Liquid membranes have inherent advantages over solvent-extraction processes, such as lower solvent inventories and no mixing between two phases. The most commonly studied liquid membrane systems are the emulsion and supported liquid membranes. The third category, broadly termed as bulk liquid membrane, differs from the other two in that the membrane is not a thin film, but consists of a bulk phase. The bulk solvent phase can be sandwiched between two microporous membranes to form a contained liquid membrane, with pressure controls ensuring that the two interfaces remain at the membrane pore surface. The membranes can be flat sheets or hollow fibres. Hollow fibre membrane contactors are favoured for their very high surface area to module volume ratios. When both feed and receiver solutions are fed through a single hollow fibre module, the technique is known as hollow fibre contained liquid membrane [1]. Two separate membrane contactors can also be used for dispersion-free extraction and stripping, with the solvent circulating between the two modules. The greatest advantage of the bulk-liquid membrane technique is that, in principle, it solves the problem of solvent loss experienced by supported liquid membranes. However, the overall mass transfer rates are lower due to greater resistance caused by the addition of an extra membrane and the presence of the bulk solvent.

The bulk liquid membrane technique, where flat sheet microporous membranes are used as phase separators between three liquid phases is the subject of the present paper. This technique is used to investigate the effect of membrane hydrophilicity on the metal transport from feed to solvent and from solvent to receiver solutions. Most studies dealing with membrane assisted metal extraction processes have used hydrophobic membranes. In this work the effect of both hydrophobic and hydrophilic membranes are tested.

## EXPERIMENTAL

Extractants used were di-2-ethylhexyl phosphoric acid (DEHPA) and 2-ethylhexylphosphonic acid mono-2-ethylhexyl ester (EHEHPA), supplied by Albright & Wilson. LIX 984 was supplied by Henkel. Diluents used were Shellsol 2046 and Shellsol D70 (supplied by Shell), Escaid 300 (supplied by Exxon) and n-heptane. Solutions of Cu, Ce and Nd were prepared by dissolution of copper sulfate, cerium(IV) sulfate tetrahydrate and neodymium carbonate respectively.

The transport of Cu, Ce and Nd was measured using a three-compartment cell containing feed, solvent and receiver solutions. Flat sheet microporous membranes were used to separate the three bulk phases, which were stirred using magnetic stirrers at constant rpm. Metal concentrations in the feed and receiver solutions were monitored continuously with a UV-VIS spectrophotometer using wavelengths (795 nm) for Cu, (575 nm) for Nd and (795 nm) for Ce. Readings were taken at intervals ranging from 2 to 10 minutes. Millipore membranes used were GVHP, GVWP and VVLP with 0.2  $\mu\text{m}$  pore size and 125  $\mu\text{m}$  thickness. Care was taken to ensure that the pores of the GVHP hydrophobic membranes were filled with solvent phase, and the pores of the hydrophilic membranes, GVWP and VVLP, were filled with aqueous phase. The experiments were run for up to 113 hours. Mass balances, calculated from concentration measurements of final solutions by ICP, were between 93 and 104%.

Equilibrium distribution coefficients ( $m$ ) in two-phase liquid-liquid systems were measured by contacting the same volume of solvent and aqueous phase, and determining the ratios of the total metal concentrations in the solvent over the metal concentrations in the aqueous phase.

## RESULTS AND DISCUSSION

### Transport of Ce with DEHPA

The transport of Ce from a feed to a receiver solution via a bulk solvent phase was measured with a three-compartment batch permeation cell. The three phases, aqueous feed, solvent and aqueous receiver solutions were physically separated by two flat sheet microporous membranes. The solvent used was 0.2 M DEHPA in n-heptane. The feed consisted of a solution of 0.0014 M Ce in 0.55 M  $\text{H}_2\text{SO}_4$  and the receiver solution was 5.5 M  $\text{H}_2\text{SO}_4$ . These conditions were chosen to maximise extraction of Ce in the feed and stripping to the receiver solution, according to reaction (1).

where  $\overline{(\text{HR})_2}$  denotes the dimeric form of DEHPA in the solvent phase.

Concentration profiles in the three bulk phases during a permeation experiment are shown in Figure 1. In the initial stages of the experiment, the decrease in Ce concentration in the feed solution was accompanied by a corresponding increase in the solvent concentration. There was a lag time before the Ce was transferred from the solvent to the receiver solution. The receiver solution concentration then increased with time and after approximately 10 hours, Ce was being transported "uphill" against its concentration gradient, driven by the counter-current coupled transport of acid from receiver to feed solution. The overall initial flux  $J_{\text{Receiver}}$  and the flux of Ce transfer from feed to solvent  $J_{\text{Feed}}$  was determined from the slope of the linear part of the curves according to equations (2) and (3).

$$J_{\text{Receiver}} = \frac{V_R}{A_R} \frac{\partial [Ce]_R}{\partial t} \quad (2)$$

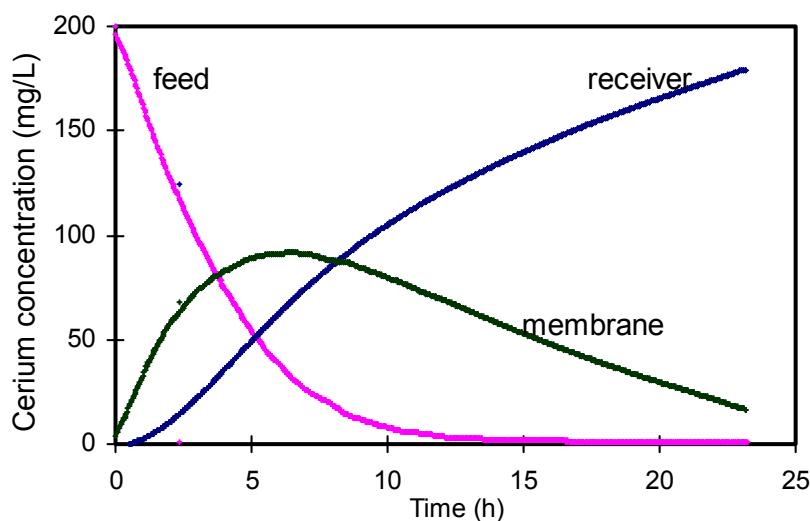

$$J_{\text{Feed}} = \frac{V_F}{A_F} \left| \frac{\partial [Ce]_F}{\partial t} \right| \quad (3)$$

where  $V_F$  and  $V_R$  are the volumes of feed and receiver solutions, respectively and  $A$  is the membrane area.

Both hydrophobic and hydrophilic membranes were tested on the feed/solvent and solvent/receiver interfaces and results are shown in Table 1. The Ce flux  $J_{\text{Feed}}$  measured from feed to solvent was 3.7 times faster for the hydrophobic GVHP membrane, compared to the hydrophilic VVLP membrane. Fluxes  $J_{\text{Receiver}}$  measured at the solvent/receiver interface, were 2.5 times faster with the VVLP hydrophilic membrane than with the GVHP hydrophobic membrane.

*Table 1. The effect of membrane type on Ce flux with DEHPA.*

Membrane interface feed/solvent		Flux ( $\text{mol m}^{-2} \text{s}^{-1}$ )	
	solvent/receiver	$J_{\text{Feed}}$	$J_{\text{Receiver}}$
hydrophobic – GVHP		$7.4 \times 10^{-6}$	
hydrophilic – VVLP		$2.0 \times 10^{-6}$	
hydrophobic – GVHP	hydrophobic – GVHP		$8.4 \times 10^{-7}$
hydrophobic – GVHP	hydrophilic – VVLP		$2.1 \times 10^{-6}$

*Figure 1. Ce concentration profiles in permeation experiment.*  
 $[\text{DEHPA}] = 0.2 \text{ M}$ , Feed:  $[\text{Ce}]_{\text{initial}} = 1.4 \text{ mM}$ ,  $0.55 \text{ M H}_2\text{SO}_4$ , Receiver:  $5.5 \text{ M H}_2\text{SO}_4$   
 Membranes: GVHP at feed interface, GVWP at receiver interface.

These results are explained by analogy to a membrane based solvent extraction system. Although these permeation experiments were undertaken with simultaneous stripping, the solvent volume was sufficiently large so that the initial stage of the permeation experiment, was essentially independent of the stripping reaction. Overall mass transfer coefficients for flat sheet, membrane based extraction are described by equations (4) and (5), for extraction with hydrophobic and hydrophilic membranes, respectively, assuming instantaneous chemical reaction at the interface [2].

$$\text{extraction with hydrophobic membrane} \quad \frac{1}{K_a} = \frac{1}{mk_o} + \frac{1}{mk_{mo}} + \frac{1}{k_a} \quad (4)$$

$$\text{extraction with hydrophilic membrane} \quad \frac{1}{K_a} = \frac{1}{mk_o} + \frac{1}{k_{ma}} + \frac{1}{k_a} \quad (5)$$

where  $m$  is the distribution coefficient,  $k_a$  and  $k_o$  are the mass transfer coefficients for the aqueous and organic diffusion layers and  $k_{mo}$  and  $k_{ma}$  are the mass transfer coefficients for hydrophobic and hydrophilic membrane diffusion, respectively.  $K_a$  is the overall mass transfer coefficient based on the aqueous phase.

The difference between equations (4) and (5) lies in the middle term. Under extraction conditions, where  $m \gg 1$ , the terms containing  $m$  in the denominator are relatively small. The term  $1/k_{ma}$  for hydrophilic membrane extraction then tends to be greater than the term  $1/mk_{mo}$  for hydrophobic membrane extraction, provided the membranes being compared have similar properties in terms of membrane thickness ( $\delta_m$ ), porosity ( $\varepsilon$ ) and tortuosity ( $\tau$ ). Under such conditions, the overall resistance to mass transfer is greater with hydrophilic membranes than with hydrophobic membranes. Since the resistance due to chemical reaction at the feed/solvent interface is independent of membrane type, it follows that similar conclusions can be drawn for mass transfer with chemical reaction, provided the resistance to mass transfer due to diffusion processes is greater than that provided by chemical reaction.

The mass transfer from solvent to receiver solution is similarly interpreted by analogy to membrane based stripping as per equations (6) and (7), where  $K_o$  is the overall mass transfer coefficient based on solvent. Again the difference between these two equations lies in the middle term. For effective stripping  $m$  must be  $\ll 1$  and therefore the terms containing  $m$  in the nominator are relatively small, (i.e., the term  $1/k_{mo}$  for hydrophobic membrane stripping is likely to be greater than the term  $m/k_{ma}$  for hydrophilic membrane stripping). The overall mass transfer resistance for stripping is therefore likely to be higher for hydrophobic membranes.

$$\text{stripping with hydrophobic membrane} \quad \frac{1}{K_o} = \frac{1}{k_o} + \frac{1}{k_{mo}} + \frac{m}{k_a} \quad (6)$$

$$\text{stripping with hydrophilic membrane} \quad \frac{1}{K_o} = \frac{1}{k_o} + \frac{m}{k_{ma}} + \frac{m}{k_a} \quad (7)$$

In the case of tetravalent Ce transfer from 0.55M H<sub>2</sub>SO<sub>4</sub> to a solvent phase containing 0.2 M DEHPA, the distribution coefficient for extraction ( $m$ ) was equal to 6.1. The values for the membrane mass transfer coefficients were calculated from equation (8), using theoretically calculated diffusivity values ( $D$ ) for Ce in sulfuric acid solution and Ce-DEHPA complex in n-heptane [3]. These calculations support the above discussion and expectation that under comparable extraction conditions, the hydrophobic GVHP membrane flux is greater than that of the hydrophilic VVLP membrane, as was observed experimentally. Similarly for stripping with a 5.5 M H<sub>2</sub>SO<sub>4</sub>, where the distribution coefficient was  $< 0.005$ , the use of hydrophilic

VVLP membrane at the receiver interface resulted in a faster overall flux than when the hydrophobic GVHP membrane was used, as shown in Table 1.

$$\text{membrane mass transfer coefficient} \quad k_m = \frac{D\varepsilon}{\delta_m \tau} \quad (8)$$

### Transport of Nd with EHEHPA

The transport of Nd was also studied in the three-compartment permeation cell. The feed solution contained 0.013 M Nd chloride at pH 1.6. The solvent used was a 0.6 EHEHPA in Shellsol D70. The receiver solution contained 1.5 M HCl. EHEHPA is an acidic extractant commonly used for the separation of rare earths. Nd is extracted from acidic solutions according to reaction (9). The measured equilibrium distribution coefficient for this system was  $m = 7.6$  for extraction, and  $m = 0.004$  for stripping.

where  $HL$  represents EHEHPA.

The effect of membrane type at the feed and receiver interface is shown in Table 2. The highest flux was obtained with a combination of hydrophobic GVHP membrane at the feed interface and hydrophilic GVWP membrane at the strip interface. The Nd flux measured from feed to solvent was 1.4 times faster for the hydrophobic GVHP membrane, compared to the hydrophilic GVWP membrane. Fluxes measured at the receiver solution were 2.8 times faster with the GVWP hydrophilic membrane than with the GVHP hydrophobic membrane. These trends are similar to those observed for the Ce system and similar arguments as those presented above apply.

*Table 2. The effect of membrane type on Nd flux with EHEHPA.*

Membrane interface		Flux ( $\text{mol m}^{-2} \text{s}^{-1}$ )	
feed/solvent	solvent/receiver	$J_{Feed}$	$J_{Receiver}$
hydrophobic – GVHP	hydrophilic – GVWP	$1.5 \times 10^{-5}$	$9.2 \times 10^{-6}$
hydrophobic – GVHP	hydrophobic – GVHP		$3.3 \times 10^{-6}$
hydrophilic – GVWP	hydrophilic – GVWP	$1.1 \times 10^{-5}$	$6.7 \times 10^{-6}$

### Transport of Cu with LIX 984

The third system tested was copper transport using LIX 984, a reagent widely used in commercial copper solvent extraction circuits. The feed solution contained 0.03 M Cu sulphate at an initial pH of 2.5. The solvent used was a 10 vol.% solution of LIX 984 in either Escaid 300 or Shellsol 2046. The receiver solution contained 2 M  $\text{H}_2\text{SO}_4$ . LIX 984 is an oxime based chelating extractant consisting of a mixture of 5-nonylacetophenoneoxime and 5-dodecylsalicylaldomixe. Cu is extracted from acidic sulfate solutions according to reaction (9). The equilibrium distribution coefficient for extraction for this system was diluent dependent with measured values  $m = 7.6$  (Escaid 300) and  $m = 71$  (Shellsol 2046).

where  $HR$  represents the ketoxime or aldoxime.

The effect of membrane type at the feed and receiver interfaces is shown in Table 3. The membrane hydrophilicity had a dramatic effect on the copper flux measured from feed to solvent. The measured  $J_{Feed}$  using Escaid 300 diluent was 14 times faster for the hydrophobic GVHP membrane, compared to the hydrophilic GVWP membrane. In contrast, the membrane hydrophilicity at the receiver interface did not have a significant impact, with measured  $J_{Receiver}$  differing by only 10% for hydrophilic and hydrophobic membranes at the receiver interface, as shown in Table 3 (test carried out using Shellsol 2046 diluent).

The fluxes measured from feed to solvent ranged between  $1\text{--}3 \times 10^{-5}$  mol m $^{-2}$  s $^{-1}$ , values which are of the same order of magnitude as fluxes measured for similar Cu systems using supported liquid membranes [4]. In the supported liquid membrane system the main resistance is reported to be due to diffusion of the extracted Cu complex through the hydrophobic membrane support. It would seem therefore that the chemical extraction reaction rate is not an important parameter in Cu transport from feed to solvent, with a hydrophobic membrane. However, the overall flux for Cu measured in the three-compartment cell was very low compared to the Cu flux measured from feed to solvent and compared to the overall flux measured at the receiver solutions for the Nd and Ce systems discussed above. The low  $J_{Receiver}$  measured for both hydrophobic and hydrophilic membranes at the receiver interface suggest that membrane resistance is not important and that the stripping reaction kinetics may play a significant role in the transport of Cu in a flat sheet contained liquid membrane system.

*Table 3. The effect of membrane type on Cu flux with LIX.*

Diluent	Membrane interface		Flux (mol m $^{-2}$ s $^{-1}$ )	
	feed/solvent	solvent/receiver	$J_{Feed}$	$J_{Receiver}$
Escaid 300	hydrophobic – GVHP	hydrophilic – GVWP	$1.2 \times 10^{-5}$	$7.1 \times 10^{-7}$
	hydrophilic – GVWP	hydrophilic – GVWP	$8.6 \times 10^{-7}$	$1.3 \times 10^{-7}$
Shellsol 2046	hydrophobic – GVHP	hydrophilic – GVWP	$2.9 \times 10^{-5}$	$7.0 \times 10^{-7}$
	hydrophobic – GVHP	hydrophobic – GVHP		$7.7 \times 10^{-7}$

## CONCLUSIONS

The flat sheet bulk liquid membrane technique was found to be particularly useful in studying the effect of membrane hydrophilicity on the Cu, Ce and Nd fluxes from feed to solvent and from solvent to receiver solution. It has been shown that in all cases the transport of metal ion from feed to solvent is favoured by the presence of a hydrophobic membrane rather than a hydrophilic membrane at the feed interface. The highest fluxes were obtained for membrane combinations of hydrophobic at the feed interface and hydrophilic at the strip interface for the Ce/DEHPA/H<sub>2</sub>SO<sub>4</sub> and Nd/EHEHPA/HCl systems. The membrane hydrophilicity at the receiver interface was found to have no significant effect on the overall flux for the Cu/LIX/H<sub>2</sub>SO<sub>4</sub> system.

## AXIAL DISPERSION CHARACTERISTICS IN HOLLOW FIBER MODULES FOR MEMBRANE EXTRACTIONS

Wang Yujun, Luo Guangsheng, Wang Yan and Dai Youyuan

Department of Chemical Engineering, Tsinghua University, Beijing, P.R. China

In hollow fiber modules, non-ideal flow caused by channeling and dead zones can greatly influence the mass transfer characteristics. The flow characteristics in hollow fiber modules have been studied by measuring shell-side and tube-side residence time distribution curves. The axial diffusion model is applied to describe the non-ideal flow. It is found that the actual flow conforms to neither the ideal plug flow nor the complete mixed flow models. The residence time distribution curves calculated using the axial diffusion model agree well with those measured. The studies show that the axial diffusion model can be applied to describe the mass transfer characteristics in hollow fiber modules. In addition, a study of the sulfanilic acid/triethylamine system, shows that mass transfer performance is significantly decreased due to axial dispersion effects.

### INTRODUCTION

A hollow fiber module (HFM) is one of the typical membrane contactors in membrane extraction, in which hundreds or even thousands of hollow fibers are usually packed in random. Chen *et al.* [1] showed by theoretical calculation that the random packing had a great effect on the uneven flow in the shell. Their experimental results indicated that 50% of the fluid flowed through only 20% of the total cross-area. Park *et al.* [2] have shown that a significant degree of non-uniformity occurs in the flow distribution in the lumen side of a HFM by a finite-difference numerical calculation method and by tracer experiments. The non-uniformity of velocity reduced the efficiency of mass transfer in the hollow fiber modules. The complicated calculation methods in the work mentioned above, has prompted the search for a simple mathematical model to describe the effects of the non-uniformity of velocity on mass transfer performance.

