for 18% v/v LIX 79/n-heptane. Table 2 presents the mass transfer coefficient of silver as a function of organic phase flow rate. Module extraction efficiency changes dramatically below  $2.77 \text{ cm}^3/\text{s}$  of organic flow rate. This means that most silver cyanide can be easily transferred into the organic phase through the interfacial reaction when the concentration of the LIX 79 is in excess due to an increase in the organic phase flow rate, since the aqueous inlet concentration of silver is only  $4.63 \cdot 10^{-4} \text{ mol}/\text{dm}^3$  and the aqueous stream flow rate,  $Q_f$ , is around  $11.1 \text{ cm}^3/\text{s}$  ( $v_f=2.5 \text{ cm}/\text{s}$ ).

*Figure 2. Effect of feed flow rate on mass transfer coefficient of silver cyanide with LIX 79 in extraction module in counter-current mode.*

*Figure 3. Effect of organic flow rate in counter-current mode (a) plot of concentration of silver vs. time as a function of flow rate (b) mass transfer coefficient as a function of linear flow velocity.*

The effect of pH on the overall mass transfer coefficient is presented in Table 3. The initial pH of 10.0 to 10.5 was observed to be optimum for mass transfer when experiments were performed in counter-current mode maintaining the aqueous flow rate at  $6.94 \text{ cm}^3/\text{s}$ . The overall mass transfer coefficient decreased to  $0.09 \cdot 10^{-6} \text{ cm/s}$  at pH 11 and practically no extraction at pH 12 was observed, as suggested by the extraction mechanism (Figure 4).

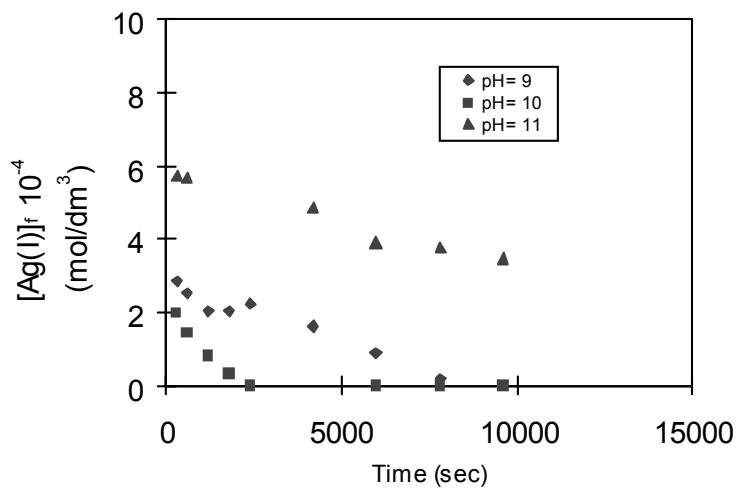

*Table 2. Mass transfer coefficients for extraction of Ag(I) from aqueous alkaline cyanide media ( $\text{pH}=10.3$ ) with 18% LIX 79 in *n*-heptane using HFNDSX technique in counter-current mode as a function of organic flow rates.*

Experiment No.	$Q_f$ ( $\text{cm}^3/\text{s}$ )	$Q_e$ ( $\text{cm}^3/\text{s}$ )	$v_f$ ( $\text{cm}/\text{s}$ )	$K_{Ag}^E \cdot 10^{-6}$ ( $\text{cm}/\text{s}$ )	$r^2$	Extraction (%)
1	11.11	2.77	0.39	0.30	0.99	92
2	11.11	5.55	0.79	0.30	0.98	96
3	11.11	6.94	0.98	0.60	0.96	94
4	11.11	8.33	1.18	0.90	0.96	100

*Table 3. Mass transfer coefficients for extraction of Ag(I) from aqueous alkaline cyanide media as a function of initial feed pH with 18% LIX 79/ *n*-heptane in counter-current mode using the HFNDSX technique.*

Experiment No.	pH	$K_{Ag}^E \cdot 10^{-6}$ ( $\text{cm}/\text{s}$ )	$r^2$	Extraction (%)
1	9	0.20	0.96	95
2	10	0.60	0.97	100
3	11	0.09	0.91	37
4	12	--	---	0

The stripping studies were performed by passing 1 M NaOH in tube side and loaded LIX 79 / *n*-heptane in shell side. More than 95% silver recovery was obtained in less than 90 minutes. This work is still continued and integrated process for recovering silver in presence of base metals is being developed from alkaline hydrometallurgical solutions.

*Figure 4. Plot of concentration of silver vs. time as a function of initial aqueous feed pH in extraction module in counter current mode.*

## SELECTIVE EXTRACTION OF LITHIUM ION WITH NOVEL LIPOPHILIC PHTHALOCYANINE DERIVATIVES AND ITS PERMEATION THROUGH SUPPORTED LIQUID MEMBRANE

Kazuo Kondo, Michiaki Matsumoto, Takashi Yoshida and Eiji Kamio

Doshisha University, Kyotanabe, Japan

New types of lipophilic phthalocyanine derivatives, hexadeca(2,2,2-trifluoroethoxy)-phthalocyanine and hexadeca(2,2,3,3,3-pentafluoropropoxy)phthalocyanine (abbreviated as H<sub>2</sub>Pc(TFE)<sub>16</sub> and H<sub>2</sub>Pc(PFP)<sub>16</sub>, respectively), were prepared. The extraction equilibria of alkali metals with H<sub>2</sub>Pc(TFE)<sub>16</sub> and H<sub>2</sub>Pc(PFP)<sub>16</sub> were investigated, and the extracted complexes and extraction equilibrium constants of the metals were estimated. The extraction rate of lithium with H<sub>2</sub>Pc(TFE)<sub>16</sub> was measured. The extraction process is considered to be limited by the diffusion of the extractant. The permeation rates of alkali metals through a supported liquid membrane containing H<sub>2</sub>Pc(TFE)<sub>16</sub> were measured. The transport selectivity of lithium was enhanced by increasing temperature and showed the value of 1.61 at 318K against potassium. Sodium permeation is limited by the reaction process at the interface. For lithium and potassium permeation the diffusion of complex in the membrane accompanying the reaction is considered to be the rate-controlling step.

### INTRODUCTION

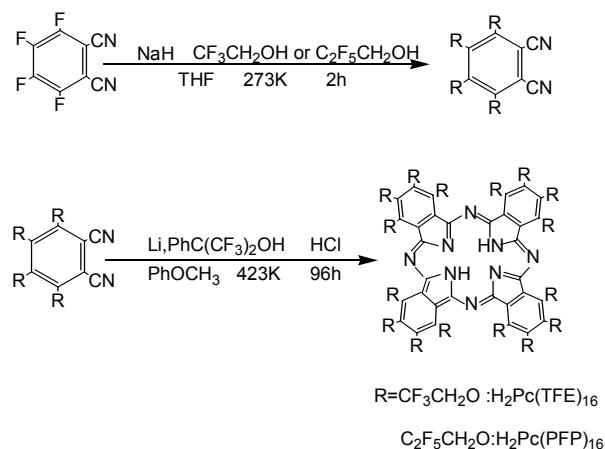

Lithium, which is used as a chargeable secondary battery for personal computers, is a scarce resource. Its use is expected to increase due to the realization of power stations with nuclear fusion and development of fuel cells [1]. In recent years, the recovery of lithium from sea, spa and waste water from geothermal power generation has been actively studied.

In this study, two types of phthalocyanine derivatives (hexadeca(2,2,2-trifluoroethoxy)-phthalocyanine and hexadeca(2,2,3,3,3-pentafluoropropoxy)phthalocyanine) were synthesized as novel macrocyclic extraction reagents. Phthalocyanine derivatives, which are stable to heat and chemical materials, have strong  $\pi$ - $\pi$  bonds. On account of the stacking effect by  $\pi$ - $\pi$  interaction, it is generally difficult to dissolve them in organic solvents. The phthalocyanine derivatives synthesized in this study have bulky alkoxy group containing fluorine, so the stacking is prevented and the solubility into organic solvents is increased. In addition, lithium is expected to be selectively extracted due to its high charge-to-radius ratio. No research has been done on the extraction kinetics of alkali metal ions except for that with crown ethers [2]. In our study, the extraction equilibrium and kinetic behaviour of alkali metals ( $\text{Li}^+$ ,  $\text{Na}^+$ ,  $\text{K}^+$ ) with the synthesized phthalocyanine derivatives are investigated and each extraction mechanism is discussed.

## EXPERIMENTAL

### Synthesis of Lipophilic Phthalocyanine Extractant

Lipophilic phthalocyanine derivatives used in this study were prepared by the two-step reactions shown in Scheme 1.

*Scheme 1. Synthesis of novel lipophilic phthalocyanine derivatives.*

### Synthesis of Phthalocyanine Containing Fluorine

4.4 g of 60% lipophilic sodium hydride ( $\text{NaH}$ ) was suspended in  $100 \text{ cm}^3$  of tetrahydrofuran (THF) in a flask.  $8.0 \text{ cm}^3$  of trifluoroethanol ( $\text{CF}_3\text{CH}_2\text{OH}$ ) or  $12.4 \text{ g}$  of pentafluoropropanol ( $\text{C}_2\text{F}_5\text{CH}_2\text{OH}$ ) was added under nitrogen atmosphere at 273 K. After that, they were agitated for 30 minutes. Subsequently,  $20 \text{ cm}^3$  of THF solution containing  $5.0 \text{ g}$  of tetrafluorophthalonitrile ( $\text{C}_6\text{F}_4(\text{CN})_2$ ) was dropped and suspended for 30 minutes at room temperature. After separating the solution by decantation, the aqueous phase was extracted with ethylether, dried with magnesium sulfate, and the ether was evaporated. The THF phase was also evaporated. The solids obtained from both phases were recrystallized from THF-*n*-hexane solution and purified with column chromatography. The obtained solution was then evaporated, and the resulting solid was again recrystallized from THF-*n*-hexane solution to obtain pure crystals.

5.2 g of tetrakis (2,2,2-trifluoroethoxy) phthalonitrile prepared above, 0.1 g of lithium powder and  $2.5 \text{ cm}^3$  of hexafluorocumin alcohol ( $\text{PhC}(\text{CF}_3)_2\text{OH}$ ) were added in  $30 \text{ cm}^3$  of anisole ( $\text{C}_6\text{H}_5\text{OCH}_3$ ) and agitated for 4 days under nitrogen atmosphere at 413- 418K. The aqueous phase was extracted with ethylether. Both the resulting aqueous and organic phases were distilled. The obtained solid was recrystallized from acetone-*n*-hexane mixture, thus green crystalline (hexadeca(2,2,2-trifluoroethoxy) phthalocyanine;  $\text{C}_{64}\text{F}_{48}\text{H}_{34}\text{N}_8\text{O}_{16}$ ) was prepared. By the same method, green crystalline (hexadeca(2,2,3,3,3-pentafluoropropoxy)-phthalocyanine;  $\text{C}_{80}\text{F}_{80}\text{H}_{34}\text{N}_8\text{O}_{16}$ ) was also prepared from tetrakis(2,2,3,3,3-pentafluoropropoxy)phthalonitrile. These were identified by IR and NMR.

### Extraction Equilibria of Alkali Metals

Extraction equilibrium experiment of alkali metal ions ( $\text{Li}^+$ ,  $\text{Na}^+$ ,  $\text{K}^+$ ) was carried out by a conventional method. Aqueous solutions were prepared by dissolving each alkali metal chloride in deionized water. The pH of aqueous solutions was adjusted with  $1 \text{ mol}/\text{dm}^3$  HCl-diethanolamine buffer solution using a pH meter. Butyl acetate was used as an organic solvent. The lithium- and sodium-ion concentrations were measured by inductively coupled plasma spectrometer (ICPS) and the potassium concentration was measured by atomic absorption spectrophotometry.

### Extraction Rate of Lithium

The extraction rate was measured using the stirred transfer cell reported in the previous paper [3] at 303 K. Equal volume of the aqueous and organic phases was contacted and they were stirred at 100 rpm. 1 cm<sup>3</sup> of the organic phase was collected at appropriate intervals. The metal complex concentration in the organic phase was determined from the absorption spectra at 699 and 733 nm measured by a spectrophotometer.