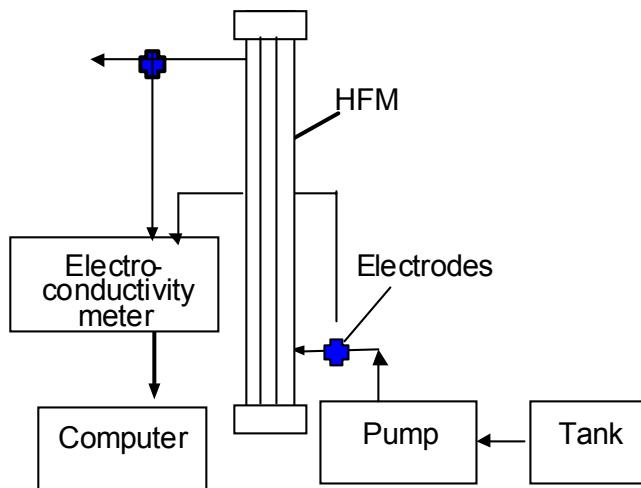

In the work discussed in this paper, tracer tests were used to examine flow characteristics and an actual membrane extraction process was used to study the influence of non-ideal flow on mass transfer characteristics.

### EXPERIMENTAL PROCEDURE

#### Determination of Flow Status

Figure 1 shows a schematic of the experimental setup used for the determination of residence time distribution (RTD) curves. A step-trace method using saturated KCl solution as tracer was applied to examine the flow status in the hollow fiber modules. For the determination of shell-side flow the tracer solution was pumped through the shell side of the module and the tube side was filled with solvent. For the determination of tube-side flow the tracer solution was pumped through the tube side and the shell side was filled with solvent. The concentration at the module inlet and outlet was monitored on-line with electro-conductivity meters.

The polypropylene hollow fiber modules used in this work were manufactured by Seawater Desalting Center of National Ocean Agency in Tianjin, China. The characteristics of these modules are shown in Table 1.

*Figure 1. Schematic of experimental setup for RTD curve determination.*

*Table 1. Characteristics of hollow fiber modules.*

No.	Module length (cm)	Module diameter (cm)	Fiber number	Fiber inner diameter $d_i$ (mm)	Membrane wall thickness (mm)	Porosity of fiber $\varepsilon$
A	33.5	3.32	3400	0.40	0.04	0.55
B	33.5	3.32	2500	0.40	0.04	0.55

#### Membrane Extraction Procedure

The actual membrane extraction system used was 20% triethylamine + 30% octanol + 50% kerosene / sulfanilic acid / water.

When extraction was carried out in a module, the aqueous phase flowed through the tube side, and the organic phase flowed counter-currently in the shell side. To avoid the breakthrough of the solvent, the pressure of the aqueous phase was 10 kPa higher than that of the organic phase. Samples at the module inlet and outlet under steady state were collected and the concentration was determined. The concentration of the sulfanilic acid was determined using a HP8452 UV spectrophotometer at 215 nm. The loaded solvent was regenerated with 10%(w/w) sodium hydroxide solution.

#### Calculation of Axial Diffusion Coefficient Pe without Mass Transfer

According to the mass conversation principle, the axial diffusion equation can be written as equation (1).

$$\frac{\partial C}{\partial \theta} = \left( \frac{E_2}{uL} \right) \frac{\partial^2 C}{\partial Z^2} - \frac{\partial C}{\partial Z} = \frac{1}{Pe} \frac{\partial^2 C}{\partial Z^2} - \frac{\partial C}{\partial Z} \quad (1)$$

where

$$C = \frac{c}{c_0}, \theta = \frac{t}{\tau}, Z = \frac{z}{L} \quad (2)$$

Pe being the only unknown parameter was determined using the stimulus-response curves.

### Calculation of True Mass Transfer Coefficients by Axial Diffusion Model

According to the axial diffusion model, equation (3) is the differential equation group for the two phases [3].

$$\begin{aligned} \frac{d^2 X}{dZ^2} - Pe_x \frac{dX}{dZ} - N_x Pe_x (X - X^*) &= 0 \\ \frac{d^2 Y}{dZ^2} + Pe_y \frac{dY}{dZ} + N_y \cdot \frac{u_y}{u_x} Pe_x (X - X^*) &= 0 \end{aligned} \quad (3)$$

The boundary conditions are:

$$\begin{aligned} Z = 0 &\quad Z = 1 \\ -\frac{dC_x}{dZ} &= Pe_x B (1 - C_{x0}) \quad -\frac{dC_x}{dZ} = 0 \\ -\frac{dC_y}{dZ} &= 0 \quad -\frac{dC_y}{dZ} = Pe_y (C_{y1} - C_y) \end{aligned} \quad (4)$$

The finite-difference method was used to solve the above equation group. When  $Pe_x$ ,  $Pe_y$ ,  $C_{x0}$ ,  $C_{x1}$ ,  $C_{y0}$  and the distribution coefficient  $m$  are known, the true mass transfer unit can be obtained. The parameters  $m$ ,  $C_{x0}$ ,  $C_{x1}$  and  $C_{y0}$  were determined by experiments and  $Pe_x$  and  $Pe_y$  were obtained from the resident time distribution curve. According to our previous work, the average distribution coefficient for the experimental system was 21.1 [4].

### Calculation of Apparent Mass Transfer Coefficients

The apparent mass transfer coefficients are the overall mass transfer coefficients obtained under the condition of plug flow. These can be obtained from the following correlation.

$$K_{aq} = \frac{Q_{aq}}{A} \frac{1}{1 - \frac{Q_{aq}}{mQ_o}} \ln \frac{c_{x0} - c_{x0}^*}{c_{x1} - c_{x1}^*} \quad (5)$$

The inlet and outlet concentration of aqueous phase was measured, and the distribution coefficient  $m$ , was 21.1.

## RESULTS AND DISCUSSION

### Typical Tube and Shell-Side RTD Curves

The RTD curves given in Figure 2, showed that the actual flow status in the tube side conformed to neither an ideal plug flow nor a complete mixed flow model. In fact back mixing and forward mixing resulted from drag associated with the inner wall of the fibers. The randomly packed and twisted fibers resulted in resistance gradients through the fiber bundles. The distribution of velocity on the tube side was therefore non-uniform. The RTD curves given in Figure 3 showed more complicated flow characteristics for the shell side than for the tube side. Compared to the case for ideal plug flow, "dead zones" and channelled flow were observed. The locations of the inlet and outlet of the module means that fluid has to flow across the fiber bundles to be evenly distributed at the cross section. As a result of the larger resistance across than along the fibers, the fluid tended to flow along the fibers thereby causing an uneven cross sectional velocity profile. In addition the non-uniform packing of the modules means that the fibers are not all straight and parallel. This arrangement, by causing channel variations along the length of the fiber bundle resulted in cross flow. The fluid tended to favor passage through the channels with large equivalent diameters. The uneven flow observed was clearly a result of the random packing of fiber bundles.

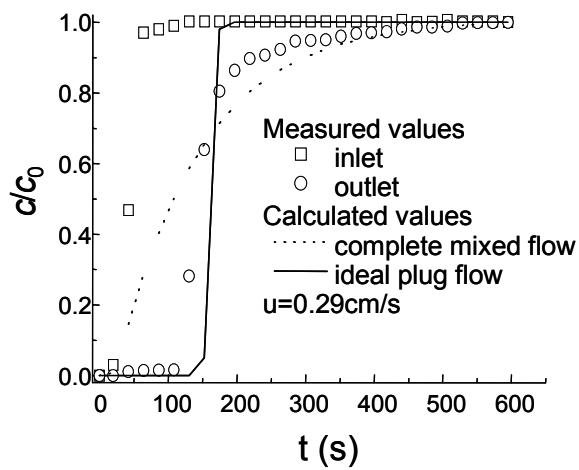

Figure 2. The RTD curves of tube side in Module B

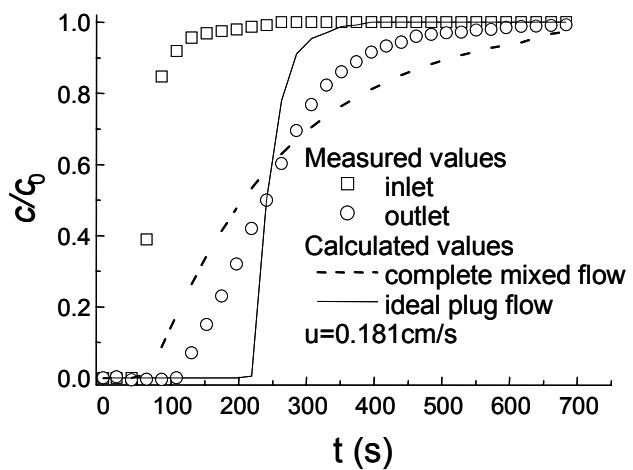

Figure 3. The RTD curves of shell side in Module A.

### Comparison of Calculated and Experimental Curves

Figure 4 showed that there was good agreement between the experimentally determined curves and those calculated using the diffusion model. The axial diffusion model in which all the non-ideal factors contribute to axial dispersion has been widely applied for the design of reactors and extraction columns. These results show that this model can be used to describe the flow characteristics in hollow fiber modules.

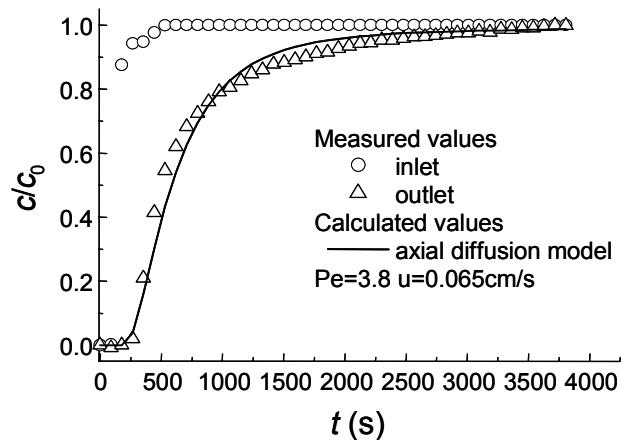

Figure 4. Comparison of experimental and calculated RTD curves of shell side in Module B.

### Influence of Velocity on Axial Dispersion

Figure 5 shows that velocity significantly affects axial dispersion. On the shell side, the resistance to flow of the fluid across the fibers increased with increasing velocity. For paths far from the inlet, lower velocities caused severe bypassing, resulting in an increase in axial dispersion. On the tube side, the influence of the drag associated with the fiber inner wall was reduced as the velocity increased. At the same time the increase in the radial mixing in each fiber, giving a more even flow distribution, resulted in a decrease in axial dispersion.

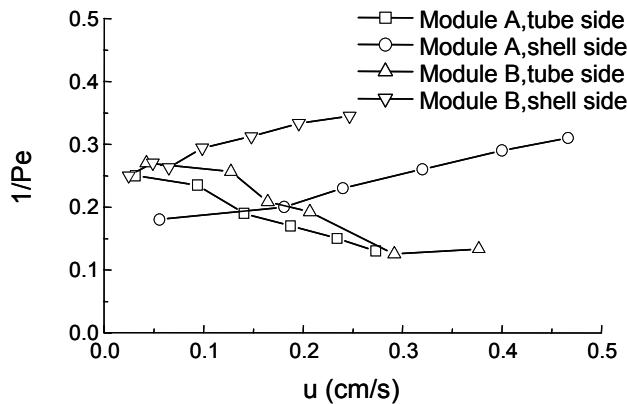

Figure 5. Influence of velocity on axial dispersion.

#### Comparison of the True and the Apparent Mass Transfer Coefficient

Figure 6 shows that the true mass transfer coefficient obtained by solving the axial diffusion equation was larger than the apparent coefficient. This indicated that the mass transfer performance was inhibited by axial back mixing. This is borne out by examination of an actual concentration profile in a hollow fiber module, given in Figure 7. The observed concentration jump at the module inlet and outlet would reduce the concentration driving force and thus reduce mass transfer performance.

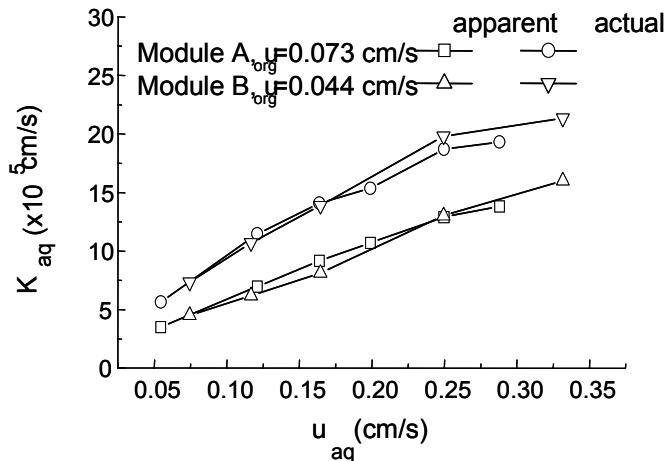

Figure 6. Comparison of the apparent and the actual mass transfer coefficients.

#### CONCLUSIONS

The flow characteristics in hollow fiber modules were studied using resident time distribution curves. They showed that the actual flow was non-ideal and conformed to neither the ideal plug flow nor the complete mixed flow models. Axial dispersion was found to decrease with an increase in flow velocity on the tube side and to increase with an increase in flow velocity on the shell side. Good agreement between the curves calculated using an axial diffusion model and experimentally determined RTD curves showed that the diffusion model can be used to describe the mass transfer characteristics in hollow fiber modules.

In a study using an actual extraction process, it was found that axial dispersion was the cause of the significant decrease in mass transfer performance.

## **SWELLING AND STABILITY OF EMULSIONS IN LIQUID MEMBRANE EXTRACTION**

**Marina Yu. Koroleva and Eugene V. Yurtov**

Mendeleev University of Chemical Technology, Moscow, Russia

Water diffusion during liquid membrane extraction often leads to emulsion swelling. The main causes of this unfavorable phenomenon are the differences of water activities in the internal and external phases. The investigation of the mechanisms of this process showed that nanodispersion droplets were carriers of water in the liquid membrane. Photomicrographs of swelling emulsions indicated the presence of nanodispersion droplets. Diffusion coefficients of nanodispersion water droplets were to a marked degree lower than that of water molecules. The velocity of water diffusion depends greatly on the gradient of electrolyte concentration and to a lower extent on the surfactant concentration in the liquid membrane.

### **INTRODUCTION**

Transmembrane water transfer in multiple emulsion leading to the emulsion swelling is a negative phenomenon, which takes place during the liquid membrane extraction. As known, such process takes place in a great extent in emulsion with Span 80 [1, 2]. The cause of this phenomenon is the difference in water activities between the internal and external water phases.

The water activity in the drop of internal phase depends on the forces that act on this drop or the pressure caused by these forces. The total pressure in the internal water phase of emulsion consists of the osmotic pressure of the brine and the Laplace pressure in the opposite direction. Laplace pressure is proportional to the interfacial tension and inversely proportional to the mean drop radius. The gravity force, water drops deformation, etc. are very small contributors to the total pressure and need not be considered in the model calculation for the liquid membrane extraction.

The scheme of varieties of water transfer in the three-phase system are shown in Figure 1. In the first case the electrolyte concentration ( $C$ ) in the internal water droplets is much higher than in the external water phase. This situation is typical for the extraction of inorganic or organic substances from dilute solutions and concentrating them in the internal water phase. Such conditions are the most negative from the point of view of emulsion swelling.

In the second case (Figure 1) electrolyte concentrations are high and equal in both water phases, so water diffusion is negligible. Such systems are seldom used for extraction.

They can be applied for recovery of substances, which adsorb on the interface in emulsion. For example, for the extraction of cholesterol from biological fluids [3] the isotonic buffer solution is used as the basic component of the internal phase in order to balance of pressures between blood and water drops in emulsion.

The two last variants are not typical for liquid membrane extraction. If the concentrations of electrolytes are very low in the external and in the internal water phases, water diffusion is extensive. As the Laplace pressure is inversely proportional to the drop radius, water diffuses from small drops to large ones. At the same time water diffusion takes place from large drops out of the emulsion to the external water phase.

If the electrolyte concentration in water drops is less than in the external phase, water diffuses out of emulsion. In the last two cases water fraction in the emulsion diminishes.

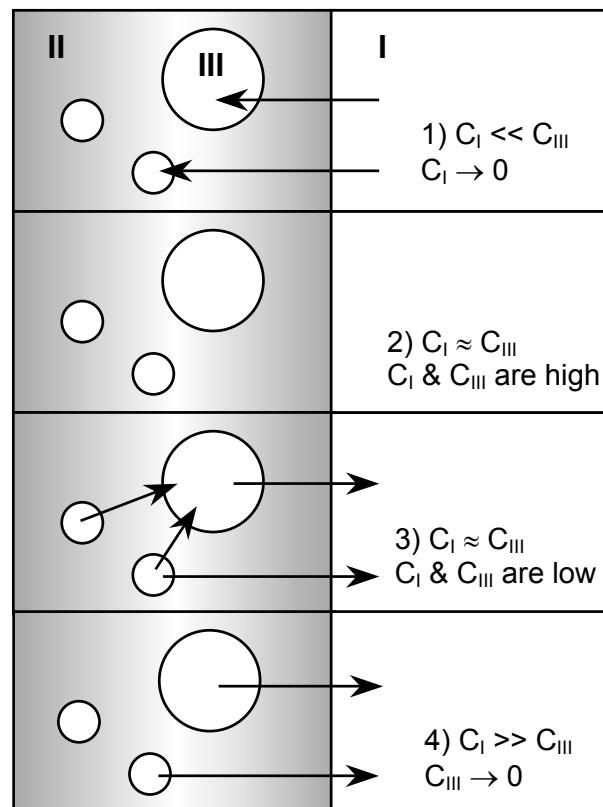

Figure 1. The directions of water diffusion at different electrolyte concentration in water phase. I, & III - external and internal water phases, II - organic liquid membrane.

### MECHANISM OF WATER TRANSFER IN THE LIQUID MEMBRANE

Water diffusion in the organic liquid membrane can be carried out by surfactant and extractant or carrier molecules. In addition to molecular mechanism, dispersed particles, such as micelles, microemulsions, and nanodispersions, can solubilize water and promote water transfer in the emulsion. These dispersed structures can be formed by surfactant and extractant. All types of water transportation take places in multiple emulsions, but their contributions are different.

Several articles were published in this field, and the related points of view can be divided into two groups: water can be transported by either microemulsion or nanodispersion [3, 4], and water can be transported by single surfactant and extractant-carrier molecules [2, 5].

The formation of microemulsion or nanodispersion droplets is promoted by the disequilibrium between the phases of the extracting emulsion, *i.e.*, by the mass transfer of the components and the solvents through the interface. Diffusion coefficients of microemulsion are much lower than those of the monomers or individual surfactant molecules [6]. To clear up the mechanism of this phenomenon we investigated transmembrane transfer of different substances in multiple emulsion.

Rhodamine C is a substance which dissolves well in water, does not dissolve in the mineral oil in the liquid membrane, does not interact with single surfactant molecules, but can be solubilized in micelles and water droplets of nanodispersion. So such dye can only be transported through the liquid membrane by surfactant micelles or nanodispersion, or as a result of coalescence of internal phase droplets leading to water phase separation.

Emulsion W/O was prepared from 3.4 M NaCl solution, mineral oil, and surfactant - sorbitanmonooleate. This emulsion was placed on a flat surface with area of  $6.5 \times 10^{-3} \text{ m}^2$ , and contacted with distilled water. Rhodamine C was added in the internal or in the external water phase.

Diffusion coefficient of water was calculated using the data from the kinetic curves of internal water phase fraction in emulsion. The diffusion coefficients of rhodamine C were obtained from the kinetic curves of rhodamine C concentration in the external water phase by means of the equation of non-stationary diffusion.

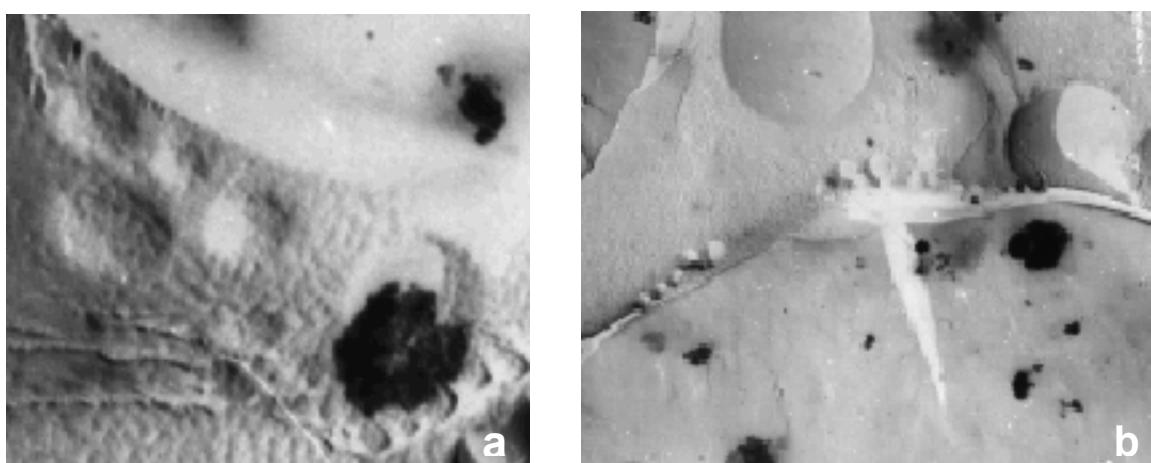

For the comparison of experimental diffusion coefficients of water and rhodamine C molecular diffusion coefficients were calculated of by Willke-Chang equation. The results are in Table 1.

*Table 1. Diffusion coefficients of water and rhodamine C.*

D experimental, $\text{m}^2/\text{s}$		D calculated, $\text{m}^2/\text{s}$	
Water	Rhodamine C	Water	Rhodamine C
$0.3 \times 10^{-14}$	$(1.4-5.6) \times 10^{-14}$	$5.4 \times 10^{-11}$	$0.7 \times 10^{-11}$

Calculated diffusion coefficients are approximately 1000 times higher than the experimental values. This fact points out that these substances are preferably transported in the form of nanodispersion.

To confirm the formation of nanodispersion droplets during water diffusion we obtained photomicrographs of emulsions. Pt/C replicas of emulsion were prepared by the freeze-etching method. Figure 2a illustrates the emulsion with nanodispersion in organic phase. The space around drops is so rough and rippled that the interface is blurred. Some droplets ( $d = 17 \sim 25 \text{ nm}$ ) are arranged near the interface of the large water drop (Figure 2b).

*Figure 2. Photomicrographs of emulsions with nanodispersion in organic phase:  
a) magnification - 80 000; b - 120 000.*

The formation of nanodispersion is confirmed by the photomicrographs and by the diffusion coefficient calculations. The main form of water diffusion in the liquid membrane is by nanodispersion droplets or solubilized micelles. Water can be also transported by molecules of surfactant or extractant-carrier, but the first mechanism is more significant.

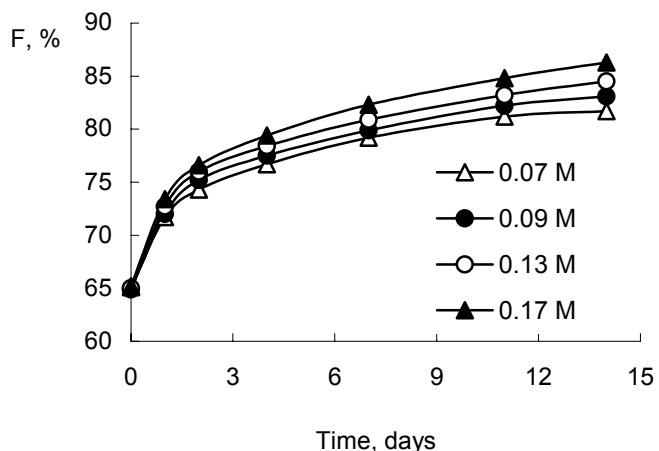

Figure 3. Kinetic curves for water transfer at different sorbitanmonooleate concentrations in emulsions.

#### INFLUENCE OF SURFACTANT ON EMULSION SWELLING

The presence of surfactant is necessary for nanodispersion droplet formation. Emulsions with sorbitanmonooleate swell in a great extent, so we investigated the kinetics of swelling in this system. Emulsion with the initial NaCl concentration of 3.4 M and different surfactant concentrations were contacted with distilled water as described above.

Figure 3 shows the kinetic curves of the alteration of  $F$ , the internal water phase fraction, in emulsions with different initial sorbitanmonooleate concentration. Water transfer continued for approximately 20-25 days, and the internal water phase concentration reached 87-92 %. Kinetics of emulsion swelling depends on surfactant concentration, but not significantly.

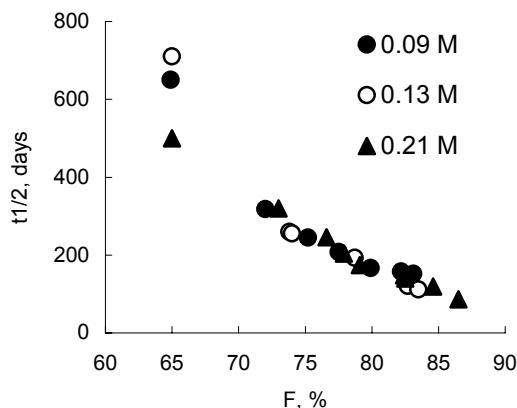

Figure 4. Half-separation of period of the water phase vs. internal phase fraction at different initial surfactant concentrations.

As published [7], raising the surfactant concentration increases the emulsion stability against coalescence. When the surfactant is present in an amount sufficient for the stabilization of all internal phase droplets formed as a result of the dispersing, a maximum stability of the emulsion is reached (0.13 M sorbitanmonooleate). With a greater concentration of the surfactant, the excess of the latter can dissolve in liquid membrane with the formation of different types of micelle structures.

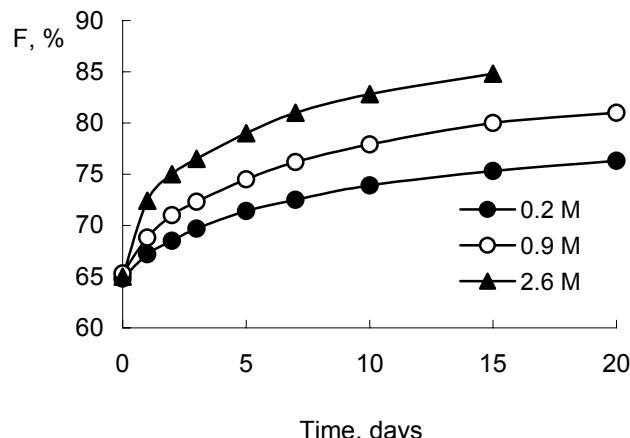

So at low surfactant concentrations (up to 0.13 M) the velocity of water diffusion increased by 20% due to the increase of interfacial area, due to the gain of surfactant micelles in the liquid membrane. Surfactant amount in emulsion does not affect the velocity emulsion swelling strongly. The considerable difference in osmotic pressure between internal and external water phases leads to the formation of great water flux. In such conditions certain amount of surfactant molecules leaves the interface in emulsion for the outward emulsion surface and takes part in nanodispersion formation.

Emulsion stability against coalescence decreases sharply because of the increasing of interface area and the insertion of surfactant partly in nanodispersion (Figure 4). The half-separation periods ( $t_{1/2}$ ) of water phase in emulsions with high internal phase fractions turn almost equal in spite of the difference in surfactant concentration.

### INFLUENCE OF ELECTROLYTE ON EMULSION SWELLING

For increasing of capacity emulsions contain the concentrated solution of complexing agent or precipitant in the internal water phase. In the case of the high difference in osmotic pressure between water phases the velocity of emulsion swelling is considerable.

We investigated this process on the model emulsion with a NaCl solution in the internal phase. Sorbitanmonooleate concentration was 0.13 M. Emulsions were contacted with distilled water. The kinetic curves of emulsions swelling are showed in the Figure 5.

*Figure 5. Kinetic curves for water transfer at different initial NaCl concentrations in the internal phase of the emulsions.*

Half-separation periods of water phase in these emulsions only differ before mass transfer. The more stable emulsions against coalescence corresponds to the higher NaCl concentration in the internal phase. Swelling of emulsions results in diminishing of half-separation periods (Figure 6). These relationships are analogous to the curves in Figure 4.

The velocity of extraction is usually greater than the velocity of emulsion swelling. Often the efficiency of extraction diminishes at approaching to quasi-equilibrium in the multiple emulsion. This connected with the dilution of the solution in water drops because of emulsion swelling. Mathematical optimization of the mass transfer process makes it possible to achieve best results in concentrating or separating of substances in the internal water phase.

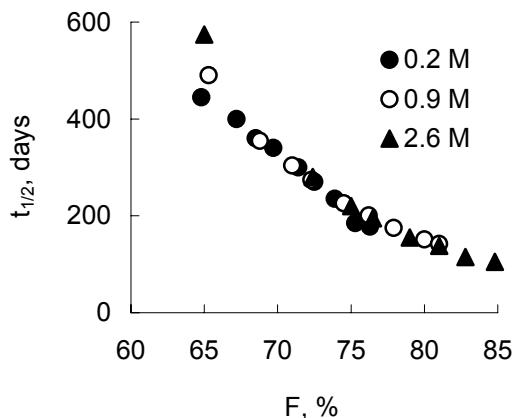

Figure 6. Half-separation of period of the water phase vs. internal phase fraction at different initial NaCl concentrations.

## CONCLUSIONS

Photomicrographs and diffusion coefficient calculation showed that the main form of water diffusion in the liquid membrane is by nanodispersion droplets or solubilized micelles. Water can be transported by surfactant or extractant-carrier in molecular form, but the first way is preferable.

Water diffusion through the liquid membrane leads to the emulsion swelling. Emulsion stability against coalescence decreases dramatically at high internal phase fractions and cannot be improved by the increasing of surfactant concentration. Mathematical modeling of the kinetics of extraction and emulsion swelling allows forecasting the optimum time of extraction process.

## COMMERCIAL-SCALE RECOVERY OF HEXAVALENT CHROMIUM FOR RECYCLE WATER BY ANION LIQUID-LIQUID EXTRACTION (A-LLX)

Bruce Monzyk, H. Nicholas Conkle, J. Kevin Rose and Satya P. Chauhan

Battelle, Columbus, OH, USA

Commercial-scale liquid-liquid extraction recovery of hexavalent chromium from surface finishing process water has been successfully demonstrated. Cr(VI) levels in the raffinate were low enough for discharge to surface waters. Less than three years' payback is expected and depends on feed chromium concentration, flow rate, and chromium concentrate recycle value. Landfill disposal is avoided. Chromium recycle enables continued use of high performance chromium especially in aerospace applications. Testing has been performed at two sites. About 1,135,200 liters of feed were processed at site 1. Hexavalent chromium removal using three extraction stages was consistently 99% or greater with residuals  $\leq 0.1$  mg/l. Entrained organics were 30-120 mg/l. Solids and stable emulsion formation were controlled using pH.

### INTRODUCTION

Hexavalent chromate [Cr(VI)] is widely used within the military and industry to meet critical high corrosion control and other metal surface finishing [SURFIN] requirements. Cr(VI) is toxic and its control generates hazardous, costly waste. Alternatives for the most demanding applications have not been found. Cr(VI) recovery technology is needed to enable continued chromium use in these critical SURFIN processes.

The current process to control Cr discharge produces large amounts of metal hydroxide sludge. Disposal of this type of hazardous waste at US military maintenance facilities [1,2], can cost over \$440/ton, and poses a continuing environmental liability. Anion liquid-liquid exchange [A-LLX] offers a way to avoid disposal by providing Cr(VI) recycle.

In previous Battelle studies, A-LLX removal technology [3-5] was shown to consistently reduce Cr(VI) levels to below 0.05 mg/l, and that further reductions were possible. A-LLX would allow the SURFIN industry to meet future, more stringent discharge requirements via "continuous improvement" techniques.

Battelle was asked [6] to: (a) construct a portable, commercial-scale A-LLX process and demonstrate it at Warner-Robins Air Logistics Center, GA, (WR-ALC) maintenance depot and the Watervliet Army Arsenal (WAA) and to (b) develop detailed cost and performance results. This paper provides the first test results using the WAA feed material.

## PROCESS DESCRIPTION

Alamine 336<sup>®</sup> is a selective extractant for Cr(VI), even over sulfate ion. Ion pairing is the primary extraction mechanism involving the capture of the bichromate anion, HCrO<sub>4</sub>. The extractant phase is 5 vol.% Alamine 336<sup>®</sup> (Cognis Corp.), 5 vol.% isodecanol (Exxon Chemical Corp.), and 90 vol.% Conoco 170 ES aliphatic diluent (Conoco, Inc.). The Cr(VI)-loaded extractant is continually regenerated and recycled, keeping working capital low and achieving low raffinate Cr(VI) levels. The high interfacial surface area provides fast kinetics even with feed Cr(VI) levels as low as 1 mg/l. Figure 1 illustrates a projected A-LLX process flow diagram. Discharge at the WAA SURFIN shop over a seven-month period was ~87,000 l/day with a Cr(VI) concentration of 13 to 52 mg/l [7]. Discussions with chemical suppliers indicate that 20,000-mg/l Cr(VI) concentrates would be viable for commercial use.

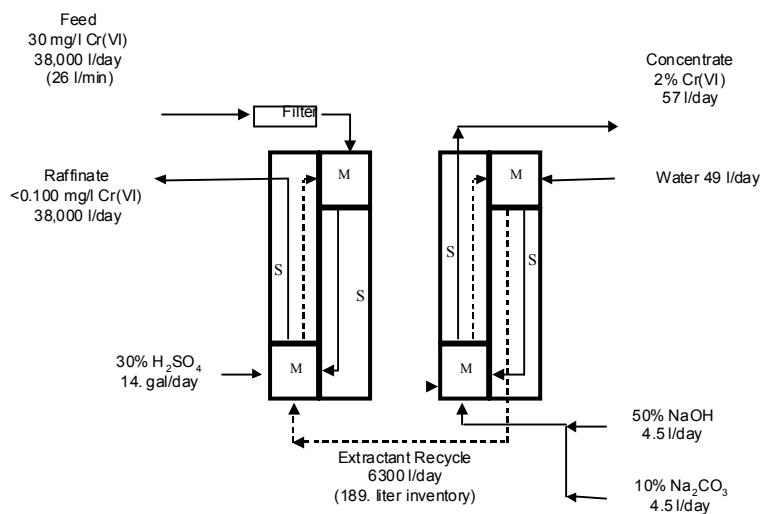

Figure 1. Full-scale A-LLX system design

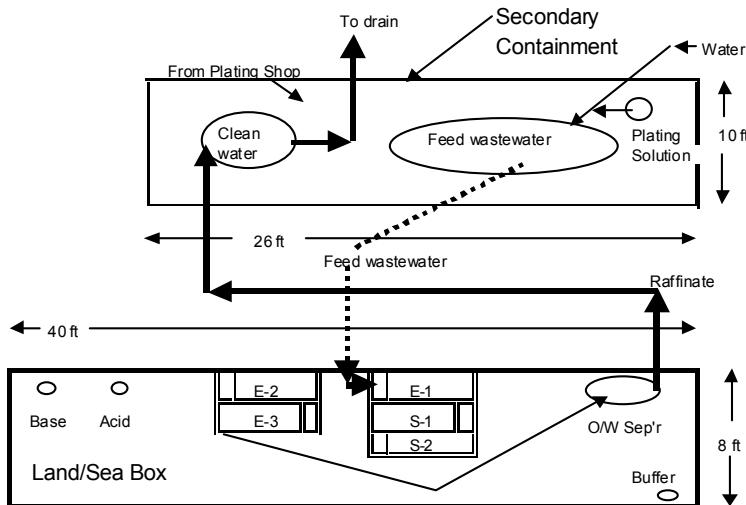

## COMMERCIAL-SCALE TEST OBJECTIVES

The objectives of the program were to construct and operate a portable, commercial-scale LLX device to validate the technical and economic basis for metal SURFIN operations. To meet this goal it was necessary to reduce Cr(VI) concentrations in the raffinate to <0.3 mg/l, and to produce a useful Cr(VI) concentrate for recycle. The economic goal was a payback period of less than 3 years.

## EQUIPMENT AND PROCEDURES

### Equipment and Design Parameters

Extraction hardware was constructed by Versatile Industries (Tucson, AZ, USA) according to Battelle's specifications based on the pilot-plant work [4-6]. All mixer settlers are constructed of polyvinylchloride and have the same dimensions: mixers (18" x 18" x 16" L x W x H) and settlers (66.5" x 18" x 16"), or 11.08 ft<sup>3</sup>. Each mixing chamber has a 12" diameter impeller attached to a variable speed  $\frac{1}{3}$  hp motor. Mixer tip speed and interface levels were adjusted to minimize entrainments. Flow was counter-current. Strippers were internally recycled. Design feed flow rate was 7 gal/min and the extractant/aqueous (E/A) ratio was 1/6. The raffinate is passed through an oil/water separator prior to discharge. Figure 2 shows the equipment layout, and Figures 3 and 4 show external and internal views of the plant.

*Figure 2. Equipment layout.*

The commercial unit was constructed with three extraction stages to take advantage of the more favorable economics of higher Cr(VI) concentrations due to the reduced total feed flow rate.

The key process control parameters, which affect acceptability of the LLX technology are:

1. Operability and reliability: As SURFIN shop and IWTP staffing is limited, the need for operator intervention was minimized.
2. Control: For pH control, individual controllers were used to deliver sulfuric acid or sodium hydroxide to E1 and E3 (acid) or to S1 (base). Water was added to S2 for water balance.
3. Extractant losses: Extractant make-up rate is an important economic consideration. An oil/water (o/w) separator was used to capture inadvertent releases of extractant.
4. Concentrate value: The Cr(VI) concentrate needs to be recycled for the objectives of the program to be met. At least one recycler indicates recycling will be attractive.
5. Economic estimates: The pilot testing indicated that payback periods of less than three years with 2-10 mg/l Cr(VI) feed levels, and shorten as the Cr(VI) levels increase and feed flow rate decrease. Full-scale operating information will be used to estimate capital and operating costs compared to conventional treatment.

The demonstration/validation tests were accomplished using the following steps:

1. A Technology Demonstration-Validation Plan [7] was prepared to communicate and guide all aspects of the field testing. It established the objectives, site preparation, operations, sampling, analyses, data collection and analysis, performance criteria, and quality assurance. This plan was reviewed by the host site organizations and site personnel involved in the testing, and covered both general and specific issues.
2. Two field tests were run, one completed and one underway as of mid-May. The first used hard chrome plating bath feed water from WAA and was performed at Battelle (Columbus, OH, USA). The second test site was WR-ALC.
3. Results of the test will be published along with appropriate guidance to assist in the full commercial implementation of the technology, including development and benefit of a standard A-LLX.
4. New permits were not required for commercial scale A-LLX testing. No special exemptions or treatability study exemptions were needed.

Figure 3. Test site photo: tanks and portable box.

Figure 4. Mixer-settlers, chemical feed tanks, surge tanks, and control.

A total of 8 runs were made to assess the viability of the A-LLX process with the WAA feed:

- Runs W-1 to W-5 established process operating conditions;
- Run W-6 determined continuous operation capability;
- Run W-7 examined process chemistry and hardware robustness performance over 20 days 24 h/day test at high Cr(VI) concentrate levels in the strip circuit;
- Run W-8 evaluated the effect of higher feed rate on performance.

Entrainment levels were determined as oil and grease values (US EPA Procedure 413.1). Cr(VI) assays were determined to 10 ppb on location using a Hach, Inc. test kit colorimetric method. Acidity, as pH, was monitored using standard industrial glass electrodes. Operations ran 24 hours per day during each extended run. It is critical that the pH values be controlled at about 3 for the extraction and about 12 for the strip circuit to avoid formation of chromium(III) hydroxide and stabilized emulsions, respectively.