### Permeations of Alkali Metals Through a Supported Liquid Membrane

A membrane material, porous tetrafluoroethylene film (thickness 47 μm; porosity 0.77) was kindly supplied by Japan Gore Tex. The supported liquid membrane (SLM) was prepared by impregnating the porous film with 0.2 mol/m<sup>3</sup> butyl acetate containing H<sub>2</sub>Pc(TFE)<sub>16</sub>. The experimental apparatus used is the same as that in the previous work [3]. The feed and stripping solutions were fed concurrently. The stripping solution was collected at appropriate intervals and the metal concentration was measured by ICPS.

## RESULTS AND DISCUSSION

### Extraction Equilibria of Alkali Metals

Figure 1 shows the effect of pH on the distribution ratio,  $D$ , defined as follows:

$$D = \frac{C_{M,aq}^0 - C_{M,aq}}{C_{M,aq}} \quad (1)$$

The distribution ratio does not depend on pH in low pH range for all metals. This suggests that phthalocyanine derivatives form ion-pair complex in the organic phase like crown ether. If it is assumed that the ligand and alkali metal ion form an extracted complex with a stoichiometric ratio of 1:1, the extraction equilibrium equation is written as follows:

The extraction equilibrium constant based on Eq. (2) was determined for the two extractants and they were listed in Table 1. In Figure 1, the distribution ratios increase with increasing pH for lithium and potassium extraction. It is found that the slope is unity between pH 8 and 9, and two over pH 9 for Li-H<sub>2</sub>Pc(TFE)<sub>16</sub> system. For Li-H<sub>2</sub>Pc(PFP)<sub>16</sub> system, the slope is unity over pH 8. These results suggest that the extraction progresses according to the following two-step cation-exchange reaction:

For Li-H<sub>2</sub>Pc(PFP)<sub>16</sub> system, the second step reaction does not occur due to the steric hindrance of side chain. For potassium extraction, the slopes were 2 and 1 over pH 8 for H<sub>2</sub>Pc(TFE)<sub>16</sub> and H<sub>2</sub>Pc(PFP)<sub>16</sub>, respectively. From the definitions of equilibrium constant and distribution ratio based on Equations (3) and (4), the following equations were established:

$$\log D = \log K_{M1} + \log \frac{[H_2R]_{org}}{[H^{+}]_{aq}} \quad (5)$$

$$\log D = \log (2K_{M2}) + \log \frac{[M^{+}]_{aq}[H_2R]_{org}}{[H^{+}]_{aq}^2} \quad (6)$$

Figure 2 shows the plots based on Eqs. (5) and (6) with the correlation coefficient  $\alpha$ . From the result, approximately straight line with slope 1 was obtained for all systems and the equilibrium constants were determined from the intercepts. They are also listed in Table 1.

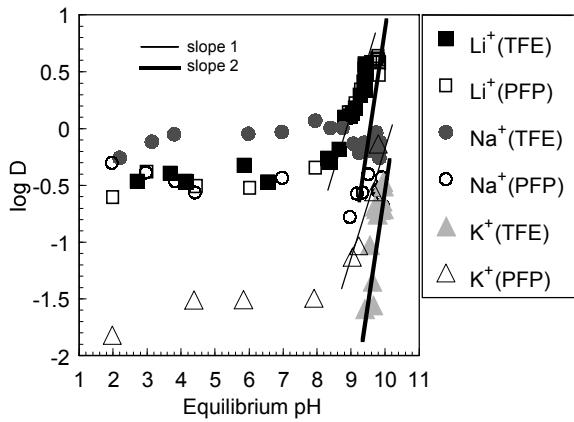

Figure 1. Relationship between  $\log D$  and pH.

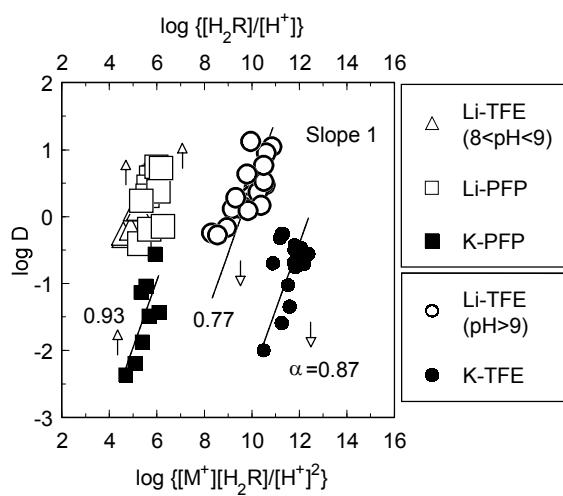

Figure 2. Determination of extraction equilibrium constants.

Table 1. Extraction equilibrium constants (logarithm values).

	Li-TFE	Na-TFE	K-TFE	Li-PFP	Na-PFP	K-PFP
$\log K_{M0}$	$1.45 \pm 0.15$	$2.14 \pm 0.16$	n.d.	$1.42 \pm 0.16$	$1.35 \pm 0.12$	$0.70 \pm 0.11$
$\log K_{M1}$	$-4.98 \pm 0.18$	-	-	$-5.46 \pm 0.13$	-	$-6.95 \pm 0.15$
$\log K_{M2}$	$-9.85 \pm 0.31$	-	$-12.7 \pm 0.26$	-	-	-

n.d. not determined

### Extraction Rate of Lithium

It was found that lithium was efficiently extracted at high pH range. So, the extraction rate of lithium was measured in the range of pH>9 with  $H_2Pc(TFE)_{16}$  as an extractant. Extraction rate was evaluated as an initial extraction rate,  $R_0$ , defined as follows:

$$R_0 = \frac{V_{org}}{A_s} \left( \frac{dC_{Li,org}}{dt} \right)_{t=0} \quad (7)$$

where,  $V_{org}$ ,  $A_s$  and  $C_{Li,org}$  denote volume of organic phase, interfacial area and lithium concentration in organic phase, respectively. The effect of extractant concentration on  $R_0$  is shown in Figure 3. From this result, the mass transfer of the extractant could be considered as the rate-determining step. Assuming that mass transfer of the extractant is the rate-determining step, the equation  $R_0 = 2k_{H2R}([H_2R]_0 - 0)$  is held. So the mass transfer coefficient of extractant,  $k_{H2R}$ , is evaluated from the following equation:

$$k_{H2R} = \frac{R_0}{2[H_2R]_0} \quad (8)$$

From Equation (8),  $k_{H2R}$  was determined as  $2.6 \times 10^{-6}$  m/s. From this result, it is suggested that the diffusion coefficient would become small because of the large cyclic structure of the phthalocyanine derivatives. Assuming that the mass transfer coefficient of complex,  $k_c$ , is approximately the same as  $k_{H2R}$  and using  $k_M$  for samarium ( $k_M = 2.2 \times 10^{-5}$  m/s) [3], the experimental results were analyzed. The solid lines in Figure 3 are the calculated results according to these assumptions.

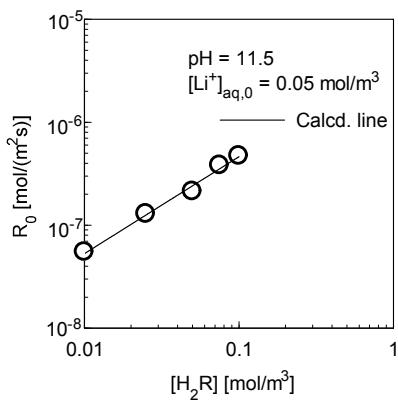

Figure 3. Relationship between initial extraction rate and extractant concentration.

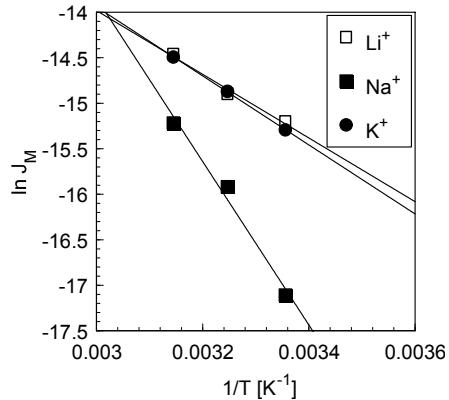

Figure 4. Arrhenius plot for permeations of alkali metal ions through SLM.

### Permeations of Alkali Metals Through Supported Liquid Membrane

The permeation rate of alkali metal ion,  $J_M$ , is defined as follows:

$$J_M = \frac{(C_{MS} \cdot Q_s)}{A_s} \quad (9)$$

The Arrhenius equation is expressed as the following equation:

$$J_M = A' \cdot \exp\left(-\frac{E_a}{RT}\right) \quad (10)$$

where  $A'$ ,  $E_a$ ,  $R$  and  $T$  represent apparent frequency factor, apparent activation energy, gas constant and temperature, respectively. Figure 4 shows the Arrhenius plots of  $J_M$  for  $\text{Li}^+$ ,  $\text{Na}^+$  and  $\text{K}^+$ . From the slope of the straight lines,  $E_a$  was determined as 29.1, 74.7 and 30.9 kJ/mol for lithium, sodium and potassium, respectively. It is generally said that the activation energy for diffusion process is under about 30 kJ/mol while that for reaction process is over about 60 kJ/mol. Therefore, it is suggested that  $\text{Na}^+$  permeation is limited by the reaction process at the interface. For  $\text{Li}^+$  and  $\text{K}^+$  permeation the diffusion of complex in the membrane phase accompanying the reaction may be considered to be the rate-controlling step.

The selectivity in the competitive transport experiment was also measured using the mixtures of alkali metals at various temperatures. The characteristic of permeation selectivity of alkali metals,  $\gamma_{M1/M2}$  was defined as follows:

$$\gamma_{M1/M2} = \frac{J_{M1}}{J_{M2}} \quad (11)$$

where subscripts M1 and M2 denote each alkali metal. The  $\gamma_{M1/M2}$  values of lithium calculated based on Equation (11) against potassium and sodium were increased with increasing temperature. This would occur because of the difference in permeation mechanisms for each alkali metal. The value of  $\gamma_{\text{Li}/\text{K}}$  was 1.61 at 318K, which showed a good selectivity for lithium.

### CONCLUSIONS

In this study, hexadeca(2,2,2-trifluoroethoxy)phthalocyanine and hexadeca(2,2,3,3,3-pentafluoropropoxy)phthalocyanine were synthesized as selective extractants for lithium. From metal-distribution experiments, the extraction equations and the equilibrium constants were determined for lithium, sodium and potassium. In addition, kinetic experiments were carried out, and it was suggested that the extraction process was limited by the diffusion of the extractant. From the obtained activation energy and the diffusion coefficient, it was

suggested that  $\text{Na}^+$  permeation was limited by the reaction process at the interface and for  $\text{Li}^+$  and  $\text{K}^+$  permeations the diffusion of complex in the membrane phase accompanying the reaction might be considered to be the rate-controlling step. The permeation selectivity of lithium against potassium and sodium was increased with increasing temperature.

## EXTRACTION OF CADMIUM FROM PHOSPHORIC ACID WITH AN EMULSION LIQUID MEMBRANE: WATER TRANSPORT AND MEMBRANE RUPTURE

T. Gallego Lizon\* and E. Susana Pérez de Ortiz

Department of Chemical Engineering and Chemical Technology,  
Imperial College of Science, Technology and Medicine, London, UK

\*Environmental Research Laboratory, GlaxoSmithKline, Old Powder Mills, Tonbridge, UK

Emulsion swelling and membrane rupture were measured during the extraction of cadmium from phosphoric acid with an emulsion liquid membrane containing the reagent Cyanex 302 and stabilised with the surfactant Arlacel C with the aim of including their effect in the process modelling. The extraction was carried out in a stirred tank over a wide range of values of surfactant concentration, homogeniser speed and emulsion phase ratio. Emulsion swelling was significant and depended on all the parameters studied, whereas rupture remained low at all conditions except at very low surfactant concentrations. Comparison of cadmium extraction rate data with swelling indicated that the mechanisms of water and cadmium transfer were independent.

### INTRODUCTION

Mechanistic modelling of solvent extraction processes in stirred vessels requires the knowledge of the interfacial area between the dispersed and the continuous phases and of the dependency of the extraction flux on chemical, physical and hydrodynamic parameters. The interfacial area is usually calculated from correlations that relate the dispersion Sauter mean diameter with the operating parameters and the physical properties of the phases. In the case of extraction with emulsion liquid membranes (ELM) the dispersed phase is an emulsion, in which the continuous phase is called the liquid membrane. During extraction, the transfer of the solute from the external phase into the liquid membrane and from there into the emulsion internal droplets is usually accompanied by water transfer to the emulsion and by emulsion rupture. This reduces the extraction efficiency through dilution of the emulsion internal phase and leakage of the extract into the feed, affects the size of the dispersed emulsion globules and changes the physical properties of the emulsion. Therefore quantification of swelling and rupture is central to ELM extraction modelling.