Cr(VI) contaminated feed water was provided by the commercial test sites. For WAA the source was a used hard chrome plating bath {73.3 g total Cr/L [17.4 g/L Cr(VI) and 55.9 g/L Cr(III)]}. This very high Cr(III)/Cr(VI) ratio did not pose a selectivity problem for the A-LLX process. This concentrate was used to prepare Cr(VI) feed for the A-LLX process by diluting with water to make a simulated rinse water with Cr(VI) concentration ranging from 2-20 mg/l.

All acids and bases were of industrial technical grade. The water used in the process was filtered city water from Columbus, Ohio, USA.

## RESULTS

The commercial-scale testing using WAA depot feed processed about 300,000 gallons (4.2 million liters) of feed during the eight runs with the following results:

- Runs W-1 – W-5 established the primary operating conditions; feed rate; E/A flow ratio; stirrer tip speeds; and pH control.
- Run W-6 demonstrated good operability and extraction performance over 5 day 24 h/day test (Figure 5) with excellent Cr(VI) removal, even with variable levels in the Cr(VI) feed water (6-16 mg/l). Table 1 provides the specific run parameters and results.
- Run W-7 demonstrated robustness and consistent performance over 20 days at 24 h/day operation with the strippers at high Cr(VI) concentrate levels (10,000 to 15,000 mg/l) (Table 1 and Figure 6). Very steady operation over the entire period is clearly illustrated. The impact of run conditions on raffinate Cr(VI) residual levels correlate well. Gradual

extractant losses, were made up at day 14. Raffinate entrainment and turbidity levels (Figure 7) were acceptable and similar to W-6.

- Run W-8 evaluated the effect of higher feed flow rate on performance, which was found to be acceptable.

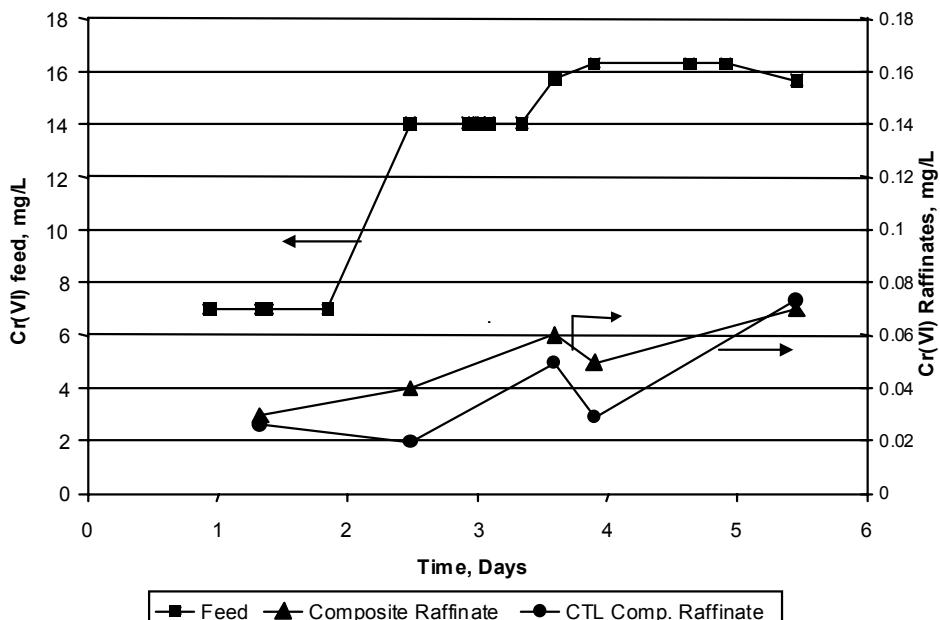

The yellow Cr(VI) color of the feed is removed across the process, giving a clear and colorless raffinate. The raffinate analyzed sufficiently low in Cr(VI) for direct discharge (Table 1).

Entrainment losses were higher than desired but expected based on the water solubility of the protonated extractant. The turbidities were excellent, <7 NTU. It is believed that the extractant is dissolved in the raffinate as the cationic (protonated) species,  $R_3NH^+$ . The fully operational plant may adjust the pH of the raffinate to produce neutral  $R_3N^-$ , which will reduce its water solubility substantially. The IWTP already makes such a pH adjustment.

*Table 1. Results Summary for Runs W-6 and W-7.*

Parameter	Run W-6 Results	Run W-7 Results
Feed	22.7 l/min; 12.8 mg/l Cr(VI)	26.5 l/min; 16 mg/l Cr(VI)
E/A	1/6	1/6
pH	2.7 (E); 12.9 (S)	2.7 (E); 13.4 (S)
Cr(VI) E-1	0.86 mg/l (93%)	1.71 mg/l (89%)
Cr(VI) E-2	0.16 mg/l (84%)	0.40 mg/l (66%)
Cr(VI) E-3	0.11 mg/l (31%)	0.19 mg/l (53%)
Cr(VI) Composite Raffinate (overall % extraction) <sup>a</sup>	0.04 mg/l (99.7%)	0.23 mg/l (98.6%); 0.11 mg/l (99.4%) over days 14-18
Cr(VI) S-1	4000 mg/l (300X concentration)	12,000 mg/l (800X)
Raffinate Entrainment	76 mg/l	119 mg/l

<sup>a</sup> Every 10 minutes, 20.00 ml of raffinate was withdrawn and pumped to a composite tank. After 24 hr, this tank was mixed, sampled and analyzed.

*Figure 5. Results from Run # W-6. Hexavalent chromium [Cr(VI)] in mg/l with run time.*

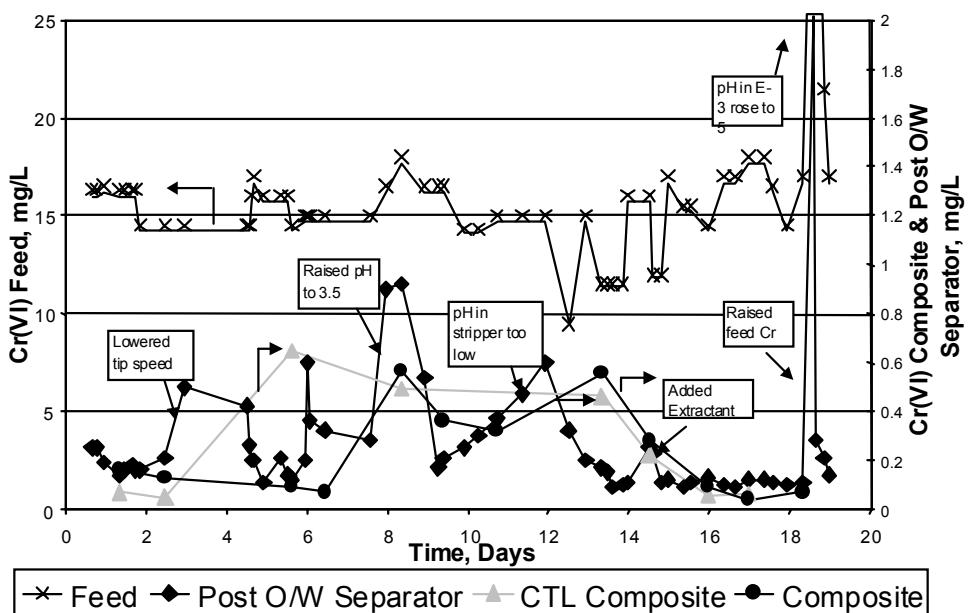

Figure 6. Run W-7: Cr(VI) concentration vs. time.

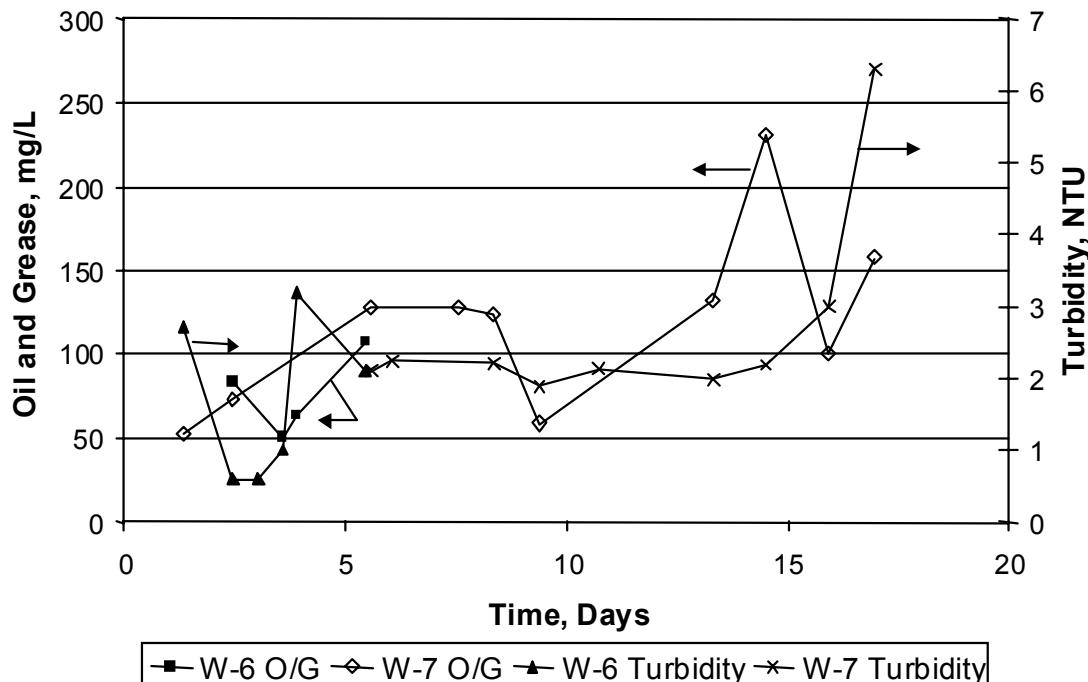

Figure 7. Entrainment losses (as oil and grease analysis), and raffinate clarity vs. time.

Figure 8 shows the clear yellow concentrated Cr(VI) product solution. The 10,000-20,000 mg/l Cr(VI) concentration is acceptable feedstock for production of Cr(VI)-based chemicals. Seven 208-liter drums of this material were produced for recycle process demonstration. Samples have been submitted to the recycler for evaluation.

As expected due to the low ionic strength of the feed water, the extractant phase picked up a fine aqueous emulsion giving it a turbid coloration, though the phases broke adequately and cleared overnight. Hence the o/w separator is beneficial.

## **CONCLUSIONS**

A-LLX was demonstrated to provide excellent Cr(VI) reduction, normally 99%+, and robust removal of Cr(VI) from SURFIN process water at economically attractive flow rates. A high selectivity for Cr(VI) over other contaminants, and the capability to substantially concentrate the Cr(VI) from very dilute feed were demonstrated, making a Cr(VI) product suitable for recycle. Therefore, landfill disposal avoidance is possible.

## **ACKNOWLEDGEMENTS**

The support from the following organizations and persons are gratefully acknowledged. The Air Force Research Laboratory [AFRL] is the lead organization: Capt. Gina Graziano and 1<sup>st</sup> Lt. Larry Cook (AFRL/MLQL) were the project managers. Lt. Joshua Knowles and Mr. Dave Bury of Robins AFB provided applications guidance and are hosting the second (ongoing) field test. Alice Fish of Watervliet Arsenal represented US Army interests and applications and provided the plant field material for the first (completed) field test. We all gratefully acknowledge funding by the US Environmental Security Technology Certification Program (ESTCP).

## OPERATION OF A NDSX PILOT PLANT FOR RECOVERY OF Cr(VI) FROM GROUND WATERS

Inmaculada Ortiz, Berta Galán, David Castañeda and Angel Irabien

Dpto. de Ingeniería Química y Química Inorgánica, Universidad de Cantabria,  
Santander, Spain

This work has focused on the study of the viability of Cr(VI) removal from ground waters and the simultaneous concentration for its reuse in chromate baths. The experimental analysis has been carried out in a non-dispersive solvent extraction pilot plant that incorporated two hollow fibre modules and used Aliquat 336 as the organic carrier and NaCl as the back-extraction agent. Ground waters with a variable concentration of chromium(VI) were pumped, collected in a high volume reservoir and conducted to the pilot plant after dilution. The results of the continuous operation of the pilot plant are reported and compared to predictions using the mathematical model previously reported by the authors.

### INTRODUCTION

Chromium(VI) is a highly toxic metal that is widely used in industrial processes such as electroplating [1,2]. Besides the huge amount of waste waters generated during rinsing steps of metal finishing industries, leaks and deposits of different forms of the metal in the ground, may lead to filtration and transport of the pollutant to ground water sites. This situation needs efficient separation technologies that in the application to effluent treatment minimize the environmental impact of waste water discharges and that can also be used for remediation of ground waters.

The extraction and concentration of Cr(VI) from rinse waters, using hollow fiber membranes and Aliquat 336 as the extractant, has been previously studied by the authors working at a laboratory scale, and the mathematical model and design parameters have been obtained [3-5]. Taking into account the good results obtained at the laboratory level, the scale-up of the process to pilot plant level was achieved and reported previously [6]. In NDSX processes, the main scale-up variable is the mass transfer area [7] that was increased almost 20 times, *i.e.*, from 1.2 m<sup>2</sup> corresponding to laboratory scale to 20 m<sup>2</sup> in the pilot plant set-up. In that work, experimental tests in the NDSX pilot plant were carried out using rinse waters of galvanic processes of a local industry, that contained an average inlet chromium(VI) concentration of 0.064 g/l [6]. These rinse waters were successfully treated in the pilot plant operating in a semi-batch mode, reducing the concentration of chromium in the extraction phase below 5 x 10<sup>-4</sup> g/l, and concentrating the metal in the back-extraction solution. The experimental results were checked against data predicted by the mathematical model previously developed, confirming that the model and the values of the design parameters estimated from laboratory- scale experiments were accurate enough for the description of the separation-concentration process at pilot-plant scale.

In this work, the NDSX pilot plant previously developed has been used for the in-situ remediation of ground waters containing chromium(VI) as main pollutant and having also the objective of chromate concentration in a back-extraction solution.

## EXPERIMENTAL SYSTEM

Table 1 gives the physico-chemical characterization of the ground waters.

*Table 1. Physico-chemical characterization of the ground waters.*

Species	Concentration (mg/l)
$\text{Cr}^{+6}$	700-2000
$\text{Ca}^{+2}$	550
$\text{Al}^{+3}$	60
$\text{SO}_4^{=}$	1750
$\text{Cl}^-$	1200
DQO	170
COT	50

Due to the high content of calcium it was necessary to reduce its concentration ahead of the NDSX process in order to avoid precipitation of calcium sulfate in the hollow fibers. Thus, a cationic ion-exchange column was incorporated to the pilot plant in order to eliminate the presence of  $\text{Ca}^{+2}$  in the feed waters. The cationic ion-exchange column was filled with Lewatit Monoplus S-100 resin.

The plant included also two hollow fibre modules, the main components of the separation process, one for the extraction and the second one for the back-extraction process. The hollow fiber modules were Liqui-Cel Extra-Flow 4"x28" membrane contactors purchased from Hoechst Celanese Corporation [6]. In the modules, the aqueous phases run through the lumen of the hollow fibres and the organic phase flows through the shell side.

Four homogenisation tanks were also necessary: one for the organic phase, one for the feed aqueous phase, and two tanks for the back-extraction aqueous streams. The tank for the organic solution had 90 l capacity and was made of stainless steel. The tanks for the aqueous solutions: feed, back-extraction and purge, had capacities of 5000 l, 100 l and 60 l, respectively, and were made of polyethylene. The aqueous-phase pipes were made of teflon and polypropylene and the organic-phase pipes were made of stainless steel.

Initially, ground waters were stored in 1000 l containers. When necessary, the ground waters were passed through the ion-exchange column and, after calcium removal, they were sent to the extraction homogenisation tank where, if necessary, a dilution process was carried out in order to decrease the initial concentration of chromium(VI) to a value of around 1 g/l. The feed solution was then filtered through a sand filter to remove remaining suspended solids and passed through a 10  $\mu\text{m}$  filter before entering the modules to prevent fouling in the hollow fibres. The feed ground waters flowed through the extraction module in a continuous mode.

The organic solution was a mixture of Aliquat 336 (0.6 M), and isodecanol and kerosene that were used as modifier and diluent, respectively. The organic phase coming out of the extraction module was sent to the back-extraction module to accomplish two different objectives: i) concentration of the removed chromium, and ii) regeneration of the organic phase.

In the back-extraction module, chromium was transported from the organic solution to the BEX solution ( $\text{NaCl}$ , 1 M) that flowed to the storage tank. A continuous purge was applied to the tank receiving the concentrated chromate solution and the tank volume was kept constant by continuous addition of fresh BEX solution.

Hollow fibre modules were thermostatized, working at a temperature of 40°C (the maximum temperature allowed by the fibres). Three heater systems were included in the plant. An on-line system for pipes and tubes and electrical resistances were placed inside the organic and BEX tanks. Due to the hydrophobic nature of the fibres, the pressure of the aqueous phase was maintained higher than the pressure of the organic phase, ensuring that no displacement of the organic phase from the pores of the hollow fibres took place. The working differential pressure between phases was 2.5 psi.

Samples were taken out at the module outlet or in the aqueous tanks and prepared for analysis. The concentration of Cr(VI) in the feed and stripping solutions was measured in a Lange LP2W photometer.

## RESULTS AND DISCUSSION

Two different tests were carried out in the pilot plant: i) analysis of the viability of chromium concentration in the back-extraction solution up to a level that would allow reuse of the compound in chromate baths, and ii) analysis of the stability of the plant at long working times.

The first experiment was carried out working in a semicontinuous mode, *i.e.*, ground waters flowed continuously, but the organic and back-extraction solutions flowed in a recycling mode. The experiment was run for 170 hours until a concentration of 20 g/l was reached; this value was considered acceptable by the chromate salts industry.

Figure 1 shows the results of this first experiment and Table 2 shows the experimental conditions. It is observed that the concentration of Cr(V) in the back-extraction solution increased with time and reached a value around 20 g/l at 170 hours. The resulting solution was analysed by a local industry that used chromate baths, confirming its suitability.

*Table 2. Experimental conditions of experiments I and II.*

		Experiment I	Experiment II
Ground waters	Cr (VI) conc. (g/l)	0.78	0.60 → 0.8
	Cl <sup>-</sup> conc. (g/l)	0.45	0.45 → 1.2
	Ca conc. (g/l)	0.04	0.04 → 0.2
	Flow rate (l/h)	60	60
	pH	7.5	9 → 10
BEX solution	CINa conc. (g/l)	35	35 → 38
	pH	7.5	10 → 11

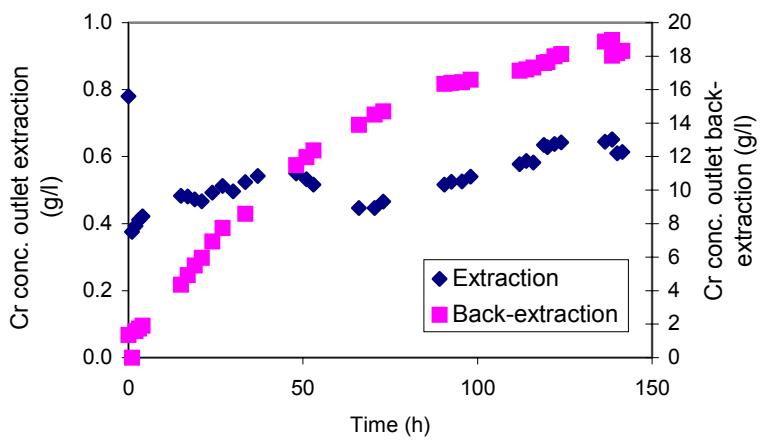

Figure 1. Extraction and back-extraction evolution of experiment I.

Once the viability of chromium concentration had been checked, the following experiment focused on the analysis of the stability of the system. Figure 2 represents the evolution of the Cr(VI) concentration in the extraction and back-extraction solutions with time.

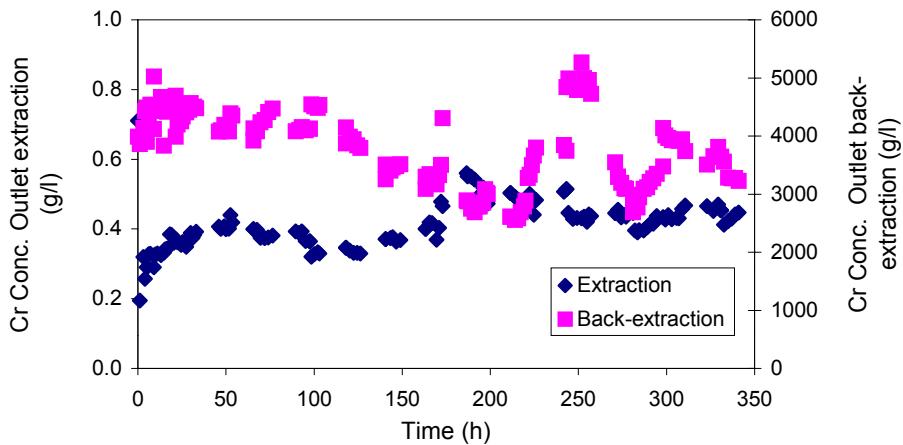

Figure 2. Extraction and back-extraction evolution in experiment II.

It is observed that the average outlet concentration of Cr(VI) in the extraction process is around 0.4 to 0.45 g/l, and the average outlet concentration in the back-extraction solution is around 4 g/l.

In both experiments, the outlet concentration of chromium in the extraction module was too high to consider that the ground waters were clean enough. Thus, further reduction of chromium concentration would be needed and would require either to flow the feed solution at lower flow rates or to carry out a second NDSX step. Both possibilities have been analysed in this work through simulation tasks. The mathematical model used in order to describe NDSX processes consisted of six nonlinear partial differential equations describing the mass transport through the membrane modules and two algebraic equations describing the equilibrium reactions. The mathematical model required also the knowledge of three characteristic parameters, two chemical equilibrium parameters of the interfacial reactions and the membrane mass transport coefficient [6]. The incorporation of additional NDSX steps required duplication of the number of differential equations but the design parameters remained the same.

After incorporation of a second NDSX step a new separation process was defined with the following steps:

- i. *Ion exchange with cationic resin Lewatit Monoplus S-100*, in order to reduce the concentration of  $\text{Ca}^{2+}$  to avoid precipitation of calcium salts in the porous hollow fiber membranes. Regeneration was carried out with NaOH.
- ii. *First NDSX step*, that incorporates two membrane modules: one for the extraction and a second one for the back-extraction process. Ground waters flow continuously from the ion-xchange column to the extraction module and then towards the third step. The organic phase circulates in a recycling mode from the extraction module to the back-extraction module. In the BEX tank a purge stream takes out the concentrated solution and the volume is kept constant by feeding fresh back-extraction solution. In the first NDSX step, a reduction of  $\text{Cr}^{+6}$  concentration below 50% of the initial value is searched whereas the stripping phase works with a concentration of 20 g/l.
- iii. *Second NDSX step*, that incorporates also one module for the extraction and a second one for the back-extraction. Ground waters come from the first NDSX step. The organic and the stripping phases work in a similar manner to the first step but the concentration of the BEX solution is kept at a lower value equal to 4 g/l. The concentration of  $\text{Cr}^{+6}$  is reduced to less than 0.1 g/l. The temperature of both NDSX steps was kept constant at 40 °C.

Figure 3 represents the flow sheet diagram of the analysed process.

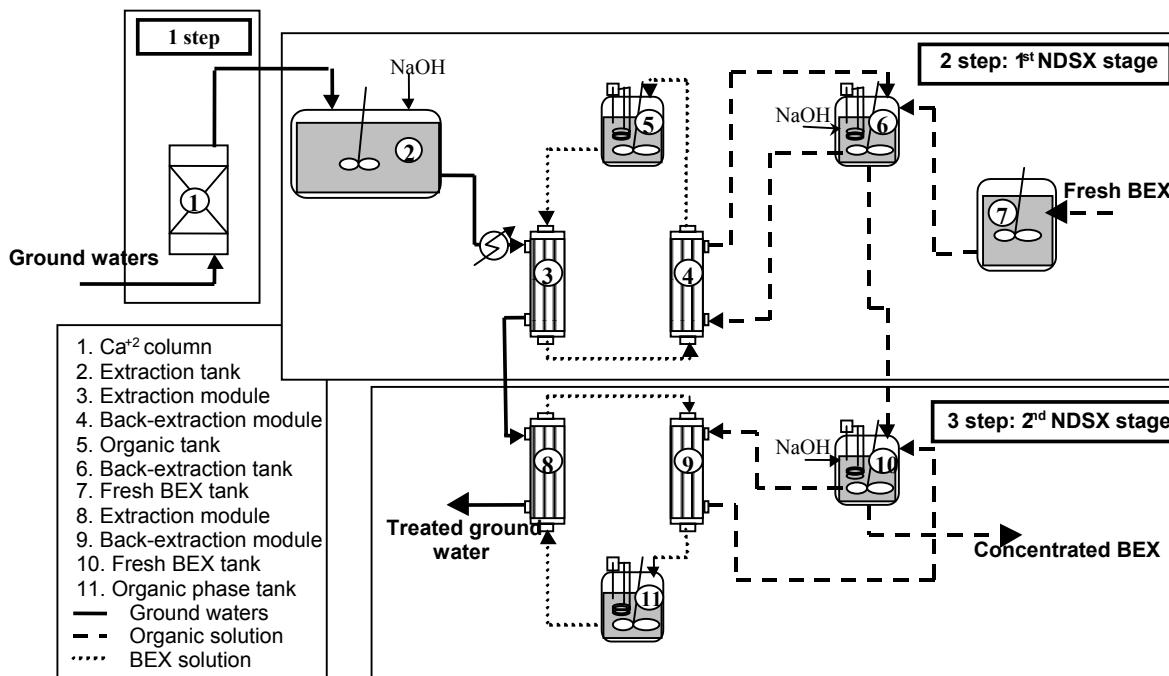

Figure 3. Flow sheet diagram of the separation process.

A sensitivity analysis of the process concentrations to the feed flow rate was performed. Table 3 reports a summary of the results obtained.

*Table 3a. Inlet and outlet conditions of the integrated process.*

Ground waters	Cr (VI) conc. (g/l) Cl <sup>-</sup> conc. (g/l) Ca <sup>2+</sup> conc. (g/l)	0.7 0.45 0.04
1 step NDSX	BEX conc. (g/l) pH	20 10.5
2 step NDSX	BEX conc. (g/l) pH	4.0 10.5

*Table 3b. Sensitivity of the concentration results to feed flow rate.*

Flow rate (l/h)	60	40	30	20	10	5
1 stage NDSX outlet conc. (g/l)	0.439	0.3339	0.259	0.156	0.072	0.050
2 stage NDSX outlet conc. (g/l)	0.231	0.1111	0.053	0.018	0.005	0.002

## CONCLUSIONS

In this work the theoretical and experimental analysis of the behaviour of a non-dispersive extraction process at pilot-plant scale has been carried out in the application to the separation and concentration of hexavalent chromium contained in ground waters.

The experimental tests working with different initial conditions checked the stability of the membrane process for times of 350 hours. Taking into account the experimental results and in order to achieve two main separation objectives, *i.e.*, cleaning of ground waters reducing the concentration of chromium and at the same time concentration of the metal in the back-extraction phase up to a level that enables reuse in chromate baths (20 g/l), an integrated process with three different steps has been defined. The sensitivity of the integrated process to changes in the feed flow rate has been analysed using the mathematical model and parameters obtained in a previous work at laboratory scale; this task was carried out working with gPROMS process software. Further work will include optimisation of the operation variables and optimum process design.

## SCREENING OF REAGENTS FOR RECOVERY OF ZINC(II) FROM HYDROCHLORIC ACID SPENT PICKLING SOLUTIONS

Magdalena Regel-Rosocka, Ireneusz Miesiac, Ana Maria Sastre\* and Jan Szymanowski

Institute of Chemical Technology and Engineering, Poznan University of Technology,

Barcelona, Spain

The extraction of zinc and iron ions, water and hydrochloric acid was studied. The extraction studies permitted to select tributyl phosphate as the most convenient reagent. Due to a high transfer of hydrochloric acid, amines were not convenient for the extraction of zinc(II) from solutions containing below 5% HCl. Moreover, the HOE® F2562 caused relatively high oxidation of Fe(II) to Fe(III). Such oxidation was also observed when ALAMINE® 336, ALIQUAT® 336 and CYANEX® 923 were used. Bulk liquid membrane experiments supported the conclusions from extraction studies demonstrating a good extraction performance of tributyl phosphate.

### INTRODUCTION

Zinc protective layers are commonly used today to protect steel goods from corrosion. Zinc layers are deposited by immersing steel goods in molten zinc at about 450°C. Good quality zinc layers need appropriate pre-treatment of surface, including washing, degreasing, removal of rust and fluxing. 20% hydrochloric acid solution is usually used for pickling carried out at room temperature. Zinc accumulates also in the pickling solution. In the batch process steel goods are hang on hooks on which zinc is also deposited. The hooks are used again and zinc dissolves in the hydrochloric acid. Such a solution contains only few g/L Zn(II) or even less. Spent pickling solutions are also used to deplete zinc layers of insufficient quality. In such a case, the concentration of zinc(II) in the spent solution may increase to few tens g/L.

Only spent pickling solution containing less than 0.5 g/L Zn(II) is processed by Ruthner process in which the hydrochloric acid is evaporated and granules of iron oxide are formed in fluidised bed at temperature above 600°C. Therefore the spent pickling solution is often neutralised with lime and disposed to the environment together with toxic zinc ions.

Solvent extraction [1-7] can be used to remove toxic zinc(II) from spent pickling solutions. The use of various extractants was proposed but detailed studies have not been published. The aim of this work was to screen various reagents and to perform more detailed studies with selected extractants. Taking into account high concentrations both of proton and chloride ions, the studies were narrowed to selected solvating (tributyl phosphate and trialkylphosphine oxides) and basic extractants (tri- and dialkylamines and quaternary ammonium salts). The selection of reagents was narrowed to industrial extractants that could be used in practice.

## EXPERIMENTAL

The following reagents were used as extractants:  
tributyl phosphate (TBP), Hoechst, Germany,  
HOE® F2562 (diisotridecylamine), Hoechst, Germany,  
ALAMINE® 304 (tridodecylamine), Cognis, Germany,  
ALAMINE® 308 (triisooctylamine), Cognis, Germany,  
ALAMINE® 310 (triisododecylamine), Cognis, Germany,  
ALAMINE® 336 (trialkylamine, C<sub>8</sub>:C<sub>10</sub> = 2:1), Cognis, Germany,  
CYANEX® 923 (trialkylphosphine oxides), CYTEC, Canada,  
CYANEX® 925 (trialkylphosphine oxides), CYTEC, Canada,  
CYANEX® 302 (trialkylmonothiophosphinic acid), CYTEC, Canada,  
triisoctylamine, Windsor Laboratories Limited, UK,  
AMBERLITE LA-2 (N-dodecyl-N-trialkylmethylamine), Fluka, Germany,  
and ALIQUAT® 336 (trialkylmethylammonium chloride, C<sub>8</sub>:C<sub>10</sub> = 2:1), Cognis, Germany.  
Decanol was used as a modifier and low aromatic kerosene Exxsol D220/230, Deutsche  
Exxon Chemical GmbH, ESSO A.G. (Germany) as a diluent.

Extraction was carried out at room temperature using 1:1 phase volume ratio. Water was usually used for stripping. A double Lewis cell described in the previous paper [8] was also used to check the performance of reagents in membrane processes. The aqueous phase contained various amounts of zinc(II), iron(II) and iron(III). The concentration of hydrochloric acid was adjusted to 1.8 or 10%, and the chloride concentration was usually constant and equal to 5 M. Analytical procedures were described in the previous paper [7].

## RESULTS AND DISCUSSION

### Classical Extraction

The screening tests in which the aqueous feed contained simultaneously Zn(II), Fe(II) and Fe(III) showed that ALAMINE® 304, ALAMINE® 308 and ALAMINE® 310 were not useful because a precipitation occurred or strong emulsions were formed. It also concerned ALIQUAT® 336, although high extractions both of Zn(II) and Fe(II) were observed. An emulsion was also formed when CYANEX® 923 was used and aqueous phase contained 10% HCl. TBP and ALAMINE® 336 extracted iron(III) very strongly. Dialkylamine (HOE F2562 and AMBERLITE® LA-2) extracted less iron(III) than trialkylamine and tributyl phosphate. Extraction isotherms for zinc(II) and iron(III) extraction given in Figures. 1 and 2 indicated high extraction abilities of the considered amines and trialkylphosphine oxides. TBP was a weak extractant when used in kerosene. However, the reagent could be used without dilution and highly loaded both with zinc(II) and iron(III). CYANEX® 302, being an acidic extractant, extracted only small amounts of Zn(II) and Fe(III) and was not used in further studies.

The results indicated that iron(III) had to be reduced to iron(II) prior to extraction. It could be achieved by depletion of bad quality zinc layers. The presence of iron(II) did not disturb the extraction of zinc(II) with TBP and amine extractants. However, some co-extraction of iron(II) was observed. The co-extraction was strong for CYANEX reagents (Figure. 3). It could be explained by the oxidation of iron(II) to iron(III) and/or the transfer of iron(II) to the organic phase together with water, e.g. in the form of reverse micelles. The latter phenomenon seemed important when undiluted or highly concentrated TBP was used. The organic phase contained about 7% of water after extraction-stripping process. The hypothesis was supported by the presence of iron(II) in the aqueous solution phase after stripping with water. The oxidation of iron(II) seemed very important in the case of trialkylphosphine oxides. It was reported that some species, including hydrophosphate and some metal cations catalyse the oxidation [9].

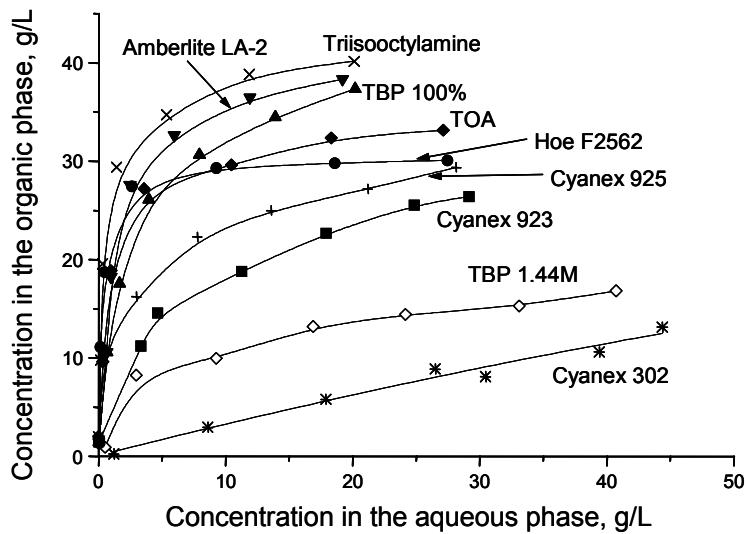

Figure. 1. Isotherms of zinc(II) extraction from 10% HCl with 1.44 M extractant solutions.

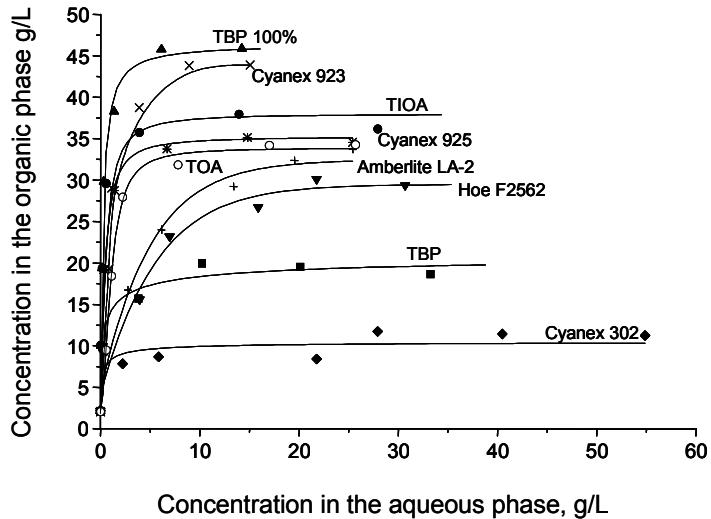

Figure. 2. Isotherms of iron(III) extraction from 10% HCl with 1.44 M extractant solutions.

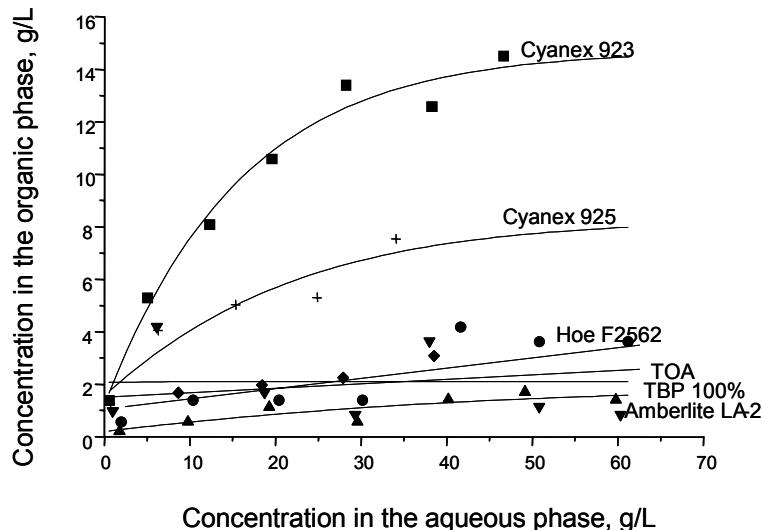

Figure. 3. Isotherms of iron(II) extraction from 10% HCl with 1.44 M extractant solutions.

The effective extraction of metal species from the aqueous feed had to be followed by effective stripping. The results shown in Table 1 indicated that both zinc(II) and iron(II) could be effectively stripped from the loaded TBP. Three stages were necessary. However, zinc(II) was inefficiently stripped from CYANEX® 923 and ALAMINE® 336. The efficiency of iron(III) stripping depended on HCl concentration and was higher for initial aqueous feed containing 10% HCl. Higher stripping of zinc(II) was achieved from HOE® F2562 and AMBERLITE® LA-2. However, the process was less effective than from loaded TBP.

The extraction and stripping experiments permitted to select TBP as the most appropriate extractant. The secondary amines could be also used.