This paper examines the effect of surfactant concentration, emulsion phase ratio and the homogeniser speed used in the preparation of the emulsion on emulsion swelling and rupture during the extraction of cadmium from phosphoric acid with an ELM containing the extractant Cyanex 302 and stabilised with the surfactant Arlacel C. Results are compared with those of the Cd extraction in order to clarify the extraction mechanisms. The incorporation of the swelling coefficient on a model of the emulsion dispersion Sauter mean diameter is presented elsewhere [1, 2].

Reports in the literature relate membrane breakage to a series of factors that include composition of the membrane phase and stirring speed [3-5]. Emulsion swelling, on the other hand, has been attributed to three different mechanisms: occlusion, secondary emulsification of the entrained solvent and external solvent permeation (osmosis). These are affected by the presence of electrolytes in the external phase, surfactant and extractant type and concentration, temperature, permeation time, solvent nature, and globule size distribution [6-9]. Here emulsion rupture and swelling are examined for a wide range of surfactant and extractant concentrations, emulsion phase ratios and homogeniser speeds.

## EXPERIMENTAL

### Reagents

The feed was a solution of CdSO<sub>4</sub> in H<sub>3</sub>PO<sub>4</sub> (30% wt P<sub>2</sub>O<sub>5</sub>). The organic phase of the water-in-oil emulsion was a solution of the reagent Cyanex 302 (Cytec Inc.) and surfactant Arlacel C (ICI Surfactants) in low odour kerosene (Aldrich Chemical Co.).

The emulsion aqueous phase (the stripping phase) contained NaCl (3 M) and HCl (1 M). Reagents 3CdSO<sub>4</sub>.8H<sub>2</sub>O (99% wt) and H<sub>3</sub>PO<sub>4</sub> (95% wt) were supplied by Aldrich Chemical Co. All reagents were used without further purification.

### Method

The experiments were conducted in a stirred tank (dimensions are given in Table 1). The emulsion was produced by blending the organic and stripping phases under intense shear (3000 rpm) using a Silverson homogeniser. The volume ratio of feed, V<sub>1</sub>, and emulsion, V<sub>e</sub>, or treat ratio (V<sub>1</sub>/V<sub>e</sub>), was held constant at a value of 20, whereas the emulsion phase ratio (V<sub>2</sub>/V<sub>3</sub>) was changed within 1 and 2.33. Surfactant concentrations ranged between 1 and 10% v/v and the reagent concentration between 0.15 and 0.91 M.

*Table 1. Tank dimensions.*

Internal diameter of vessel	0.09 m
Liquid height in vessel	0.125 m
Impeller diameter	0.0365 m
Impeller type	flat blade turbine
No. of blades	6
Blade length	0.009 m

The feed and the emulsion were placed in the tank and the impeller was carefully placed at the interface. Stirring was started and samples of the continuous and emulsion phases were taken and analysed for cadmium and sodium concentrations. The concentrations of Cd<sup>++</sup> and Na<sup>+</sup> in the continuous and internal phases were measured by atomic absorption spectrophotometry using a Perkin-Elmer premix burner spectrophotometer. Emulsion swelling was calculated from the emulsion volume change with time. Water content in the organic phase was measured using Karl Fisher titration after separation of the emulsion phases using a known volume of *n*-butanol (10%). Emulsion rupture was calculated by analysing the continuous phase for the presence of Na<sup>+</sup>, initially only present in the stripping phase. In order to check the possibility of Na<sup>+</sup> transport across the membrane by hydration of the carrier rather than by emulsion rupture, experiments were conducted in a quiescent cell, as described below.

## RESULTS AND DISCUSSION

In all experiments, results were evaluated by using the following relations:  
Swelling,

$$Sw(\%) = \frac{(V_3^t - V_3^o) + V_3^R + (V_2^t - V_2^o)}{V_3^o + V_2^o} \cdot 100 \quad (1)$$

where  $V$  is the volume of the phase, subscripts 2 and 3 indicate membrane and internal phases and superscripts  $t$ ,  $o$  and  $R$  denote given time  $t$ , initial conditions, and variations due to rupture respectively.  $V_3^R$  is the internal phase volume loss due to rupture.

Percentage membrane rupture ( $R\%$ ) was calculated from the sodium concentrations in the external phase using the equation:

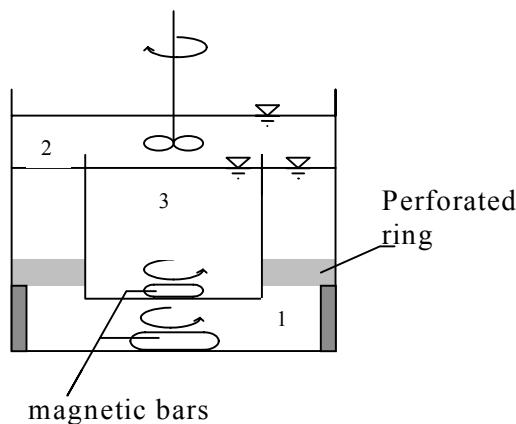

$$R(\%) = \frac{[Na^+]_1^t V_1^t}{[Na^+]_3^o V_3^o} \cdot 100 \quad (2)$$

where  $[Na^+]$  is the concentration of sodium, subscripts 1 and 3 denote the continuous and internal phase respectively and superscripts  $t$  and  $o$  denote time  $t$  and the initial conditions. In order to check if there was  $Na^+$  transport across the membrane experiments were conducted in a non-dispersive quiescent cell (Figure 1). Results showed no significant variations in  $Na^+$  concentration in either phase over a period of 11 hours. This indicated that there was no  $Na^+$  transport through the membrane due to reaction, osmosis or hydration.

The standard experimental conditions are given in Table 2.

*Table 2. Standard experimental conditions.*

$[Cd]_{feed}$	$0.00042 \pm 0.00002 M$	$N_{homogeniser}$	$3000 \pm 30$ rpm
[Arlacel C]	$5\% \pm 0.1\% v/v$	$N_{stirrer}$	$300 \pm 1$ rpm
[Cyanex 302]	$0.3 \pm 0.01 M$	$V_1/V_e$	20
		$V_2/V_3$	1.0

*Figure 1. Non-dispersive cell containing phases 1, 2 and 3.*

### Effect of Surfactant Concentration

Figure 2 shows the effect of the surfactant concentration on water transport for Arlacel C concentrations between 1% and 10% v/v at Cyanex 302 concentration of 0.3 M. As can be seen, increasing the surfactant concentration resulted in a practically linear increase in emulsion swelling, with a slope of 3.75. This is likely to be the result of water transport by the hydrated surfactant, or to the formation of surfactant reversed micelles. The calculated molecular ratios of water to surfactant in the membrane of 3.5, 2.9 and 1.6 for surfactant

concentrations of 3, 5 and 10 %, respectively, are lower than those expected for reversed micelles. However, either structure of the hydrated surfactant molecules can provide a shuttle mechanism for the osmotically induced water transport. Thus the higher the surfactant concentration, the higher the amount of water transferred during a fixed time. This is not the case for Cd (Figure 4), as the transfer of Cd is mediated by Cyanex 302 and not by the surfactant. However, although surfactants in general decrease the rate of transfer, in some cases they are reported to enhance extraction rate due to the formation of mixed reversed micelles. The possibility of increased swelling due to secondary emulsification of the external phase into the emulsion at the higher values of surfactant concentration was also examined from the results in Figure 4. It was concluded that this is unlikely since this would lead to increased Cd extraction with surfactant concentration.

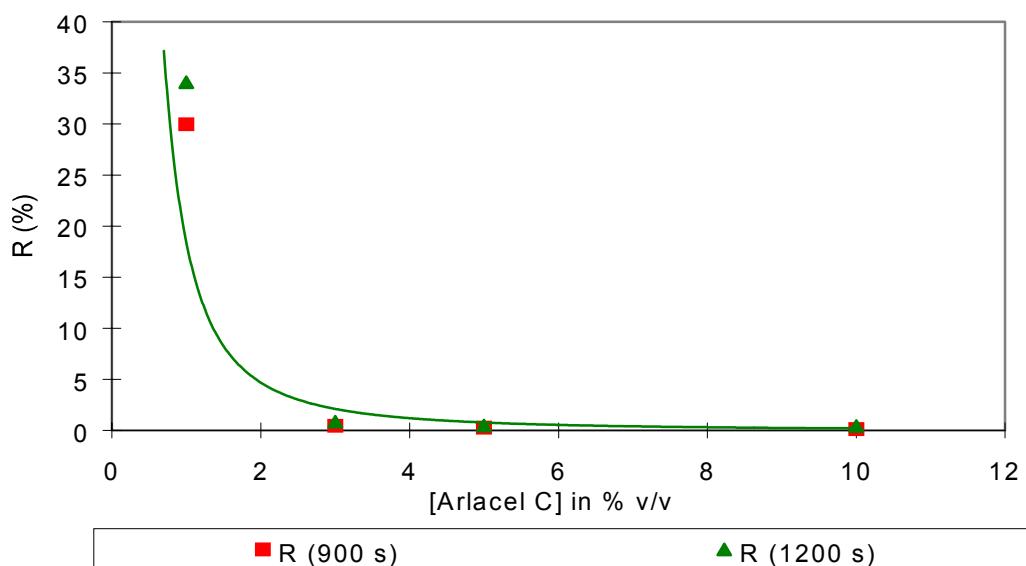

Figure 2. Effect of surfactant concentration on swelling and water content in the membrane after 1200s. Cyanex 302 concentration: 0.3 M.

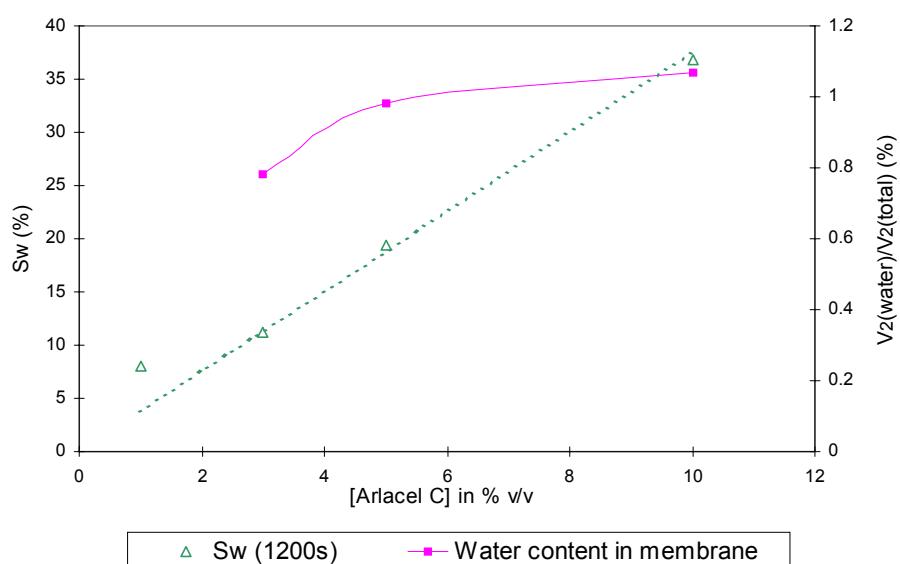

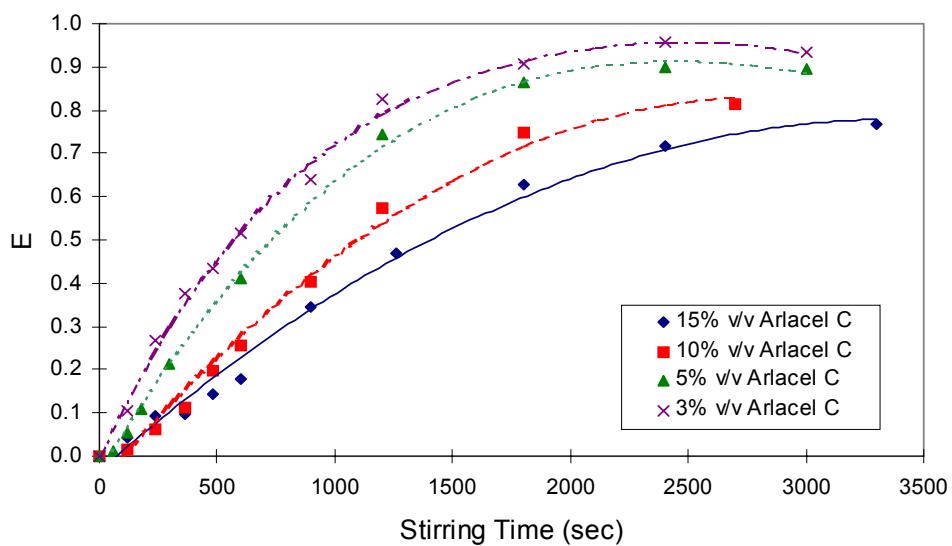

Figure 3. Effect of surfactant concentration on rupture.