*Table 1. Stripping of zinc(II) and iron from loaded organic phases with water in three stages (loaded zinc(II), app. 5 g/L).*

Reagent	%S <sup>Zn</sup>	%S <sup>Fe</sup>
TBP 100%	98.0	98.4

1.44 M ALAMINE 336	4.9 12.5*	70.3** 38.6***
30% ALAMINE LA-2	84.8	5.3
30% HOE F2562	100.0	7.7

\*diluted organic phase contained over 10 g/L iron ions

\*\*10% HCl in the aqueous feed

\*\*\*1.8% HCl in the aqueous feed

### Membrane Extraction

The bulk membrane experiments showed that only TBP could be used as a carrier (Figure 4). However, a great accumulation of zinc(II) in the membrane phase was observed. Maximum of zinc(II) concentration in the strip was observed. It was caused by a strong co-extraction of hydrochloric acid and back-transfer of zinc(II) from the strip phase to the membrane. That atypical phenomenon was caused by a competition of zinc(II) and hydrochloric acid transfer. The HCl content in the strip phase increased monotonically with time and achieved 0.5 M after 90 minutes. That concentration was high enough to stop further transfer of zinc(II) to the strip. Moreover, the back extraction of zinc(II) from the strip to the membrane was observed after 110 minutes. The transfer of water to the membrane phase also occurred and at the end of the process the content of water in TBP was 6.5-8.1% depending on zinc(II) concentration in the feed. The problem was overcome when the hydrochloric acid in the aqueous strip was neutralised. The transfer of zinc(II) and HCl from the aqueous feed to the strip phase depended on the concentration of chloride ions. An increase of the Cl<sup>-</sup> concentration affected positively the extraction of zinc(II) but negatively the stripping.

It was also possible to use AMBERLITE® LA-2 (Figure. 5) but as in the case of TBP zinc(II) accumulated in the membrane phase and its transfer to the aqueous phase was slow.

HOE® F2562 extracted only small amounts of zinc(II) to the membrane phase and transferred negligible amounts to the strip. The transfer was retarded by the interfacial phase, which could be clearly observed. Thus, the reagent showing good extraction performance was not suitable for the membrane process.

The experiments permitted to select TBP and AMBERLITE® LA-2 as appropriate extractants/carriers.

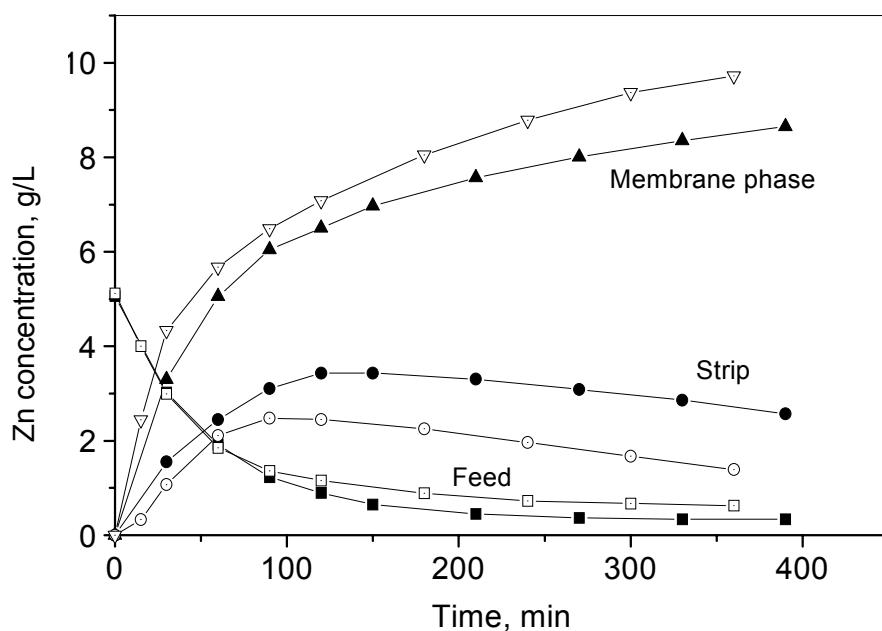

Figure. 4. Extraction-stripping of zinc(II) by TBP (undiluted) in bulk liquid membrane process (aqueous feed: 5 g/L Zn(II) and 10% HCl, chloride concentration: 3.40 M (full points) and 5.00 M (empty points), squares – feed, triangles – membrane and circles – strip).

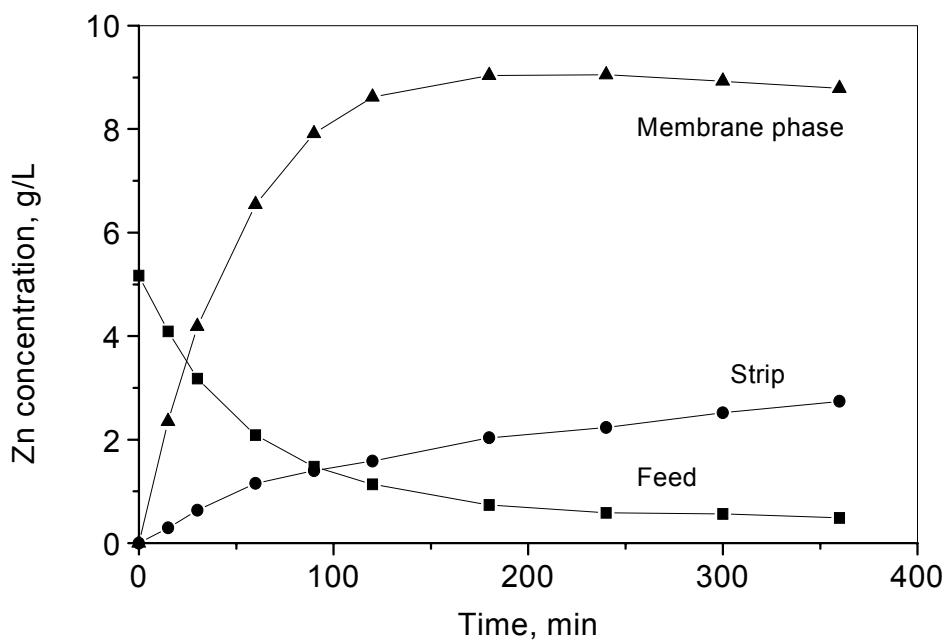

Figure. 5. Extraction-stripping of zinc(II) by 1.44 M AMBERLITE® LA-2 in bulk liquid membrane process (aqueous feed: 5 g/L Zn(II) and 10% HCl, chloride concentration: 3.40 M).

## A CONTINUOUS SOLVENT EXTRACTION PROCESS FOR REFINING OF PICKLING BATHS

L. Caron, D. Pareau, M. Stambouli and G. Durand

Laboratoire de Chimie et Génie des Procédés, Ecole Centrale Paris,  
Chatenay-Malabry Cedex, France

A process flowsheet for the elimination of copper contained in sulphuric acid pickling baths of steel pieces has been developed. A preliminary study of solvent extraction options has lead to the choice of a suitable extracting system containing both Cyanex 302 and LIX 860. With this extractant mixture, copper is quantitatively and selectively extracted in a few minutes. The stripping step has been optimised with the use of thiourea as stripping agent. A regeneration step of the extractant is necessary because of the degradation of Cyanex 302. The feasibility of copper deposition from the strip solution has been demonstrated. A continuous micro-pilot scale test has been performed with good results (constant and low copper concentration in the pickling bath and electrowinning of copper) and a model has been developed for the design of the industrial process.

### INTRODUCTION

After use the pickling baths of interest in this study contain sulphuric acid (2 mol/L), iron (Fe(II) for the major part) and traces of other metals such as copper that can cause problems in the pickling process. These baths must be changed periodically, leading to the loss of residual acid and the formation of sludges. The development of a process that would allow better utilization of the baths by maintaining the copper concentration constant is therefore of interest and forms the subject of this paper.

### SOLVENT EXTRACTION OF COPPER

Oximes are well known extractants for copper, but they usually have a low efficiency in acid solutions. Salicylaldoximes on the contrary offer more promise: LIX 860 ( 5-salicylaldoxime) is able to extract copper by chelation in sulphuric acid [1,2]. The extractant is selective for copper over iron(III) and iron(II) [3,4,5].

Among the organophosphoric extractants, only thiophosphoric agents extract copper at high acidity. Tait [6] and Sole [7] confirmed the copper extraction efficiency of Cyanex 301 and 302 (bis 2,4,4-trimethylpentylidithiophosphinic acid and bis 2,4,4-trimethylpentylmonothiophosphinic acid, respectively). While iron(III) is also slightly extracted, iron(II) is not extracted at all. Copper stripping is however very difficult.

Laboratory batch experiments were then performed using these extractants to identify a suitable extractant system for further continuous test work.

## Experimental

Aqueous and organic phases were contacted in an agitated vessel at a constant temperature (varying from 25 to 80°C, because industrial baths operate at 60-70°C). The aqueous solutions contained 2 mol/L sulphuric acid, 5 to 100 mg/L copper and 1.5 g/L iron(III) (Prolabo reagents). Iron(II) being not extracted at all was not used in these batch laboratory experiments. LIX 860 (Henkel) and both Cyanex (Cyanamid) reagents were diluted in dodecane (Prolabo). Iron and copper were analysed by atomic absorption spectrometry (Varian AA 300).

### Copper Extraction with LIX 860

The extraction can be represented by the following equation:

where s is the aggregation number of LIX 860 (HR).

The concentration of copper has no influence on its distribution ratio D: so the extracted complex contains only one atom of copper. The extraction efficiency is however rather low: D is about 0.5 for 0.5 mol/L LIX 860 and 2 mol/L H<sub>2</sub>SO<sub>4</sub>.

The concentration of LIX 860 was varied between 0.1 and 1.6 mol/L; the major form of the oxime under these conditions is the dimer [1,2]. In addition the sulphuric acid concentration was varied from 1 to 4 mol/L. The results are presented in Figure 1, where ln D/[H<sup>+</sup>]<sup>2</sup> is plotted versus ln [(HR)<sub>2</sub>]. A straight line is obtained with a slope 1.1; then (2+p)/s = 1 and as s = 2, p = 0. The extracted complex is therefore CuR<sub>2</sub>.

The selectivity for copper over iron is quite good; under the same conditions the distribution ratio of iron is indeed lower than 0.007.

Despite its good selectivity LIX 860 is not efficient enough to extract copper quantitatively.

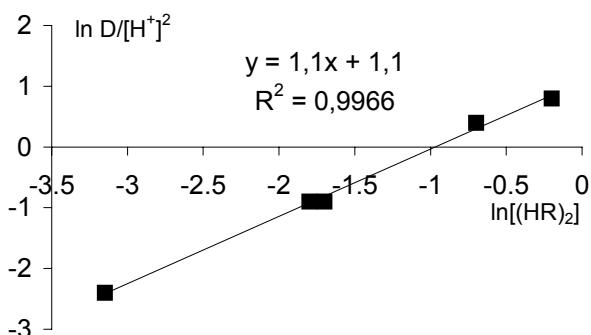

Figure 1. Determination of the extracted complex stoichiometry for the LIX 860/Cu system.

### Copper Extraction with Cyanex 301

At room temperature copper is quantitatively extracted in less than 30 seconds when Cyanex 301 is in excess over Cu. Solution conditions tested were: 48 mg/L Cu, 1500 mg/L Fe(III), 2 mol/L H<sub>2</sub>SO<sub>4</sub> and 0.076 mol/L Cyanex 301. Iron (III) extraction is both low and slow: only 30 mg/L is extracted in 3 hours.

The variation of temperature has no effect on these results; between 40 and 80°C, copper is quantitatively extracted in 10 minutes along with less than 0.2 mg/L Fe(III) (for 0.076 mol/L Cyanex 301).

Cyanex 301 is clearly an excellent extractant for copper in the presence of iron.

The stripping is however very difficult; the only possible solution is a mixture of thiourea and sulphuric acid. Many other stripping solutions were tested without success [8]. The concentrations of both reagents were varied and the results are given in Table 1 (10 minutes contact time, 0.076 mol/L Cyanex 301).

*Table 1. Influence of thiourea and sulphuric acid concentrations on copper stripping from Cyanex 301.*

H <sub>2</sub> SO <sub>4</sub> , mol/L	0	0.5	1	2	1	1	1	1
Thiourea, mol/L	0.1	0.1	0.1	0.1	0.2	0.3	0.4	0.5
Stripping, %	<1	11	21	33	82	88	90	97

Copper stripping is therefore possible provided thiourea and sulphuric acid are present in sufficient concentration.

### **Copper Extraction with Cyanex 302**

Like with Cyanex 301 the extraction of copper is quantitative, but much slower. To reach 90% extraction, 17 and 48 minutes are needed for 0.074 and 0.028 mol/L Cyanex 302, respectively. By comparison quantitative extraction is achieved in 3 minutes for 0.076 mol/L Cyanex 301.

By plotting  $\ln C/C_0$  versus time, where C and  $C_0$  are the copper concentrations at t and t = 0, straight lines were obtained, confirming that the limiting reaction is first order with respect to the metal. The slope p of these straight lines show linear dependence to Cyanex 302 concentration. The reaction is therefore first order with respect to Cyanex 302.

Efficient copper stripping is achieved for the same strip solution mixtures that proved efficient for Cyanex 301.

### **Degradation of Cyanex 301 and Cyanex 302**

Both molecules are oxidised into disulfide by contact with the aqueous solution. The rate of degradation is greater for Cyanex 301 than for Cyanex 302 (8 days compared to 40 days); Cyanex 302 was therefore selected for further study. The degradation product is a disulfide having poor extracting properties. This degradation is however reversible by contacting degraded organic solution with reducing agents such as hydrogen, nickel, iron or zinc [9].

### **Copper Recovery with Mixtures of Cyanex 302 and LIX 860**

LIX 860 extracts copper quickly, but poorly. On the contrary Cyanex 302 extracts it quantitatively, but slowly. By mixing both extractants, a rapid and quantitative extraction may be expected, as tested below.

#### **Copper extraction**

A positive effect on the extraction kinetics was observed in preliminary experiments, copper was quantitatively extracted as for Cyanex 302, but the extraction is quicker. A kinetic study was performed in an agitated vessel (stirrer speed - 1500 rpm). For each experiment  $\ln C/C_0$  was plotted versus time, resulting in a straight line (slope -p). Several chemical parameters were varied and their influence on p was studied. The results are given in Table 2.

Table 2. Influence of LIX 860 and Cyanex 302 concentration on  $p$  at 70°C.

LIX 860 mol/L	0	0.025	0.050	0.150	0.250	0.150	0.150	0.150
Cyanex 302 mol/L	0.028	0.028	0.028	0.028	0.028	0.038	0.052	0.080
$p$ min <sup>-1</sup>	0.06	0.10	0.15	0.32	0.54	0.20	0.28	0.41

$p$  is proportional to the LIX 860 concentration when the Cyanex 302 concentration is constant ( $r^2 = 0.997$ ).

A reaction scheme is proposed with three reactions: the first is the first order reaction observed for Cyanex 302, the second, the rapid extraction equilibrium of copper by LIX 860 and the third, the substitution in the extracted complex, of LIX 860 by Cyanex 302.

$k_1$  and  $k_3$  are the kinetic constants of (1) and (3) and  $K_{2\text{is}}$  the equilibrium constant of (2).

The reaction rate can be written as:

$$r = k_1 [\text{Cx}] [\text{Cu}] + k_3 K_2 [\text{Cu}] [\text{LIX}]^n [\text{Cx}]^m,$$

$r$  being the copper quantity extracted by volume and time unities.  $p$  is then proportional to  $[\text{Cx}] \{ k_1 + k_3 K_2 [\text{LIX}]^n [\text{Cx}]^{m-1} \}$ .

By plotting  $p/[\text{Cx}]$  versus  $[\text{LIX}]$  (Figure 2), a straight line is obtained; moreover  $p/[\text{Cx}]$  does not depend on  $[\text{Cx}]$ . So both  $n$  and  $m$  are equal to 1.

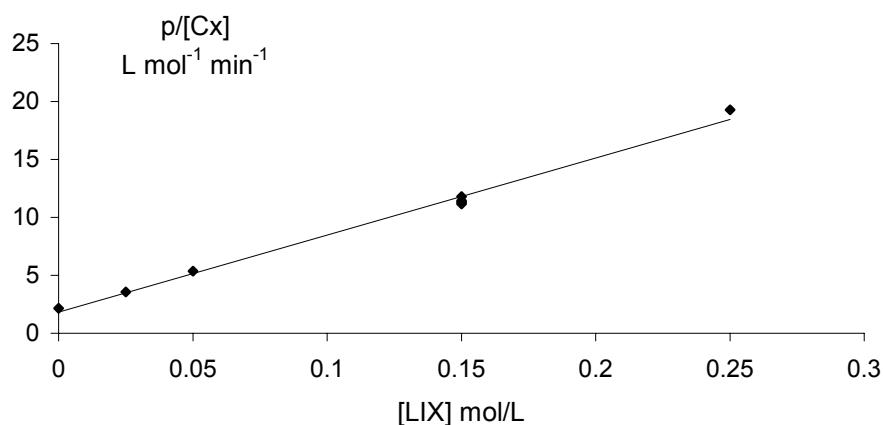

Figure 2. Testing of the kinetic model.

LIX 860 then acts as a catalyst for phase transfer.

### Stripping of copper

Again various mixtures of thiourea and sulphuric acid were studied. The concentration of LIX 860 was found to have no influence on the distribution ratio of copper:  $D = 0.09 \pm 0.006$  for LIX 860 between 0 and 0.05 mol/L. This result was obtained for a strip solution containing 0.1 mol/L thiourea and 1 mol/L sulphuric acid and for 0.028 mol/L Cyanex 302. The inference is that LIX 860 is not included in the stripping mechanism.

The results of stripping experiments for constant LIX 860 concentration (0.025 mol/L) are given in Table 3.

Table 3. Influence of various parameters on copper stripping from LIX 860/Cyanex 302.

Acid, mol/L	0.1	0.25	0.45	0.70	1	1	1	1	1	1	1
Thiourea, mol/L	0.1	0.1	0.1	0.1	0.1	0.05	0.075	0.15	0.2	0.1	0.1
Cyanex 302, mol/L	0.074	0.074	0.074	0.074	0.074	0.074	0.074	0.074	0.028	0.25	
D	4.6	2.5	1.1	0.8	0.6	5.0	1.5	0.16	0.07	0.09	3.2

The extracted complex is  $\overline{\text{CuA}_p(\text{HA})_q}$  with Cyanex 302 being mainly dimer,  $(\text{HA})_2$ .  $p$  may be equal to 1 or 2, depending whether copper is Cu(I) or Cu(II) in the organic phase. The complex of thiourea (TU) with copper involves only copper(I). So if the extracted complex contains Cu(II), this latter is reduced by thiourea during stripping, leading to the formation of formamidine disulfide (FDS).

The reaction equations for stripping may be written as follows:

Finally the distribution ratio of copper is expressed as follows:

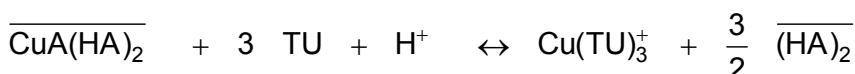

$$D = K \frac{\overline{[(\text{HA})_2]}^{\frac{p+q}{2}}}{[\text{TU}]^{r-p+1}} \frac{[\text{FDS}]}{[\text{H}^+]^p}^{\frac{p-1}{2}}$$

The slope method has given the following results:

- In  $D$  versus  $\ln [\text{H}^+]$  is a straight line of slope  $-1$
- In  $D$  versus  $\ln [\text{Cyanex 302}]$ : slope  $1.5$
- In  $D$  versus  $\ln [\text{TU}]$ : slope  $-3$

Then:  $p = 1$ ;  $q = 2$ ;  $r = 3$ .

The stripping equilibrium is then:

Copper is monovalent in the organic complex; it is reduced and extracted by Cyanex 302 at the same time. Cyanex 302 is oxidised to disulfide.

## COPPER ELECTRODEPOSITION

Electrodeposition was examined as a means of recovering copper from the loaded strip solution. The electrolysis device had a cathode consisting of a fixed bed of graphite pellets and two DSA anodes. Tests varying the thiourea concentration were performed using a current density of  $1.1 \text{ mA/cm}^2$  and a solution containing  $400 \text{ mg/L}$  copper and  $1 \text{ mol/L}$  sulphuric acid. For thiourea concentrations above  $0.2 \text{ mol/L}$ , there is no deposition. For lower concentrations, the rate of deposition is greater when the thiourea concentration is smaller. After 30 minutes the deposition yield is 25% for thiourea  $0.15 \text{ mol/L}$  and 60% for thiourea  $0.1 \text{ mol/L}$ . The feasibility of the process is then demonstrated.

A solution containing  $0.1 \text{ mol/L}$  thiourea and  $1 \text{ mol/L}$  sulphuric acid may be chosen; the copper electrodeposition is feasible, the stripping efficiency with such a solution is also convenient ( $> 90\%$ ). The solution coming from the electrodeposition step is optimally recycled to the stripping step provided thiourea is not reduced in the electrodeposition step; further experiments are needed to verify the feasibility of this recycling.

## PROCESS FLOWSHEET

The flowsheet shown in Figure 3 was tested at a micro-pilot scale in a continuous operation. The bath was agitated and the temperature maintained at  $60^\circ\text{C}$ . A concentrated copper solution ( $10 \text{ g/L}$ ) was continuously added to simulate the dissolution of copper from metal pieces. The bath composition was:  $2 \text{ mol/L}$  sulphuric acid,  $60 \text{ g/L}$  Fe(II),  $0.9 \text{ g/L}$  Fe(III) and  $9 \text{ mg/L}$  Cu. An aqueous phase (A) was withdrawn from the bath and sent to the extraction step (a single stage) from which it returned less concentrated in copper.

The stripping solution (L) comprised  $0.075 \text{ mol/L}$  thiourea and  $1 \text{ mol/L}$  sulphuric acid. This solution entered the stripping section (4 stages) without copper and leaves it with a rather high metal concentration.

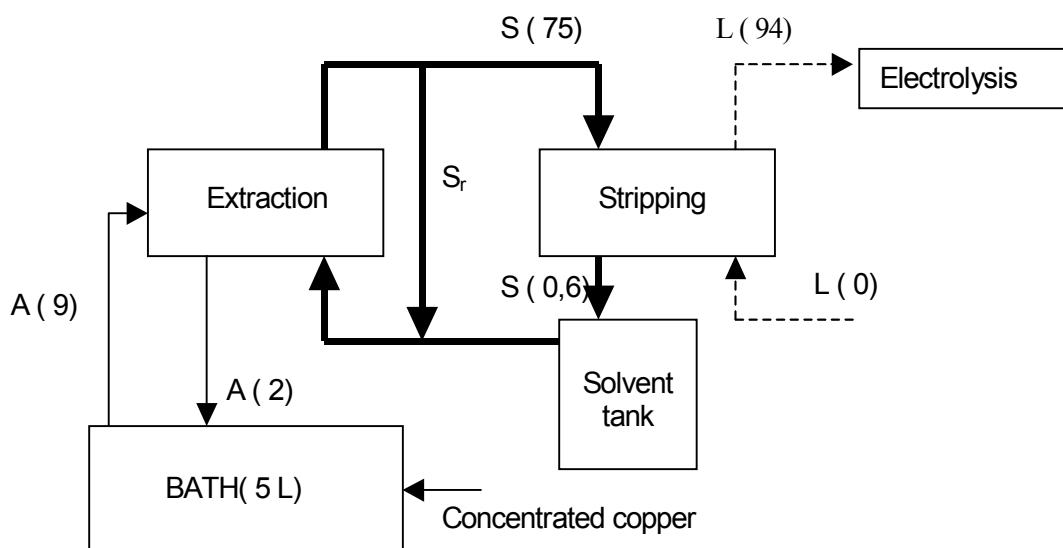

Figure 3. Flowsheet of the proposed process  
(the numbers in parentheses give the copper concentrations in mg/L).

The organic solution contained  $0.037 \text{ mol/L}$  Cyanex 302 and  $0.15 \text{ mol/L}$  LIX 860. Only a small part of this flow (S) goes to the stripping section; the major part ( $S_r$ ) is directly recycled to the extraction stage in order to increase the interfacial area in it.

For operation at the following flowrates: A = 160 mL/min; S = 15 mL/min;  $S_r$  = 85 mL/min; L = 13 mL/min, the steady-state (after 5 hours) copper concentrations (mg/L) indicated in parentheses in Figure 3 were obtained. The results show that only two stages of the stripping section are efficient; the flowrate of the stripping solution might therefore be reduced. The stripping solution contains only 10 mg/L Fe(III) which will be a very little nuisance for the electrolysis if the compartments of the device are separated.

A degradation of Cyanex 302 has been observed after 28 hours leading to a reduced extracting power. Cyanex 302 is oxidised by copper(II) during its extraction, this reaction being irreversible in the conditions of the process; this degradation is however reversible in reducing chemical conditions. It is then necessary to add in the process a Cyanex 302 regeneration by means of a reducing agent (nickel (0) or hydrogen) as proposed by Rickelton *et al.* [9].

## CONCLUSION

Technical viabilities of the proposed SX process for elimination of copper in pickling baths have been successfully demonstrated. At steady state the copper concentration of the bath is maintained to a low level (2 mg/L) as required; copper is recovered in the electrolysis step. Due to the degradation of Cyanex 302 a supplementary step of regeneration is necessary.

## COPPER RECOVERY FROM SPENT AMMONIACAL ETCHING SOLUTIONS

M. Rosinda, C. Ismael and Jorge M. R. Carvalho

Dep. Eng. Química, Instituto Superior Técnico, Lisboa, Portugal

The extraction of copper using LIX 84-I was investigated. It was established the extraction isotherm for the system LIX 84-I ( $\text{HR} = 0.72 \text{ M}$ ) in Shellsol T/ etching effluent ( $\text{Cu}^{2+} = 121.6 \text{ g.L}^{-1}$ ,  $\text{NH}_4\text{Cl} = 4 \text{ M}$  and  $\text{NH}_3 = 3 \text{ M}$ ). The stripping of a loaded organic phase (LIX 84-I =  $0.74 \text{ M}$ ,  $\text{Cu}^{2+} = 19.9 \text{ g.L}^{-1}$ ) was carried out with an aqueous solution of sulphuric acid ( $150 \text{ g.L}^{-1}$ ) and the stripping isotherm was produced. For both process (extraction and stripping) the number of stages required for an industrial situation was determined.

Copper extraction from acidic sulphate solutions using LIX 84-I was studied in order to define the stoichiometry of copper extraction and to calculate the value of 1.7 for the thermodynamic equilibrium constant.

### INTRODUCTION

Today because of environmental concerns there is a general trend to recycle resources and to minimize the discharge of effluents containing hazardous metals. Effluents from the printed circuit board industry contain  $130\text{-}160 \text{ g.L}^{-1}$  Cu and  $7\text{-}9 \text{ M}$  ( $\text{NH}_4\text{Cl} + \text{NH}_3$ ). The recovery of copper from such effluents is advantageous due to the economic value of the copper and to the effluent recycling possibilities the removal of copper presents.

The extraction of copper from ammoniacal media can be carried out with hydroxyoxime extractants [3-6]. In this study LIX 84-I (2-hydroxy-5-nonyacetophenone oxime) is used. To be able to simulate the solvent extraction process requires data relative to the equilibrium constants of the extracted metal. The values found in literature are valid only for specific extraction conditions [7,8]. It was therefore decided to introduce the thermodynamics of solutions, mainly the non-ideal behaviour of the aqueous phase (Pitzer's model [9]) in order to establish the thermodynamic equilibrium constants of the copper/LIX 84-I system.

The stoichiometry of the extraction equilibrium of copper with hydroxyoximes can be expressed as follows [10,11,12]:

The thermodynamic equilibrium constant (non-ideal aqueous solution) for this reaction is equal to:

$$K^o = \frac{c_{CuR_2.nHR,org} a_{H_{aq}^+}^{2+n}}{a_{Cu_{aq}^{2+}} c_{(HR)_m}^m} = \frac{c_{CuR_2.nHR,org} c_{H_{aq}^+}^{2+n}}{c_{Cu_{aq}^{2+}} c_{(HR)_m}^m} \frac{\gamma_{H^+}^2}{\gamma_{Cu^{2+}}} \quad (2)$$

where  $a$  is the activity,  $c$  the concentration and  $\gamma$  the activity coefficient.

The application of logarithms to this expression leads to:

$$\log D' = \log K^o - 2 \log a_{H_{aq}^+} + \frac{2+n}{m} \log c_{(HR)_m} \quad (3)$$

where  $D' = \frac{c_{CuR_2.nHR,org}}{a_{Cu_{aq}^{2+}}}$ . The expression (3) can be used.

## EXPERIMENTAL

### Reagents

LIX 84-I was kindly supplied by Cognis (Ireland) and was received diluted in an aliphatic hydrocarbon diluent (kerosene). The organic phases used, in this work, were obtained by dilution of LIX 84-I solution in Shellsol T (aliphatic hydrocarbon from Shell). A Portuguese printed circuit board producer supplied real effluent. Other aqueous solutions were prepared using pro-analysis chemical reagents.

### Equipment and Procedure

The organic and aqueous phases were contacted by vigorous mixing in a mechanical mixer with temperature control for at least 12 h. The concentrations of copper in both phases were analysed directly by atomic absorption spectrophotometry.

## RESULTS AND DISCUSSION

### Extraction and Stripping of Copper with LIX 84-I

Table 1 presents data relative to the loading capacity of LIX 84-I solutions achieved after two consecutive contacts of the organic phase with the real effluent (phase ratio A:O = 3:1, T = 25°C).

*Table 1. Loading capacity of LIX 84-I solutions.*

LIX 84-I* in Shellsol T (% (v/v))	Cu <sub>org</sub> (M)
5	0.051
10	0.107

\* LIX 84-I solution as received from Cognis

If it is assumed that copper exists in the loaded organic phase as the  $\text{CuR}_2$  complex, the Cognis solution contains 2.10 M LIX 84-I (*HR*). Taking this result into account it was decided to continue the extraction of copper from the real effluent with an organic phase containing 0.72 M hydroxyoxime. Figure 1 shows the extraction isotherm for the system copper/LIX 84-I. As can be observed, more than 99% of copper can be removed from the effluent in three stages at A:O phase ratio of 1:7.

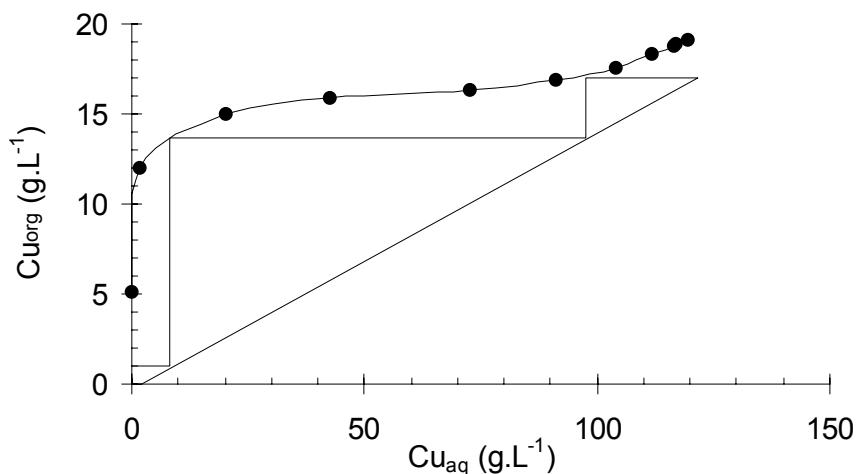

Figure 1. Equilibrium isotherm for copper extraction. (Aq. phase –  $\text{Cu} = 121.6 \text{ g.L}^{-1}$ ,  $\text{NH}_3 = 3 \text{ M}$ ,  $\text{NH}_4\text{Cl} = 4 \text{ M}$ ; Org. phase – LIX 84-I(*HR*) = 0.72 M in Shellsol T;  $T = 25^\circ\text{C}$ ).

Stripping of loaded organic phase ( $\text{Cu}^{2+}_{\text{org}} = 19.9 \text{ g.L}^{-1}$ ) was investigated using different concentrations of sulphuric acid solution and contacting at an A:O phase ratio 3:1. Copper removal of 75, 83, 86, 85, 85% was obtained for 50, 100, 130, 150, 200  $\text{g.L}^{-1}$  of  $\text{H}_2\text{SO}_4$ . The use of 150  $\text{g.L}^{-1}$   $\text{H}_2\text{SO}_4$  is adequate, this being the typical concentration in copper tank house electrolyte. Figure 2 shows that 99% copper stripping from loaded organic phase can be achieved in three counter-current stages at the A:O phase ratio of 1:2.5.

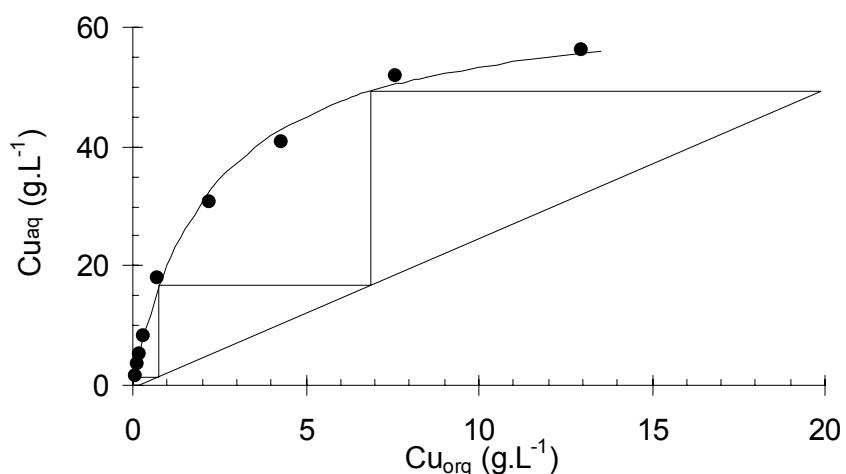

Figure 2. Equilibrium isotherm for copper stripping. (Aq. phase –  $\text{H}_2\text{SO}_4 = 150 \text{ g.L}^{-1}$ ; Org. phase – LIX 84-I(*HR*) = 0.74 M in Shellsol T,  $\text{Cu}^{2+} = 19.9 \text{ g.L}^{-1}$ ;  $T = 25^\circ\text{C}$ ).

These results allow the conclusion that the removal of copper with LIX 84-I, from ammoniacal media, is efficient. In consequence, there is a logical interest in the simulation of the extraction process. To achieve this purpose, different parameters are needed, including the equilibrium constant for the system copper/LIX 84-I.

### Equilibrium Studies in the System LIX 84-I/CuSO<sub>4</sub>/Na<sub>2</sub>SO<sub>4</sub>/H<sub>2</sub>SO<sub>4</sub>

The equilibrium studies were performed in sulphate/sulphuric acid media. In the CuSO<sub>4</sub>/Na<sub>2</sub>SO<sub>4</sub>/H<sub>2</sub>SO<sub>4</sub> system, assuming complete dissociation of Na<sub>2</sub>SO<sub>4</sub>, the species Cu<sup>2+</sup>, Na<sup>+</sup>, H<sup>+</sup>, SO<sub>4</sub><sup>2-</sup>, CuSO<sub>4</sub> and HSO<sub>4</sub><sup>-</sup> remain in solution. The calculus of the respective activities involves the following system of equations:

$$m_{HSO_4^-} + m_{SO_4^{2-}} = m_{(CuSO_4+H_2SO_4+Na_2SO_4)_{total}} \quad (4)$$

$$m_{Cu^{2+}} + m_{CuSO_4} = m_{(CuSO_4)_{total}} \quad (5)$$

$$m_{H^+} + m_{Na^+} + 2m_{Cu^{2+}} = m_{HSO_4^-} + 2m_{SO_4^{2-}} \quad (6)$$

$$Cu^{2+} + SO_4^{2-} \leftrightarrow CuSO_4 ; K_{CuSO_4}^o = \frac{\gamma_{CuSO_4}}{\gamma_{Cu^{2+}} \gamma_{SO_4^{2-}}} \times \frac{m_{CuSO_4}}{m_{Cu^{2+}} m_{SO_4^{2-}}} = 229 \quad (7)$$

$$HSO_4^- \leftrightarrow H^+ + SO_4^{2-} ; K_{a2}^o = \frac{\gamma_{H^+} \gamma_{SO_4^{2-}}}{\gamma_{HSO_4^-}} \times \frac{m_{H^+} m_{SO_4^{2-}}}{m_{HSO_4^-}} = 0.0105 \quad (8)$$

for m the molar concentration. The activity coefficients were estimated using Pitzer's model [9].

In order to define the stoichiometry and thermodynamic equilibrium constant for copper extraction studies, the influence of pH and extractant concentration on the equilibrium were studied. The use of equation 3 is helpful to define the stoichiometry of copper/LIX 84-I reaction. As shown in Figure 3, slopes of straight lines are ~ 2, which confirms the dependence of copper extraction on pH.

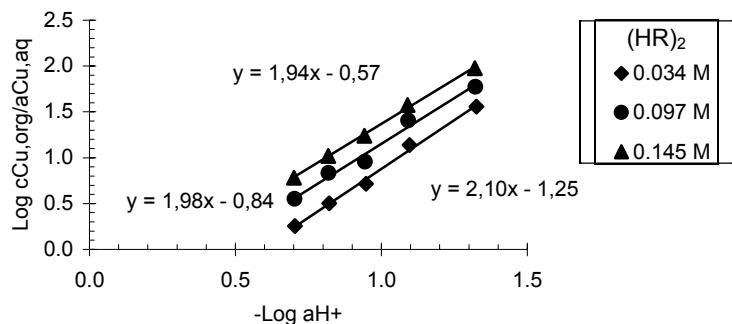

Figure 3. Influence of H<sup>+</sup> on copper extraction. (Aq. phase: CuSO<sub>4</sub> = 4.58 × 10<sup>-3</sup> mol/kg H<sub>2</sub>O; Na<sub>2</sub>SO<sub>4</sub>; H<sub>2</sub>SO<sub>4</sub> (Ionic strength = 0.70 M); Org phase: LIX 84-I ((HR)<sub>2</sub>) in Shellsol T; T=25°C).

The *log-log* plot of  $D_{\text{Cu}}$  versus  $(\text{HR})_2$  is shown in Figure 4. A straight line with slope equal to 1 was obtained, indicating the formation of  $\text{CuR}_2$ . Hence, the overall stoichiometry of the extraction equilibrium can be written as:

The extraction equilibrium constant,  $K^\circ$ , was determined from the intercept of straight lines shown in Figures 3 and 4. A value of 1.7 was obtained. This value is lower than the value of 13.2 obtained by Hu and Wiencek [12]. This discrepancy can be related to their use of a different diluent (tetradecane). Otherwise they assumed that LIX-84 molecules are monomers.

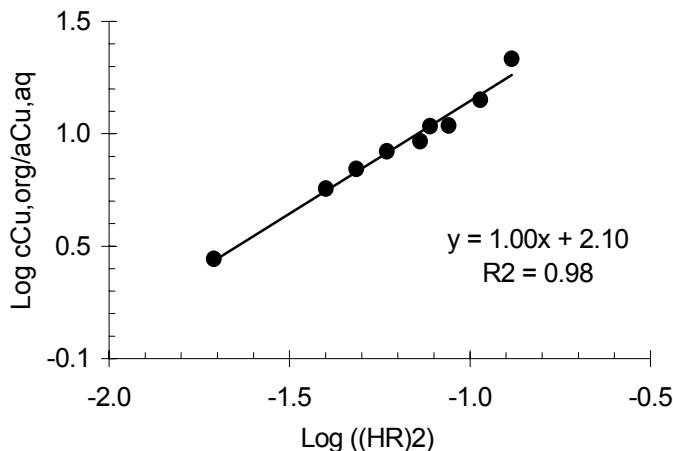

Figure 4. Influence of extractant concentration on copper extraction.  
(Aq. phase:  $\text{CuSO}_4 = 4.40 \times 10^{-3}$  mol/kg  $\text{H}_2\text{O}$ ;  $\text{Na}_2\text{SO}_4 = 0.184$  mol/kg  $\text{H}_2\text{O}$ ;  $\text{H}_2\text{SO}_4 = 0.207$  mol/kg  $\text{H}_2\text{O}$  (Ionic strength = 0.70 M); Org phase: LIX 84-I in Shellsol T;  $T = 25^\circ\text{C}$ ).