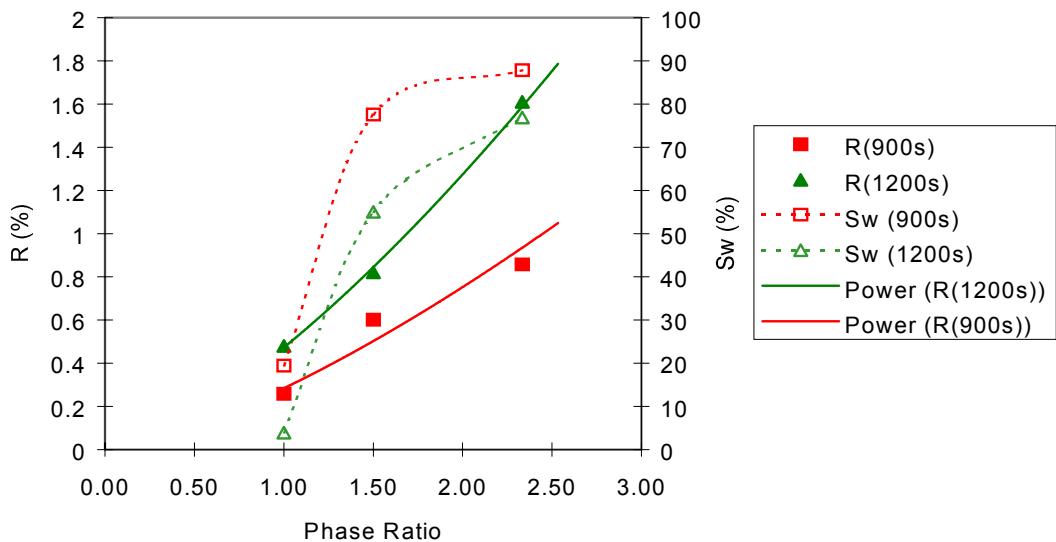

*Figure 4. Effect of surfactant concentration on Cd<sup>2+</sup> extraction, where E is the ratio of Cd extracted over the initial Cd concentration.*

#### **Effect of Emulsion Phase Ratio ( $V_2/V_3$ )**

As shown in Figure 5, changing the phase ratio between 1 and 2.33, which corresponds to an increase in the organic phase volume fraction, resulted in an increase in swelling from 24 to 87% and also an increase in rupture. This would confirm that the water transport mechanism across the membrane is carrier mediated since the amount of surfactant in the membrane increases with phase ratio. In this case the rate of Cd extraction also increased [10] due to the increase in the amount of reagent.

Phase ratio also increased membrane rupture from 0.5 to 1.6 %, probably due to the large increase in swelling leading to droplet coalescence.

*Figure 5. Effect of phase ratio on swelling and rupture.*

### Effect of Homogeniser Speed

Results obtained at a permeating time of 1200 s have been plotted in Figure 6. As can be seen, increasing the homogeniser speed from 2000 to 5000 rpm resulted in a substantial increase in swelling. The viscosity of the emulsion measured at a shear rate of  $9\text{ s}^{-1}$  increased by 100% from 0.15 Nm/s for an emulsion prepared at 2000 rpm to 0.30 Nm/s for one at 4000 rpm probably due to the decrease in droplet size with increasing homogeniser speed. This increased the emulsion globule sizes in the tank with the consequent decrease in total interfacial area between the emulsion and the external phase. This was reflected by a decrease in Cd extraction rate [10]. The increase in swelling is more difficult to explain as results show an increase in the rate of water transfer, thus suggesting that this is controlled by the extent of the interface between the stripping phase, i.e., by phenomena taking place at the internal interface and not by diffusional resistances in the membrane.

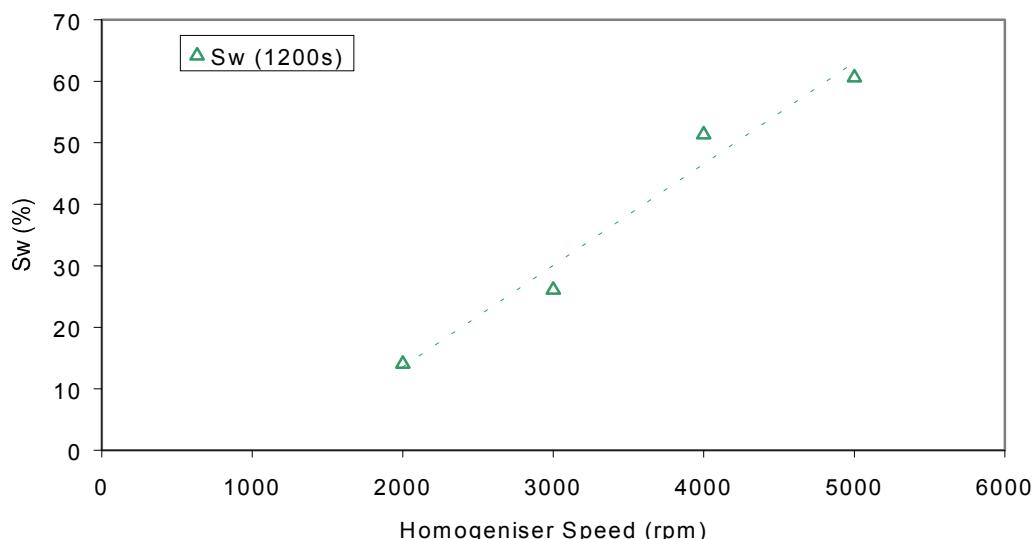

Figure 6. Effect of homogeniser speed on swelling at a stirring time of 1200 s.

### CONCLUSIONS

From the work presented above it has been observed that, for the conditions investigated, membrane rupture was considered unimportant for a surfactant concentration above 1% v/v. Similarly, it was determined that surfactant concentration was unlikely to increase Cd extraction through the membrane.

## TRANSFER PROPERTIES OF CADMIUM(II) AND ZINC(II) FROM HYDROCHLORIC ACID WITH HEH/EHP USING MICROPOROUS HOLLOW FIBER MEMBRANE

F. Luo, Q. Jia, D. Q. Li and Y. L. Wu

Laboratory of Rare Earth Chemistry and Physics, Changchun Institute of Applied Chemistry, Chinese Academy of Sciences, Changchun, China

In this work, 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester in kerosene is used to extract the transition elements Zn and Cd from hydrochloric acid solution in a hollow fiber membrane extractor. The effects of  $H^+$  concentration, extractant and metal ion concentrations and different ammoniation rates of extractant on the total mass transfer coefficients based on the water phase ( $K_w$ ), have been investigated. The results show that the mass transfer coefficient decreases with the increase of  $H^+$  concentration, but that the value of  $K_w$  for  $Cd^{2+}$  is smaller than that for  $Zn^{2+}$ . This means the mass transfer resistance of  $Cd^{2+}$  is larger than that for  $Zn^{2+}$ . When the value of  $K_w$  reaches  $1.0 \times 10^{-6} \text{ m.s}^{-1}$ , the difference of pH between Zn and Cd ( $\Delta pH^{Zn}_{Cd}$ ) is 1.49. The mass transfer coefficient increases slightly with the increase of extractant concentration and decreases with the increase of the ammoniation rate of extractant. It is possible to carry out the separation of  $Zn^{2+}$  and  $Cd^{2+}$  by properly controlling the acidity of the aqueous solution because of the existence of this kinetics competition.

### INTRODUCTION

With the development of chemical industry, removing and refining the valuable metals in dilute solutions or difficult separation systems has become an important aspect of research. With the higher demands on environmental protection, it is necessary to find clean and effective processes. The extraction technique using hollow fiber membrane is a new separation method that combines the processes of liquid-liquid extraction and membrane extraction. Extraction with hollow fiber modules (HFM) is fast because of a large surface area per unit volume. The extractant and feed can be contacted at high speed, even if their densities are identical. There are no problems with 'flooding' or 'loading', and no direct contact of water phase and organic phase. As a result, HFM may offer advantages over conventional extraction equipment [1]. In addition the method is an environmentally friendly process.

It is well known that cadmium and zinc coexist because cadmium ore is often found intergrown with zinc ore. Because of the toxicity of Cd it is important to separate Cd from Zn in solution. This paper examines liquid-liquid extraction in a hollow fiber membrane module. Typically, feed solution containing the solute of interest flows through the lumen of the fibers, and extractant flows outside the fibers, on the shell side. Solute diffuses out of the feed solution, through the fibers' porous wall, and into the extractant. 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester (HEH/EHP) is an effective extractant for separating rare earths, and has been widely used in hydrometallurgy. In this paper, an investigation into the use of HEH/EHP-kerosene to extract the transition elements Zn and Cd from hydrochloric acid solution in a hollow fiber membrane extractor is presented.

## EXPERIMENTAL

The HEH/EHP used was dissolved in sulfured kerosene, supplied by the Jiangxi Fengxin Chemical factory. A stock solution of  $Zn^{2+}$  and  $Cd^{2+}$  was prepared by dissolving  $ZnCl_2$  and  $CdCl_2 \cdot 2.5H_2O$  respectively. The pH values of the aqueous solutions were measured with pHs-3C model acidity meter (made in Shanghai). The concentrations of  $Zn^{2+}$  and  $Cd^{2+}$  were determined by EDTA titration. For solution flow, BT01-100 model Lange static flow pumps (made in Hebei) were used. Hollow fiber membrane, made of polyvinylidene fluoride and polytetrafluoroethylene was provided by the Changchun Institute of Applied Chemistry. The extractor was composed of a glass tube and two HFMs [2]. The characteristics of a hollow fiber and the membrane extractor are summarized in Table 1.

*Table 1. Specifications of a hollow fiber and the membrane extractor.*

Membrane polymer	polyvinylidene fluoride and polytetrafluoroethylene
Length of module (mm)	300
No. of fibers in a module	2
Inner diameter of module (mm)	8.00
Inner fiber diameter (mm)	0.70
Outer fiber diameter (mm)	1.20
Average pore size ( $\mu m$ )	0.06
Membrane wall porosity (%)	81
Flexibility of membrane	Good
Acid resistance of membrane	General

The aqueous solution was fed circularly into the lumen of the fiber at a flow rate of  $11.5 \text{ cm}^3 \cdot \text{min}^{-1}$ , while the organic solution was fed circularly into the annulus of the extractor in a counter-current mode at a flow rate of  $6.0 \text{ cm}^3 \cdot \text{min}^{-1}$  [3]. Since the fibers are hydrophobic, the pores of the membrane were filled with organic solution. The aqueous-phase pressure was maintained higher than the organic-phase pressure to prevent leakage of the organic phase from the pores into the aqueous phase. The aqueous solution was sampled at intervals until equilibrium was achieved. The mass transfer coefficient was calculated using the following:

$$\begin{aligned} & \left\{ \frac{1/Q_w - 1/(m \cdot Q_s) \exp\{-4K_w V_m / d\}[1/Q_w - 1/(m \cdot Q_s)]}{1/V_w + 1/(m \cdot V_s)} \right\} \ln \left[ \frac{\Delta C_A}{C_A^o} \right] \\ & = -t \left\{ 1 - \exp \left[ -\frac{4K_w V_m}{d} \left( \frac{1}{Q_w} - \frac{1}{m \cdot Q_s} \right) \right] \right\} \end{aligned} \quad (1)$$

where,

$$\ln \left[ \frac{\Delta C_A}{C_A^o} \right] = \ln \left\{ \frac{C_A \left[ 1 + \frac{V_w}{m V_s} \right] - C_A^o \frac{V_w}{m V_s} - C_A^{s,o} / m}{C_A^o - V_A / m} \right\} \quad (2)$$

$C_A^0$  and  $C_A^{s,o}$  denote the initial solute concentrations in the aqueous and organic phases respectively. In these experiments,  $C_A^{s,o}$  was equal to zero.  $Q_w$  and  $Q_s$  are the flows of the aqueous and organic phases.  $V_w$  and  $V_s$  are the volumes of the aqueous and organic phases, which were always 40 ml in these experiments.  $V_m$  is the fiber volume;  $d$  the fiber diameter and  $m$  the partition coefficient. In the Eq. (1) and (2),  $C_A$  is the parameter that varies with time and all the other parameters related to the device or its operation are kept constant in each experiment.  $K_w$  can be obtained by interpolation with the slope of the curve of  $\ln[\Delta C_A / C_A^o]$  vs.

time,  $\ln[\Delta C_A/\Delta C_A^0]$  being calculated according to Equation (2).

Experimental temperature was controlled at  $25\pm1^\circ\text{C}$ .

## RESULTS AND DISCUSSION

### Reaction Mechanism of Membrane Extraction

The mass transfer process of  $\text{Zn}^{2+}$  and  $\text{Cd}^{2+}$  in two phases was assumed as a false first-order reaction, so that the extraction reaction could be simplified to:

where (a) denotes species in the aqueous phase, (o) species in the organic phase and M stands for metal ion. Eq. (3) can be expressed as follows:

$$q_f = \frac{C_o - C_e}{C_o} \ln\left(\frac{C_o - C_e}{C_t - C_e}\right) \quad (4)$$

$$q_b = \frac{C_e}{C_o} \ln\left(\frac{C_o - C_e}{C_t - C_e}\right) \quad (5)$$

where,  $C_o$ ,  $C_t$  and  $C_e$  are the initial, t and equilibrium concentration of metal ion respectively. t is the reaction time,  $q_f$  and  $q_b$  are positive and inverse apparent rate constants, respectively. If the assumption of Equation 3 is correct, the plots of  $\ln[(C_0 - C_e)/(C_t - C_e)]$  vs. t should be straight lines. Plots shown in Figure 1 show linear relationships and therefore the membrane extraction can be assumed to obey the false first-order reaction mechanism proposed.

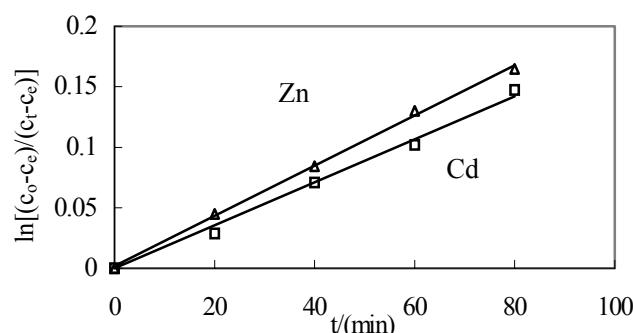

Figure 1. Plots showing the false first-order reaction for  $\text{Zn}^{2+}$  and  $\text{Cd}^{2+}$ .

### Effect of the Aqueous Phase Acidity on the Mass Transfer Coefficient

The acidity of the aqueous phase, being the main factor influencing the separation of metal ions, was investigated first. The results are shown in Figure 2. The results showed that  $K_w$  decreased with the increase of  $\text{H}^+$  concentration and those values of  $K_w$  for  $\text{Cd}^{2+}$  were smaller than for  $\text{Zn}^{2+}$ . Therefore the mass transfer resistance for  $\text{Cd}^{2+}$  was greater than for  $\text{Zn}^{2+}$ . When the value of  $K_w$  reached  $1.0 \times 10^{-6}$  m/s, the  $\Delta\text{pH}_{\text{Cd}}^{\text{Zn}}$  measured was 1.49. This provides a theoretical basis for the separation of  $\text{Zn}^{2+}$  and  $\text{Cd}^{2+}$ .

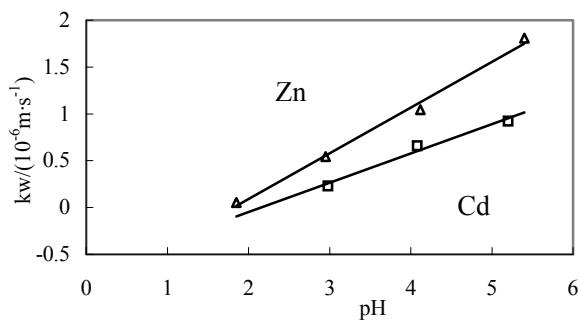

Figure 2. Effects of acidity of aqueous phase on the mass transfer coefficient.  
 $[Cd^{2+}] = 0.948 \times 10^{-3} \text{ mol L}^{-1}$ ;  $[Zn^{2+}] = 1.012 \times 10^{-3} \text{ mol L}^{-1}$ ;  $[HEH/EHP] = 0.1151 \text{ mol L}^{-1}$ .

### Controlling Step of Membrane Extraction

From previous experimental results [5,6], it was concluded that the rate of extraction is controlled by a chemical reaction in the lower region of pH and by diffusion in the higher region of pH. So the extraction mechanism of a hollow fiber membrane can be explained using a diffusion model accompanied by an interfacial reaction.

In the hydrophobic membrane, oil phase penetrates into the micropores of membrane and reaction takes place at the inside surface of a hollow fiber. In the hydrophilic membrane, aqueous phase penetrates into the membrane and reaction takes place at the outer surface [4].

$$\text{For hydrophobic membrane: } \frac{1}{K_w} = \frac{1}{k_w} + \frac{d_i}{mk_m d_{lm}} + \frac{d_o}{mk_o d_o} \quad (6)$$

where  $k_w$ ,  $k_m$  and  $k_o$  are mass transfer coefficients in aqueous film, membrane phase and oil film, respectively.  $d_i$ ,  $d_o$  and  $d_{lm}$  are the inner and outer diameter of a hollow fiber and their logarithmic mean, respectively.  $m$  is the distribution coefficient, which was obtained from the equilibrium study at each experimental condition of hollow fiber runs.

Because the hollow fibers used are hydrophobic membranes and their distribution coefficient  $m \approx 1$ , so the mass transfer resistance across the oil film could not be neglected in the analysis. The results are shown in Figure 3.

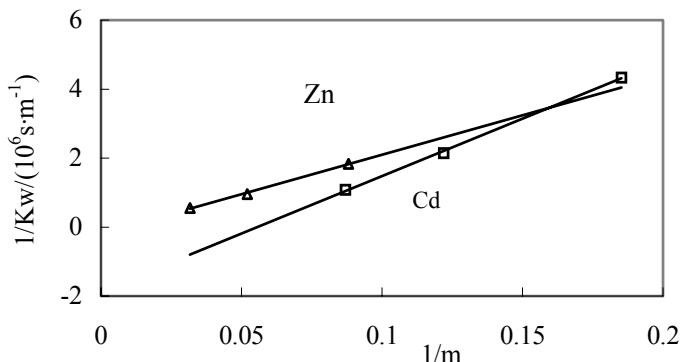

Figure 3. Plots of membrane resistance for  $Zn^{2+}$  and  $Cd^{2+}$ .

The first terms of Equation (6) for  $Zn^{2+}$  and  $Cd^{2+}$  ( $1/k_w$ ) are intercepts of the lines and because they were less than zero this indicates negligible mass transfer resistance of the aqueous film. The slopes of lines were  $(d_i/(k_m d_{lm}) + d_i/(k_o d_o))$  and were higher than that in the aqueous film. Because the slope for Cd was larger than that for Zn, the mass transfer resistance for  $Cd^{2+}$  was bigger than that for  $Zn^{2+}$ . It can therefore be concluded that the mass transfer rates for  $Zn^{2+}$  and  $Cd^{2+}$  are controlled simultaneously by the mass transfer resistance of the membrane and the organic phase.

### Effect of Extractant Concentration on the Mass Transfer Coefficient

The effect of extractant concentration on mass transfer coefficient is shown in Figure 4. The mass transfer coefficient was shown to increase with an increase in extractant concentration.

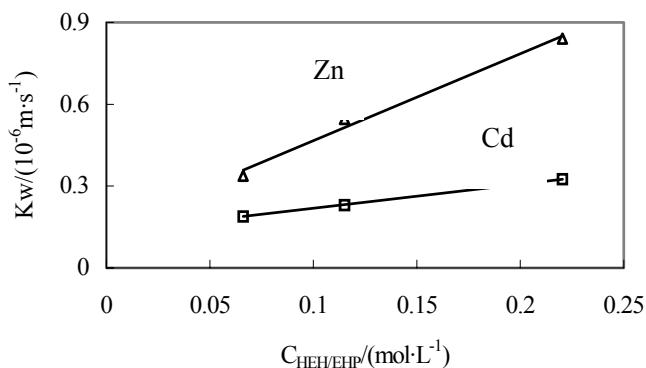

Figure 4. Effects of extractant concentration on the mass transfer coefficient.  
 $[Cd^{2+}] = 0.948 \times 10^{-3} mol \cdot L^{-1}$ ;  $[Zn^{2+}] = 1.012 \times 10^{-3} mol \cdot L^{-1}$ ;  $pH = 2.95$ .

### Effect of Ammoniation Rate of Extractant on the Mass Transfer Coefficient

Ammoniation rate of extraction was defined as follows:

$$AmmoniationRate = \frac{[NH_4^+]_0}{[HEH / EHP]_0} \quad (7)$$

Increasing the ammoniation rate of the extractant is expected to favor the extraction of rare earths [7]. From Figure 5 it was seen that the mass transfer coefficients in fact decreased with an increase in the ammoniation rate of the extractant. It is speculated that this may be because the mass transfer of  $NH_4^+$  was faster than that for the metal ion [7], and the ammonium compound formed in the aqueous phase, thus restrained the mass transfer of metal ions. These results show that it would be possible to separate  $Zn^{2+}$  and  $Cd^{2+}$  from rare earths by changing the ammoniation rate of the extractant.

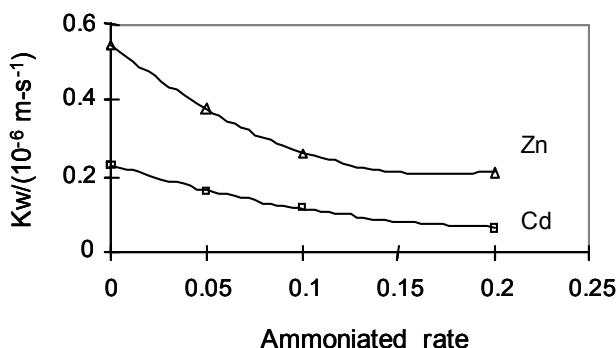

Figure 5. Effects of ammoniation rate of extractant on the mass transfer coefficient.  
 $[Cd^{2+}] = 0.948 \times 10^{-3} mol \cdot L^{-1}$ ;  $[Zn^{2+}] = 1.012 \times 10^{-3} mol \cdot L^{-1}$ ;  $[HEH/EHP] = 0.1151 mol \cdot L^{-1}$ ;  $pH=2.95$ .

## CONCLUSIONS

In this paper the extraction mechanism of metal ions in hollow fiber membrane extractor was explained as a false first order reaction. The mass transfer rates for Zn<sup>2+</sup> and Cd<sup>2+</sup> are controlled simultaneously by the resistance of aqueous phase and membrane and organic phase. The mass transfer coefficient decreased with the increasing of H<sup>+</sup> concentration and the ammoniation rate of the extractant and increased slightly with an increase in extractant concentration. When the value of kw arrived at 1.0×10<sup>-6</sup> m.s<sup>-1</sup>, ΔpH<sup>Zn</sup><sub>Cd</sub> was 1.49. It is possible to separate Zn<sup>2+</sup> and Cd<sup>2+</sup> by controlling the acidity of the aqueous solution properly because of the existence of the kinetics competition.

## ACKNOWLEDGEMENT

# A KINETIC STUDY OF THE EXTRACTION OF ZINC FROM HYDROCHLORIC ACID SOLUTIONS BY A SURFACTANT LIQUID MEMBRANE CONTAINING TRIOCTYLAMINE

S. Pérocheau, M. Stambouli, D. Pareau and G. Durand

Laboratoire de Chimie et Génie des Procédés  
Ecole Centrale Paris, Châtenay-Malabry Cedex, France

The surfactant liquid membrane extraction (SLM) is very promising for environmental uses but its application to industrial effluents is very reduced due to the complexity of the transfer phenomena. A more accurate comprehension of them will lead hopefully to an industrial development of this process.

The single drop method has been used to study the transfer of zinc from an hydrochloric solution into a W/O emulsion containing a tertiary amine. The main result is a surprising amount of extraction during the drop formation. Both extraction reactions (during the drop formation and during its rise in the column) have been carefully studied leading to the identification of the limiting steps. During the drop formation zinc transfer is controlled by an interfacial chemical reaction involving two extractant molecules; on the contrary during the drop rise, the extraction regime is mixed, suggesting a diffusion limitation in addition to the chemical reaction. These original results can be used to design new contactors for SLM extraction, better adapted than the classical solvent extraction devices commonly used.

## INTRODUCTION

SLM extraction is derived from solvent extraction. Due to the extremely high interfacial areas and the interesting volume ratios this process is a very promising separation technique for treatment of diluted polluted effluents as for pollutant concentration in order to valorise it [1,2]. SLM industrial development however needs a very accurate comprehension of the transfer phenomena occurring within the emulsion.

This kinetic study is based on the choice of a model chemical system and a specific experimental device. Zinc extraction in chloride solutions by trioctylamine (TOA) in xylene [3] has been studied. The single drop method, commonly used in solvent extraction [4], has been selected for this study because of many advantages: moderate agitation to prevent emulsion breakage, high specific interfacial area in contrast with a diffusion cell where the interfacial area is saturated with surfactant molecules preventing the solute transfer [5].

## EXPERIMENTAL

The aqueous solutions were prepared by dissolving zinc chloride (Acros, >98%) in the presence of hydrochloric acid (Labosi, 36%). TOA (Acros, 98%) was previously purified with activated carbon and diluted in xylene ( Aldrich). SPAN 80 ( sorbitan monooleate from Labosi) was chosen as a surfactant. Zinc analyses were performed by atomic absorption spectrometry ( Varian AA300) and by plasma emission (Jobin Yvon Y32). Emulsions were prepared with a mixer Ultra Turrax ( 6000 rpm). Size distribution was determined by a laser granulometer (Mastersizer X, Malvern). Droplet diameters vary between 1.6 and 2.6  $\mu\text{m}$ .

Solvent extraction studies were performed in thermostated reactors. The single drop experiments were realised in four thermostated columns with 30, 45, 95 and 135 cm heights. The injection device is a capillary at the bottom of the column; by varying the capillary diameter, droplets of various sizes are obtained. Droplets are collected at the top of the column, zinc is analysed in the internal phase of the emulsion after electrocoalescence.

## PRELIMINARY STUDY IN SOLVENT EXTRACTION

The extraction reactions of zinc by TOA in chloride solutions may be written as follows :

where TOAHCl stands for the amine salt.

The distribution ratio of zinc may be expressed by the following equation, taking into account the existence of more than one extracted complex:

$$D = \frac{[\text{Cl}^-]^2 \cdot \sum_n K_{\text{ex},n} [\overline{\text{TOAHCl}}]^n}{(1 + \sum_{i=1}^4 \beta_i [\text{Cl}^-]^i)} \quad (1)$$

$K_{\text{ex},n}$  is the equilibrium constant of formation of  $(\text{TOAHCl})_{n-2} (\text{TOAH})_2 \text{ZnCl}_4$ ;  $\beta_i$  is the formation constant of  $\text{ZnCl}_i^{(2-i)}$ .

By taking into account the dimerisation of TOAHCl [5] (dimerisation constant = 83) and by assuming the existence of a single extracted complex, the slope method allows to estimate  $n$ , by plotting  $\log D$  versus  $\log [\text{TOAHCl}]$ . The slope of the straight line obtained is  $n$ . The concentration of TOA has been varied between  $10^{-3}$  and  $10^{-1}$  mol/L with:  $[\text{Cl}^-] = 0.5$  mol/L ;  $[\text{Zn}] = 10^{-4}$  and  $5.10^{-4}$  mol/L. The results are illustrated in Figure 1.

The slope value suggests the existence of two different organic complexes with  $n = 2$  and 3. By exploiting the results with the two reactions, the extraction constants have been determined with a good accuracy:

$$K_{\text{ex},2} = (2.6 \pm 0.6) 10^5 \quad ; \quad K_{\text{ex},3} = (2.9 \pm 0.3) 10^7$$

The influence of SPAN 80 on the extraction of zinc has been investigated, because of its necessary use for the preparation of the emulsion. Equal volumes of aqueous phase ( $[\text{ZnCl}_2] = 10^{-3}$  mol/L ;  $[\text{HCl}] = 0.50$  mol/L) and organic one ( $[\text{TOAHCl}] = 10^{-2}$  mol/L ;  $[\text{SPAN}] : 0 - 3$  % ; xylene) have been contacted; more than 2% SPAN ( 0.028 mol/L) leads to a decrease in the extraction which is attributed to interactions between extractant and surfactant and formation of micelles. This phenomenon will not be observed in SLM because the surfactant molecules will be in majority adsorbed at the much greater interface and the extractant is continuously regenerated by rapid stripping [2].

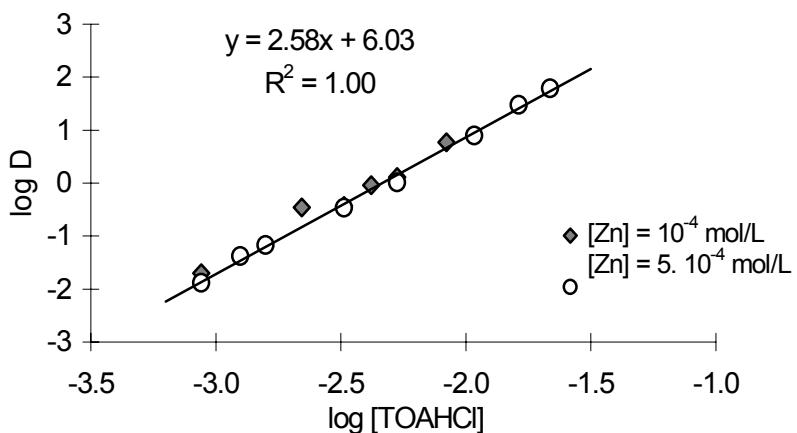

Figure 1. Determination of the extracted complexes stoichiometry.

The stripping phase is a strong acid:  $\text{HNO}_3$ ,  $\text{H}_2\text{SO}_4$ ,  $\text{HCl}$ , giving a rapid ( $< 2$  min) and quantitative stripping of zinc. In order to simplify the phenomena, it has been preferred to limit the number of chemical species and then to adopt  $\text{HCl}$  for stripping reagent.

The breakage rate of the emulsion has been measured by a tracer method; lithium has been added to the internal phase of the emulsion; its presence in the external phase after contact of it with the emulsion is only due to the emulsion breakage. An optimal concentration of SPAN of 3% has been adopted in order to minimize the breakage of the emulsion; by increasing the SPAN concentration above 3%, the extraction rate significantly decreases.

The optimal formulation of the emulsion for equal volumes of organic and aqueous phases is:

Internal phase :  $\text{HCl}$  (0.1 mol/L)

Organic membrane : TOA ( $2 \cdot 10^{-2}$  mol/L) ; SPAN 80 (3%) in xylene.

In these conditions the stability of the emulsion is satisfactory and the parasite phenomena of osmosis and inclusion are not observed within 15 minutes.

## KINETIC STUDY OF THE TRANSFER DURING THE DROP RISE

### Modeling

The following hypotheses have been adopted [3, 6] :

- The transfer resistance is limited in the external phase (phase 3): the transfer flux  $\Phi$  is expressed by  $\Phi = k_3 \cdot (C_3^0 - C_3^i)$ ,  $C_3^0$  and  $C_3^i$  being zinc concentrations in the external phase, in the bulk and at the interface respectively
- The transfer across the membrane is rapid and the stripping reaction is very rapid: there is no accumulation of zinc in the membrane (phase 2)
- The chemical extraction reaction takes place at the external interface with a rate expressed as follows:  

$$r = k_n \cdot [\text{Zn}^{2+}]_i \cdot [\text{Cl}^-]_i^m \cdot [\text{TOAHCl}]_i^n = k_{cn} \cdot C_3^i \cdot C_e^n$$
 $[\text{Cl}^-]_i$  is constant and has been introduced in  $k_{cn}$ ; TOA being in great excess,  $[\text{TOAHCl}]_i$  is constant too and noted  $C_e$ .

In pseudo stationary state, equality of the fluxes leads to:

$$C_3^i = \frac{k_3}{k_{cn} \cdot C_e^n + k_3} \cdot C_3^0 \quad (2)$$

The material balance is then:

$$d(V_1 C_1) = S_3 k_c C_3^i C_e^n dt \quad (3)$$

where  $S_3$  is the external interfacial area,  $V_1$  is the internal phase volume and  $C_1$  is the concentration in the internal phase (phase 1).

Integrating equation (3) gives:

$$C_1(t) = \left( \frac{S_3}{V_1} \cdot C_3^0 \cdot K \right) \cdot t + C_x \quad (4)$$

$C_x$  is the concentration of zinc in the internal phase after the drop formation and  $K$  is the global transfer conductance (diffusion + reaction):

$$\frac{1}{K} = \frac{1}{k_3} + \frac{1}{k_{cn} \cdot C_e^n} \quad (5)$$

Two limiting cases are considered:

- i.  $k_3 \ll k_{cn} \cdot C_e^n$  (diffusion regime):  $K \approx k_3$   $C_3^i \rightarrow 0$
- ii.  $k_3 \gg k_{cn} \cdot C_e^n$  (chemical regime):  $K \approx k_{cn} \cdot C_e^n$   $C_3^i \rightarrow C_3^0$

### Validation of the Model

The emulsion drop diameter is equal to  $(4.3 \pm 0.1)$  mm; their mean velocity is 7.0 cm/s. The results are gathered in Figure 2.

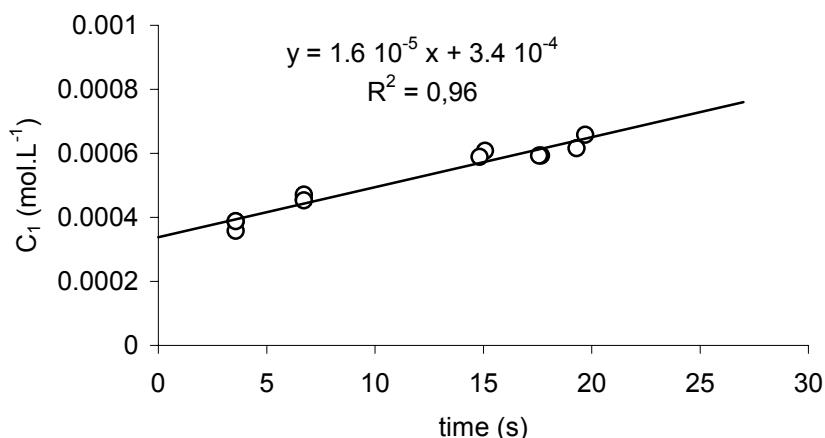

Figure 2. Experimental validation of the kinetic model.

The validity of the model is attested by the linearity of the curve (Figure 2). The slope of this straight line is proportional to  $K$  and the amount of the metal extracted during the drop formation is given by the origin ordinate. Here  $C_x$  is surprisingly high compared to  $SX$  common results. This phenomenon is quite original.

### Influence of Hydrodynamic Parameters

The chemical parameters being constant, the drop diameter has been varied from 2.5 to 5.1 mm. There is a slight effect on  $K$  suggesting a diffusion participation in the limiting step.

### Influence of chemical parameters

The TOA concentration has been varied from  $7.8$  to  $14.7 \cdot 10^{-3}$  mol/L; for example results for a diameter 2.6 mm are given in Figure 3.

These results show that the extraction reaction involves three TOA molecules; the kinetic constants have been estimated:

$$k_3 = 2.4 \cdot 10^{-4} \text{ (cm/s)} ; \quad k_{c3} = 3.0 \cdot 10^2 \text{ (cm/s)(mol/L)}^{-3}$$

In the concentration range explored these two constants are of the same order of magnitude: the regime is then mixed.

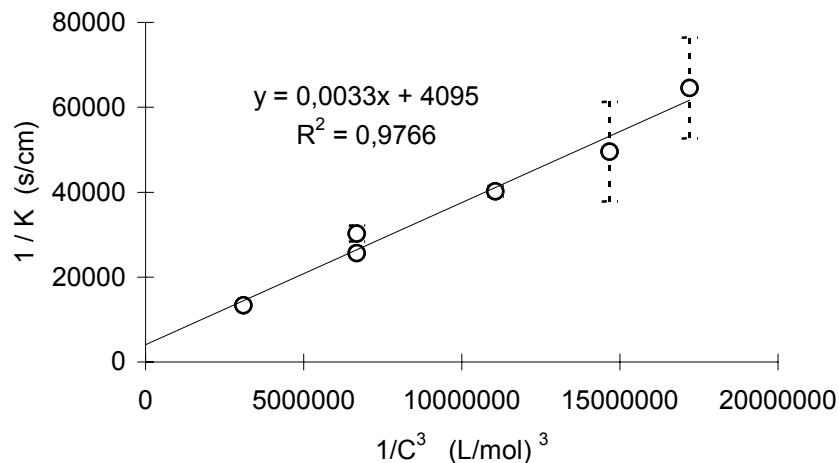

Figure 3. Influence of TOA concentration on  $K$ .

## KINETIC STUDY DURING THE DROP FORMATION

### Modeling

Considering the small formation times transfer is described by Higbie model. The growth of the emulsion drop is described by the model of progressive addition of fluid elements at the drop surface [8].

By integrating equation (3), identical equations are obtained for both limiting cases:

$$C_x = \alpha_1 \cdot K_{g1} \cdot C_3 \cdot t_f \cdot d^{-1} \quad \text{with } t_f \text{ formation time, } d \text{ final diameter.}$$

For the two different cases:

- i. diffusion regime :  $K_{g1} \approx k_3 \text{ moyen}$        $\alpha_1 = 8,9$
- ii. chemical regime :  $K_{g1} \approx k_{cn} \cdot C_e^n$        $\alpha_1 = 7,2$

### Nature of the Transfer Regime

It was not experimentally possible to vary significantly the drop diameter. So only the influence of TOA concentration may give information on the nature of the kinetic regime.

As can be seen in Figure 4, zinc transfer is controlled by a chemical reaction involving two TOAHCl molecules (slope 1.96). The kinetic constant  $k_{c2}$  is equal to  $180 \text{ (cm/s)(mol/L)}^{-2}$ .

### Interpretation

A quite original mechanism is proposed allowing to describe all the experimental results, insisting on the specific behaviour of the emulsion drop during its formation.

The limiting step of the whole process is the replacement at the interface of the adsorbed complex  $(TOAHCl)ZnCl_2$  by a molecule of free TOAHCl.

The rate is then written :

$$r = k_c^* \cdot [\text{TOAHC}]^2 \cdot [\text{TOAHC}]_{\text{ads}}$$

During the drop formation, the surfactant is located at the internal interface. The external interface is saturated by TOAHC so:  $[\text{TOAHC}]_{\text{ads}} = \text{constant}$ ; the second order with respect to TOA is explained. Progressively the surfactant migrates to the external interface replacing then TOAHC. Adsorbed TOAHC becomes minor and  $[\text{TOAHC}]_{\text{ads}} = \alpha_2 \cdot [\text{TOAHC}]$ ; the third order is then explained. A such mechanism is totally original.

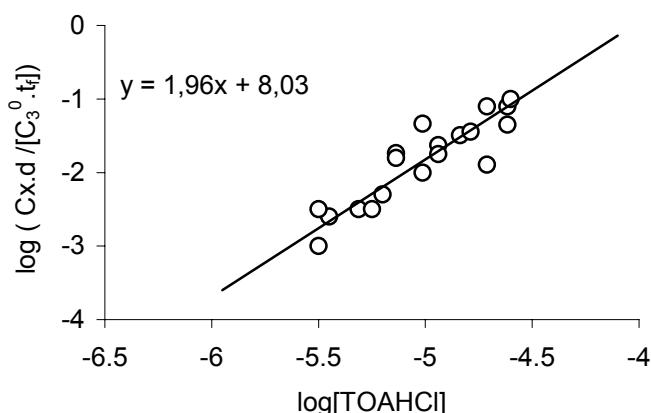

Figure 4. Influence of TOA concentration on the extraction during drop formation.

## CONCLUSION

The single drop method is suitable for the kinetic study of transfer for the extraction of zinc by SLM. A kinetic model has been proposed and discussed.

Whereas the side effects are in SX always negligible, they are here surprisingly high (during drop formation). An original mechanism has been established taking into account all the experimental results. It is based on a drastic change in the transfer process on both points of view (diffusion and reaction) between the drop formation and its rise in the column. These specific results will be exploited to conceive a new type of contactor, better adapted to SLM process, *i.e.*, favouring many steps of drop formation.

## **EXTRACTION AND SEPARATION OF NICKEL AND COBALT BY ELECTROSTATIC PSEUDO LIQUID MEMBRANE (ESPLIM)**

**P. S. Heckley, D. C. Ibana and C. McRae\***

Nickel Hydrometallurgy Group, WA School of Mines,

Curtin University of Technology, Kalgoorlie, Australia

\*School of Chemistry, Macquarie University, Sydney, Australia

The extraction and separation of nickel and cobalt using Electrostatic Pseudo Liquid Membrane (ESPLIM) was investigated. An ESPLIM reactor was constructed and extraction tests were undertaken to determine the effects of various experimental variables on the extraction and separation of nickel and cobalt. At optimum conditions, devised as a result of this investigation, a nickel/cobalt ratio of 1000 in the raffinate from a synthetic feed solution containing 10,000 ppm nickel and 1000 ppm cobalt was achieved. Separation of nickel and cobalt from a pregnant leach solution (PLS) was achieved in two stages.

### **INTRODUCTION**

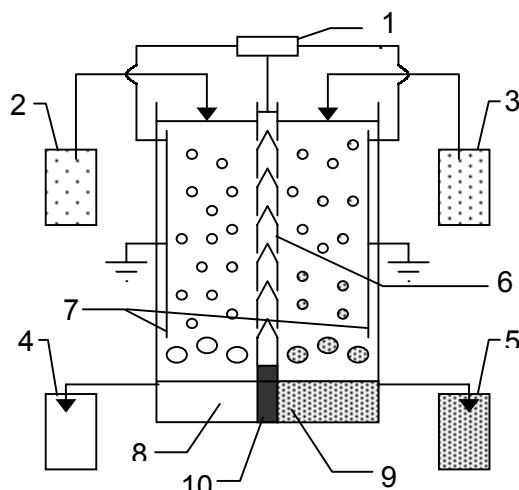

The extraction and separation of nickel and cobalt from pressure acid leach (PAL) solutions is currently a major research interest particularly in Western Australia where three new nickel laterite projects have recently commenced operation. These new generation nickel laterites projects have an initial combined output of approximately 63,000 t of nickel and 4000 t of cobalt. Although their process flowsheets have significant differences, all use PAL technology to dissolve the nickel and cobalt, and solvent extraction to separate and purify the nickel and cobalt.

Electrostatic pseudo liquid membrane is a novel separation technique, which combines the advantages of solvent extraction, liquid membrane and electrostatic dispersion. Like liquid membrane, extraction and stripping in ESPLIM occurs simultaneously and thus operate under non-equilibrium conditions. Agitation is by means of electrostatic dispersion, which provides a more efficient phase dispersion leading to higher mass transfer rates than mechanical agitation. Pioneered by Gu [1], the technique has since been applied in the extraction of, among others, nickel from rinse water [2], europium [3], and the separation of aluminium, lanthanum, samarium and yttrium [4] in bench scale studies.

This study is part of a project to develop the technique in separating and purifying nickel and cobalt from PAL generated leach solutions of nickel laterites by the direct solvent extraction route. This involves extracting Co together with the Mn, Cu, and Zn leaving a nickel SX feed (NSF) containing the Ni, as practised in Bulong Nickel Operation.

## DESCRIPTION OF THE ESPLIM REACTOR

The reactor used in the present study (Figure 1) is similar to the one developed by Gu [6] except for some modifications in the baffle and electrode design to improve extraction efficiency. The reactor consists of a rectangular tank separated into two compartments—extraction and stripping cells—by a perforated baffle plate. The baffle was constructed from a 6 mm wide plastic sheet with  $\Delta$ -shaped grooves cut into it and was sandwiched between two PTFE-coated stainless steel perforated plates (1 mm wide), which act as electrodes. Below the baffle plate is a blank plate separating the extraction and striping settlers. On the walls of the tank opposite the baffle are mounted steel plate electrodes insulated with a PTFE jacket. Except for the electrodes, the entire unit was constructed out of acrylic.

- (1) High voltage power supply (2) Feed solution (3) Strip solution (4) Raffinate  
(5) Concentrate solution (6) Baffle plate/electrode (7) Wall mounted electrode  
(8) Extraction settler (9) Stripping settler (10) Blank separation plate.

Figure 1. Schematic diagram of the ESPLIM cell.

The tank is filled with the extractant and the feed and stripping solutions are pumped onto the top of their respective cells. Under the influence of high voltage electrostatic charge these aqueous droplets break into fine droplets as they fall by gravity facilitating high mass transfer rates between the two phases.

The reaction in the extraction cell leads to a concentration gradient, which acts as the driving force for the diffusion of the extracted metal complexes towards the stripping cell. In the stripping cell, the reaction is reversed resulting in an increase in the concentration of the regenerated extractant, which drives its diffusion back into the extraction cell. Once out of the influence of the electrostatic field, aqueous droplets begin to coalesce and then fall into their respective settlers.

## MATERIALS AND METHODS

The reactor used in this study had an internal dimension of 50 mm W  $\times$  40 mm L  $\times$  140 mm H. The power supply, capable of supplying between 0.5 to 15.0 kV of AC, as well as the syringe pumps used were purpose built.

All extraction tests were carried out using Cyanex 272<sup>®</sup> (10%) dissolved in Solvent HF<sup>®</sup>. The Cyanex 272 was supplied by Cytec<sup>®</sup> and Solvent HF was supplied by Mobil Oil (Australia); both were used as supplied. Tributylphosphate (TBP) was added when a phase modifier was used. Sodium acetate (AR) was used as pH modifier. The strip solution was prepared from analytical grade sulfuric acid (1 M). The synthetic feed solutions were prepared using AR grade CoSO<sub>4</sub>.7H<sub>2</sub>O and NiSO<sub>4</sub>.6H<sub>2</sub>O. The actual leach solutions were taken from Bulong Nickel Operation.

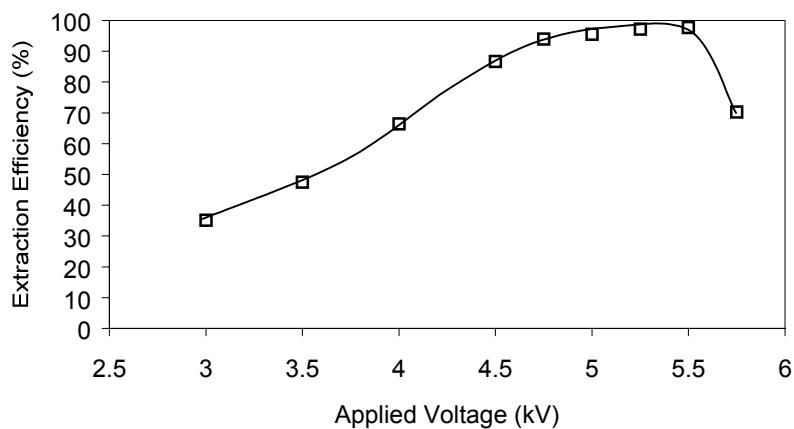

Each extraction test was started by filling the reactor with the extractant. The electrodes were connected to the power supply, the desired voltage was selected and the power was turned on. The feed and stripping solutions were pumped in and the timer was started. The raffinate and stripping solutions were initially allowed to accumulate until the respective settlers were filled and these levels were maintained by opening their respective valve to allow excess volume to flow to their respective reservoirs.

All metal assays were carried out by atomic absorption spectrophotometry (Varian SpectrAA 50).

## RESULTS AND DISCUSSION

### The Effect of Applied Voltage

The effect of applied voltage on extraction efficiency was investigated using synthetic cobalt feed (1000 ppm) solution and 1 M H<sub>2</sub>SO<sub>4</sub> strip solution. It was found that increases in the applied voltage from 3.0–5.5 kV resulted in increases in extraction efficiency from ~40 to 98% (Figure 2). This trend is consistent with the theory of electrostatically enhanced mass transfer. Accordingly, imposing an electrostatic field on an electrolyte droplet falling through a continuous non-conducting phase causes its deformation and increases its horizontal velocity component. At sufficiently high field intensity, the interfacial tension is overcome and the droplets disintegrate into smaller droplets resulting in an increase in surface area and thus mass transfer. This was confirmed by determining the effect of applied voltage on the droplet size (Figure 3).

*Figure 2. The effect of applied voltage on cobalt extraction.  
(Feed flow rate: 60 mL/h; Strip flow rate: 14 mL/h)*

In addition, the increases in the horizontal velocity component of the droplets associated with the increases in applied voltage resulted in increases in hold up. Similarly the associated increases in interfacial turbulence promoted internal mixing resulting in continuous replenishment of interface with the reacting metal ions. Clearly, both contributed to the observed increases in mass transfer.

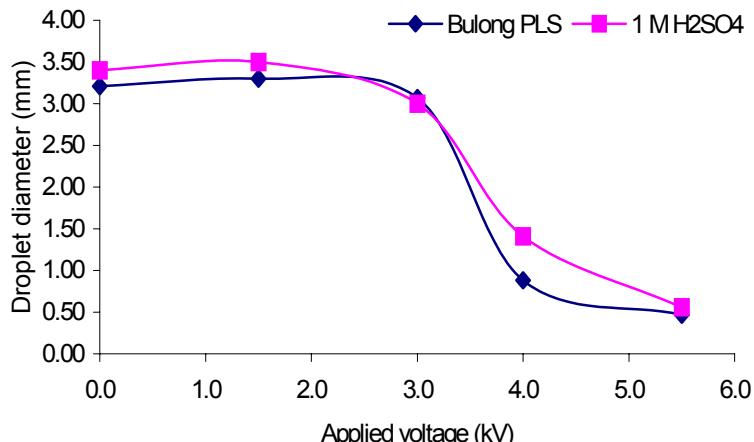

Figure 3. The effect of applied voltage on droplet size.  
(Feed flow rate: 60 mL/h; Strip flow rate: 14 mL/h).

The decrease in extraction associated with a further increase in applied voltage to 5.75 kV appeared to be due to leakage and swelling. That is, under this field strength, much smaller droplets were produced. Coupled with an increase in their horizontal velocity component, crossing over of these droplets, *i.e.*, strip droplets to extraction cell (leakage) or feed droplets to stripping cell (swelling) occurred leading to a decrease in extraction efficiency.

#### The Effect of pH

The effect equilibrium pH on the extraction of nickel and cobalt was investigated using separate solutions using 1000 ppm solutions of each metal. The feed flow rate was maintained at 64 mL/h while the strip flow rate was maintained at 12 mL/h. The results (Figure 4) were found to be comparable with the established isotherms of these metals, which were determined by conventional shake out tests. These results indicated that the chemical factors in the extraction process by means of ESPLIM are similar to those by conventional SX technique.

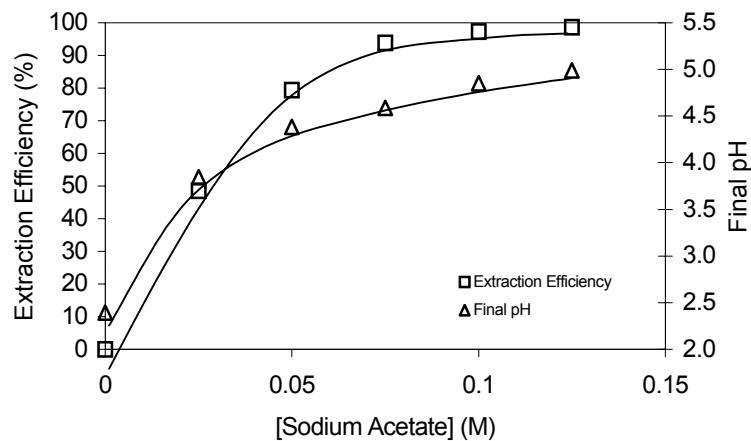

Figure 4. The effect of pH on the extraction of cobalt.

### The Effect of Feed and Strip Flow Rates

To determine the effect of the feed flow rate on the extraction of cobalt, several extraction tests were carried out under comparable conditions (feed solution containing 1000 ppm  $\text{Co}^{2+}$ , 13 mL/h, applied voltage of 5.5 kV) except that different feed flow rates were used (60-141 mL/h). The results (Figure 5) showed that, at constant strip flow rate (13 mL/h), substantial increases in the feed flow rate (60-141 mL/h) resulted in a slight decrease in extraction efficiency (<10%). This was accompanied by substantial increases in the concentration of the stripped cobalt. This indicated that as the rate of extraction increases, the rate of stripping also increases leaving only a small difference in the free extractant concentration. This is significant as it offers some flexibility in the practical application of the process. For instance, in a multi-stage extraction application, it is possible to use a much higher feed rate in the first stage to increase the throughput but a lower feed rate in the succeeding stage when the aim is high extractions and low raffinate values.

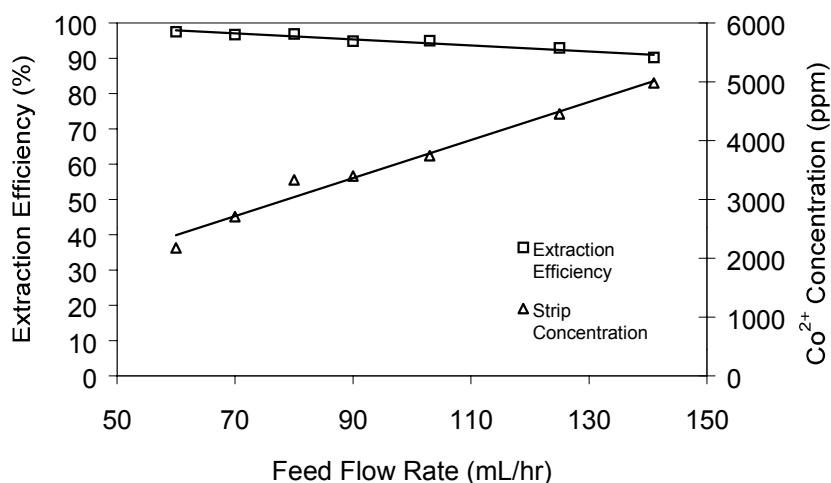

Figure 5. The effect of feed flow rate on cobalt extraction.

Consistently, increases in strip flow rates (13-26 mL/h) at constant feed flow rate (141 mL/h) resulted in slight increases in extraction efficiency (Figure 6). This indicated slightly faster stripping rates than extraction rates and thus higher free extractant concentration. The decrease in the strip concentration was due to dilution. In practical application, this can be upgraded by recirculation.

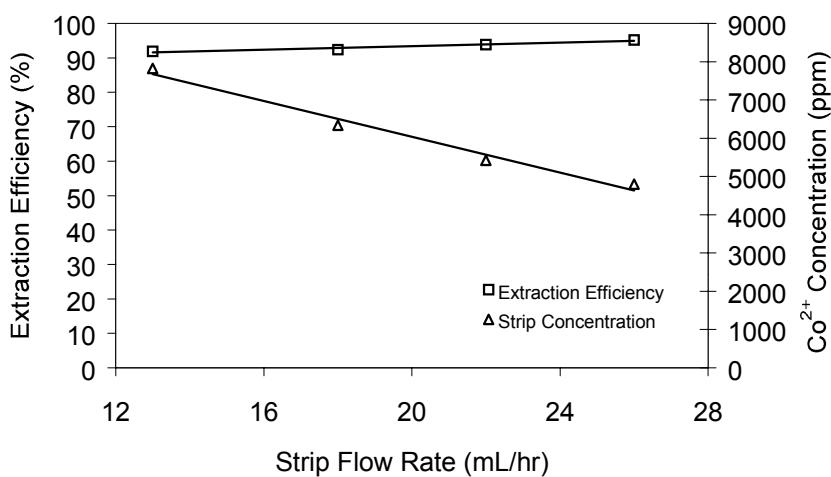

Figure 6. The effect of strip flow rate on cobalt extraction.

### **Separation of Cobalt from Nickel**

Separation of nickel and cobalt was attempted first by using a synthetic feed solution containing 10,000 ppm nickel and 1000 ppm cobalt. The experiment consisted of passing the feed through the ESPLIM reactor once, collecting the raffinate, adjusting the pH if necessary and then passing it through the ESPLIM again. The objective was to produce a nickel raffinate with a low cobalt content (*i.e.*, high Ni/Co ratio) to simulate the direct extraction of nickel and cobalt route as practised in Bulong Nickel Operation. The extraction tests were carried out under the following conditions as previous tests indicated that they provide optimum cobalt extraction: feed flow rate of 60 mL/h, strip flow rate of 14 mL/h, applied voltage of 5.5 kV and a slanted pH profile of ~4.9 to >5.

Typical results, summarised in Table 1, showed that a raffinate nickel/cobalt ratio of 1000 can be achieved in a 2-stage extraction. Consistent with established isotherm for cobalt, the pH of the raffinate after two stages should be over pH 5.0 to ensure satisfactory cobalt removal.

*Table 1. Separation of cobalt from nickel.*

Test number	Stage number	Feed pH	Feed Ni conc. (ppm)	Feed Co conc. (ppm)	Raffinate pH	Raffinate Ni/Co ratio
3a	1 <sup>st</sup> Stage	6.50	10610	977	4.85	49
3b	2 <sup>nd</sup> Stage	5.65	10588	203	5.03	1000

The application of the technique in the separation of nickel and cobalt from actual pregnant leach solutions (PLS) was attempted using PLS from Bulong Nickel Operation. Under comparable conditions to the above experiments, a 60 ppm cobalt raffinate was achieved after one stage. Second stage extraction resulted in cobalt raffinate values of 1 ppm or less in the nickel feed solution (NSF) clearly indicating a 2-stage extraction is sufficient. A comparable testwork, undertaken elsewhere, showed that a similar separation of Bulong PLS required 5 stages when using a conventional mixers-settlers.

### **CONCLUSIONS**

The separation of nickel and cobalt by Electrostatic Pseudo Liquid Membrane (ESPLIM) was attempted. It was found that the main variables that affect the extraction and separation are the applied voltage, feed and strip flow rates and pH. The optimum conditions devised as a result of this investigation were an applied voltage of 5.5 kV, feed flow rate of 60 mL/h, strip flow rate of 14 mL/h, pH of ~ 5.0. Under these conditions, cobalt raffinates with a nickel:cobalt ratio 1000 is achieved in a 2-stage extraction from a typical PLS solution used in the direct extraction route of nickel and cobalt.

### **ACKNOWLEDGEMENTS**

The authors thank Kalgoorlie Metallurgical Laboratories and MERIWA for the postgraduate scholarship of one of the authors (P. Heckley), Bulong Nickel Operation for supplying PLS and Cytec and Mobil Oil (Australia) for supplying Cyanex 272 and Solvent HF, respectively.

## MEMBRANE SELECTION IN MEMBRANE ASSISTED METAL EXTRACTION AND STRIPPING PROCESSES

Karin H. Soldenhoff and Jennifer K. McCulloch

Australian Nuclear Science & Technology Organisation, Sydney, Australia

This study investigates the transport of three, industrially relevant metal extraction systems, using a flat sheet bulk liquid membrane technique. The systems tested are:

- i) Cerium extraction with di-2-ethylhexyl phosphoric acid and stripping with sulfuric acid;
- ii) Neodymium extraction with 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester and stripping with hydrochloric acid; and
- iii) Copper extraction with a ketoxime/aldoxime reagent and stripping with sulfuric acid.

The metal ions, Cu, Ce and Nd, are transported from feed to receiver solution by a counter-current coupled transport mechanism. It has been shown that in all cases, for membranes of similar thickness and porosity, the transport of metal ion from feed to solvent is favoured by a hydrophobic membrane rather than a hydrophilic membrane at the feed interface. The highest fluxes are obtained for membrane combinations of hydrophobic at the feed interface and hydrophilic at the strip interface for the Ce and Nd systems. The membrane hydrophilicity at the receiver interface was found to have no significant effect on the overall flux for the Cu system.