The effect of temperature on copper extraction was studied in the range  $19.5^\circ\text{--}60^\circ\text{C}$ . The results are shown in Figure 5.

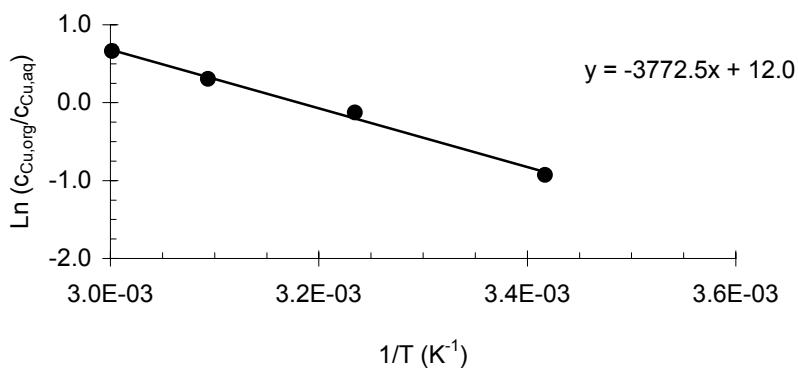

Figure 5. Influence of temperature on copper extraction. (Aq. phase:  $\text{CuSO}_4 = 4.37 \times 10^{-3}$  M;  $\text{Na}_2\text{SO}_4 = 0.181$  M;  $\text{H}_2\text{SO}_4 = 0.202$  M; Org phase:  $(\text{HR})_2 = 0.146$  M in Shellsol T; A/O = 1).

Analysing Figure 5 it is concluded that an increase in temperature reduces the extraction efficiency. Using the value of straight-line slope the  $\Delta H^\circ$  was calculated. This is  $31.3 \text{ kJ.mol}^{-1}$  indicating that the extraction process is endothermic.

## CONCLUSIONS

The extraction of copper from ammoniacal etching solution with LIX 84-I is very effective. The thermodynamic equilibrium constant for copper was determined to be 1.7. In the organic phase copper is in the form of CuR<sub>2</sub>.

Three stages are necessary to carry out either extraction or stripping, for 99% efficiency, under the following conditions:

- extraction of copper from an effluent from printed circuit board plant (copper = 121.6 g.L<sup>-1</sup>, NH<sub>4</sub>Cl = 4 M, NH<sub>3</sub> = 3 M using 0.72 M of LIX 84-I(HR) in Shellsol T) at A:O phase ratio of 1:7.
- stripping of loaded organic phase (LIX 84-I(HR) = 0.74 M, Cu<sup>2+</sup> = 19.9 g.L<sup>-1</sup>) with aqueous sulphuric acid solution (150 g.L<sup>-1</sup>) at A:O phase ratio of 1:2.5.

## ACKNOWLEDGEMENTS

The authors wish to thank to Helena Ribeiro, André Pereira, Ivo Reia, Miguel Pereira and Rodrigo Lourenço who carried out the experimental studies. Dr Werner Schwab (Cognis – Germany) and Cognis Ireland are thanked for providing the extractant used in this work.

## RECOVERY OF NICKEL FROM SPENT ELECTROLESS NICKEL PLATING BATHS BY SOLVENT EXTRACTION

Mikiya Tanaka, Mikio Kobayashi and Tsutomu Seki\*

National Institute of Advanced Industrial Science and Technology, Tsukuba, Japan  
\* Chiba Institute of Technology, Tsudanuma, Japan

For the purpose of establishing a recycling process for an electroless nickel plating bath, the solvent extraction and stripping of nickel from spent baths has been investigated using LIX 84I as the extractant. It is shown that nickel can be extracted with good selectivity at a pH greater than 6. A concentrated nickel sulfate solution ( $\text{Ni} > 100 \text{ kg/m}^3$ ) is obtained using 1 kmol/m<sup>3</sup> sulfuric acid, nickel sulfate ( $\text{Ni} 50 \text{ kg/m}^3$ ) solution as the stripping reagent. Organophosphorus extractants such as di(2-ethylhexyl)phosphoric acid and PC-88A are applicable to remove iron and zinc as impurities before the extraction of nickel with LIX 84I. PC-88A is more advantageous because the co-extraction of nickel is lower.

### INTRODUCTION

With the increasing importance of electroless nickel plating technology in many fields such as the electronic and automobile industries, the treatment of the spent baths is becoming a serious problem. These spent baths contain iron and zinc as impurities, organic acids as complexing reagents, and phosphonate ions as the oxidized species of the reducing reagent, as well as several grams per liter of nickel. The spent baths are currently treated by a conventional precipitation method, but a method with no sludge generation is desired. With this in mind, we are tackling the development of a nickel recycling process from the spent baths using solvent extraction and have recently reported the possibility of recovering nickel from a weakly acidic spent bath using a typical chelating reagent, LIX 84I [1-3].

In this paper, the applicability of LIX 84I for the recovery of nickel from three kinds of spent baths is studied together with the detailed stripping conditions. Removal of iron and zinc as impurities from the spent baths with organophosphorus acids [4] is also discussed.

### EXPERIMENTAL

#### Spent Baths and Reagents

Three kinds of spent baths (A, B, and C) discharged from an electroless nickel plating plant in Japan were used for the extraction experiments. Chemicals used in this experiment were all reagent grade except for the extractants and diluent. LIX 84I (Cognis), di(2-ethylhexyl)phosphoric acid (D2EHPA, Daihachi), and PC-88A (Daihachi) were used as received. These were respectively dissolved in Shellsol D70 (Shell Chemicals) in order to prepare the working organic phases. The concentrations of the extractants were 20 vol% for LIX 84I and 10 vol% for D2EHPA and PC-88A. Various concentrations of sodium hydroxide and hydrochloric acid as well as ion exchange-distilled water were used as pH adjusting reagents.

### **Extraction, Stripping, and Analysis**

In the experiment investigating the pH dependency of the extraction, the working organic phase, spent bath, and pH adjusting reagent were poured into a stoppered conical flask at a volume ratio of 5:4:1, and shaken in a water bath maintained at  $298 \pm 0.1\text{K}$  for more than 24 hours to ensure equilibrium. After shaking, the mixture was centrifuged, and the organic phase was pipetted out. In the nickel stripping experiment, the organic phase containing  $8.77\text{ kg/m}^3$  was first prepared by contacting 20 vol% LIX 84I with  $1.00\text{ kmol/m}^3 (\text{NH}_4)_2\text{SO}_4$ - $0.1\text{ kmol/m}^3 \text{NiSO}_4$ - $0.4\text{ kmol/m}^3 \text{NaOH}$  solution at a volume ratio of 1:3 in a separatory funnel at room temperature followed by washing with water. The organic phase obtained was then contacted with  $0.92\text{ kmol/m}^3 \text{NiSO}_4$ - $1.00\text{ kmol/m}^3 \text{H}_2\text{SO}_4$  solution (nickel concentration was  $54.0\text{ kg/m}^3$ ) at different volume ratios in the same manner as in the extraction experiment. The metal contents in the aqueous phases after extraction and stripping were determined by ICP-AES (Seiko SPS4000). The metal contents in the organic phase after extraction and stripping were determined by ICP-AES after stripping the metals in the organic phases using an excess volume of  $1\text{-}2\text{ kmol/m}^3$  hydrochloric acid. The pH values in the aqueous phases were measured by a pH meter (Toa HM-50AT). Sulfate, phosphinate, and phosphonate ions as well as the organic acids in the spent baths were determined by a capillary electrophoresis apparatus (Otsuka CAPI-3200).

## **EXPERIMENTAL RESULTS AND DISCUSSION**

### **Compositions of the Spent Baths**

The compositions and pH values of the spent baths were measured, and the results are shown in Table 1. Spent bath A is a typical weakly acidic bath with a high accumulation of phosphonate and sulfate ions. Spent bath B is also weakly acidic; however, the concentrations of the phosphonate and sulfate ions are low and that of zinc is the highest among these three baths. Spent bath C is almost neutral and contains boron with a high accumulation of phosphate and sulfate ions.

*Table I. The compositions ( $\text{kg/m}^3$ ) and pH values of the spent baths A, B, and C.*

Component	A	B	C	Component	A	B	C
Sodium	66	24	90	Lactic acid	31	3	8
Nickel	4	6	6	Propionic acid	2	0	35
Iron	0.1	0.003	0	Malic acid	0	24	0
Zinc	0.01	0.07	0.007	Succinic acid	0	7	0
$\text{SO}_4^{2-}$	48	7	64	Boron	0	0	0.8
$\text{H}_2\text{PO}_2^-$	16	19	12	Glycine			30
$\text{HPO}_3^{2-}$	98	17	100	pH	4.5	4.8	6.0

### **Extraction with LIX 84I**

Figures 1, 2, and 3 show the extraction percentages of nickel, iron, and zinc with LIX 84I as a function of the equilibrium pH values from the spent baths A, B, and C, respectively.

In spent baths A and B, when water is used as a pH adjusting reagent (that is, the extraction was done substantially without pH adjustment), the extraction percentages of nickel are only 34% (pH 4.1) and 43% (pH 4.4), respectively. However, when the pH is increased to greater than 6, the extraction percentages of nickel are enhanced to more than 99.9% (99.94% at pH 6.2 and 99.97% at pH 6.1 for spent baths A and B, respectively). Since the extraction percentages of iron and zinc are low throughout the pH range in this experiment, it is expected to selectively extract nickel leaving most of iron and zinc in the raffinate.

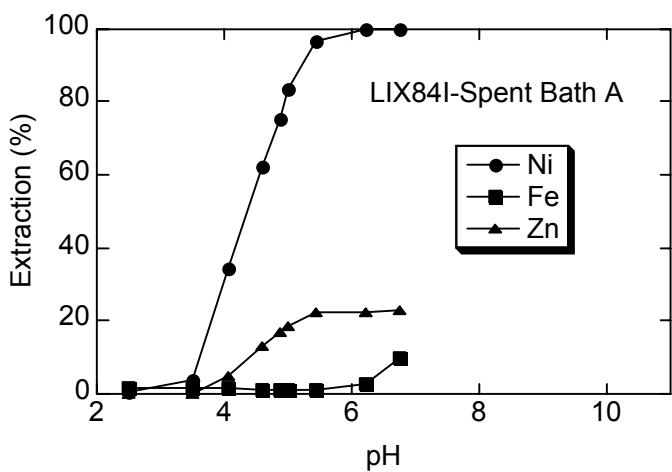

Figure 1. The effect of equilibrium pH on the extraction of metals from spent bath A with 20 vol% LIX 84I dissolved in Shellsol D70 at 298K.

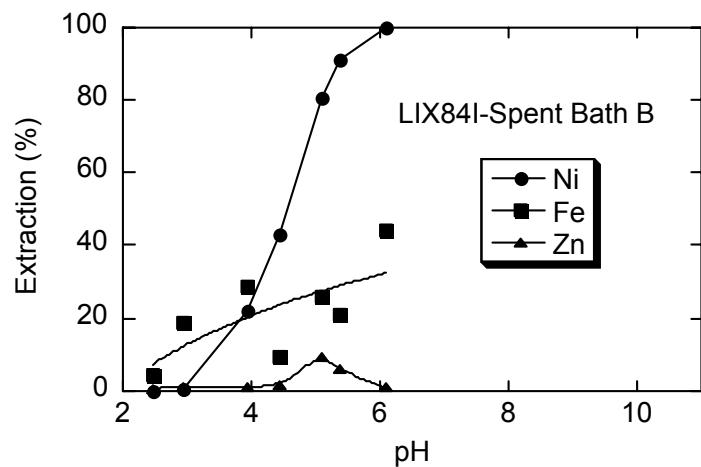

Figure 2. The effect of equilibrium pH on the extraction of metals from spent bath B with 20 vol% LIX 84I dissolved in Shellsol D70 at 298K.

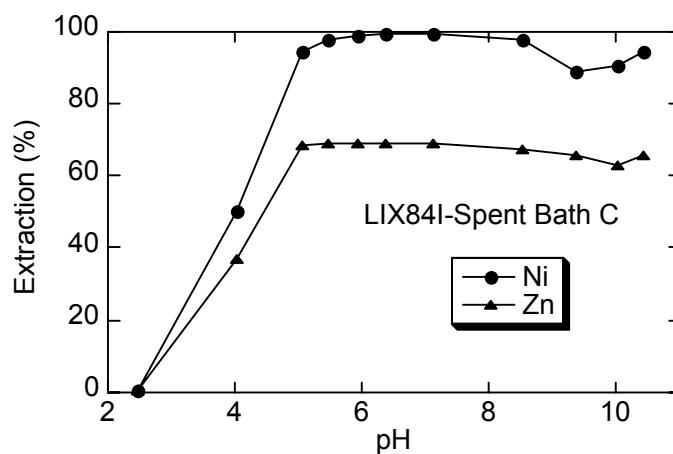

Figure 3. The effect of equilibrium pH on the extraction of metals from spent bath C with 20 vol% LIX 84I dissolved in Shellsol D70 at 298K.

In spent bath C, when the extraction is done substantially without pH adjustment, the extraction percentage is greater than 99.0% (pH 5.9). About 70% of the zinc was also extracted when the pH is greater than 5; however, the concentration of zinc in the spent bath C is so low that the coextraction of zinc would cause little problem when the recovered nickel is reused in the electroless plating process.

The McCabe-Thiele analysis of the nickel extraction isotherm of spent bath A at the initial pH of 6.4 reveals that when the ratio of the flow rates (aqueous to organic) is 2, the number of stages necessary to completely extract the nickel by countercurrent contact is 2. By using the two-stage extraction, 4 kg/m<sup>3</sup> nickel in spent bath A would be reduced to 0.0006 kg/m<sup>3</sup> [2, 3].

### Stripping of Nickel from LIX84I with Sulfuric Acid

In our previous studies [2,3], the effect of pH on the nickel stripping percentage with sulfuric acid was studied at 298K using 20 vol% LIX 84I dissolved in Shellsol D70 containing 9.1 kg/m<sup>3</sup> of nickel. As a result, more than 99% of the nickel was stripped at the equilibrium pH of less than 2.7 (the initial sulfuric acid concentration was greater than 0.17 kmol/m<sup>3</sup>). The concentration of nickel in the obtained aqueous phase after stripping was low, because the phase ratio in that experiment was unity. For the reuse of the recovered nickel sulfate solution as a source of nickel for the electroless nickel plating baths, the concentration of nickel should be as high as possible, and the free sulfuric acid remaining in the solution should be as low as possible.

In order to assess the operational conditions for obtaining such a solution, the stripping isotherm of nickel from nickel-loaded LIX 84I was constructed using the 0.92 kmol/m<sup>3</sup> NiSO<sub>4</sub>-1.00 kmol/m<sup>3</sup> H<sub>2</sub>SO<sub>4</sub> solution as the stripping reagent (Figure 4). The stoichiometric relation of the stripping of nickel from LIX 84I by acid is known to be expressed by the following equation [2,3].

Here, HR and the bar denote the monomer of the active component of LIX 84I and the organic phase species, respectively. As seen in this equation, one nickel ion in the organic phase exchanges with two hydrogen ions in the aqueous phase during stripping. The dotted line in Figure 4 signifies the theoretical maximum nickel concentration after stripping calculated by assuming that all of the hydrogen ions in the sulfuric acid are exchanged with the nickel ion in the organic phase when the amount of nickel in the initial organic phase stoichiometrically exceeds that of the hydrogen ion in the initial aqueous phase.

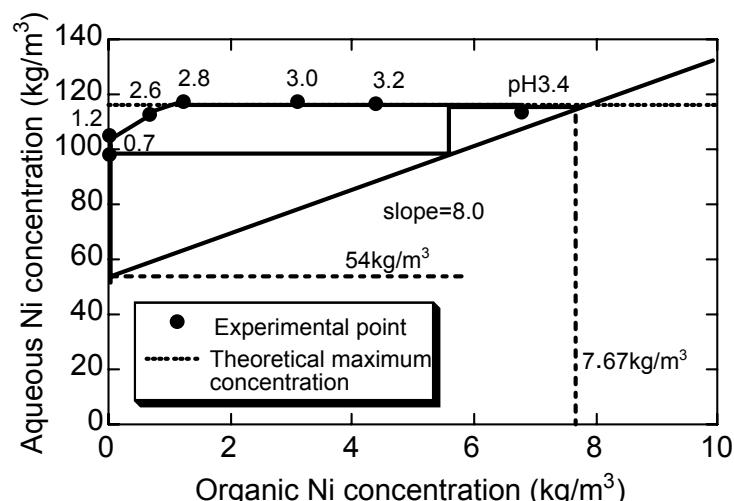

Figure 4. Stripping isotherm of nickel from 20 vol% LIX 84I dissolved in Shellsol D70 containing 8.77 kg/m<sup>3</sup> of nickel with 0.92 kmol/m<sup>3</sup> NiSO<sub>4</sub>-1.00 kmol/m<sup>3</sup> H<sub>2</sub>SO<sub>4</sub> solution.

According to the experimental results, with the increasing nickel concentration in the organic phase, the nickel concentration in the aqueous phase is enhanced, reaches the theoretical maximum value ( $117 \text{ kg/m}^3$ ) when the nickel concentration in the organic phase is  $1.21 \text{ kg/m}^3$ , and remains almost constant thereafter. The pH value continues to increase after the nickel concentration in the aqueous phase becomes almost constant and seems to approach 4.99, which is the pH value of the  $1.92 \text{ kmol/m}^3$  nickel sulfate solution ( $117 \text{ kg/m}^3$  nickel). This suggests that a small amount of hydrogen ion in the aqueous phase is exchanging with nickel in the organic phase even after the nickel concentration in the organic phase becomes almost constant.

The McCabe-Thiele analysis reveals that when the ratio of the flow rates (organic to aqueous) is 8 and the nickel concentration in the feed organic phase is  $7.67 \text{ kg/m}^3$ , two stage countercurrent contact can reduce the nickel concentration in the organic phase to a trace level and concentrate the nickel in the aqueous phase from  $54 \text{ kg/m}^3$  to  $117 \text{ kg/m}^3$ .

As shown here, it is possible to obtain concentrated nickel sulfate solution (nickel concentration  $> 100 \text{ kg/m}^3$ ) at pH 3.3. The impurity contents in this solution would be sufficiently low and thus can be used as a nickel source for the electroless nickel plating process.

Although the use of the concentrated nickel sulfate solution as the stripping reagent would depress the stripping efficiency as shown in equation (1), it enables one to obtain very concentrated nickel sulfate solution which is convenient for recycling to electroless nickel plating process.

### **Extraction with D2EHPA and PC-88A**

In order to recover nickel with a higher purity and simplify the treatment of the aqueous raffinate after the extraction with LIX 84I, the application of D2EHPA and PC-88A has been investigated by using spent bath B to remove iron and zinc before extracting the nickel with LIX 84I.

Figures 5 and 6 present the extraction percentages of nickel, iron, and zinc as a function of the equilibrium pH values with D2EHPA and PC-88A, respectively. When water is used as the pH adjusting reagent; that is, the extraction is substantially done without any pH adjustment, the extraction percentages of nickel, iron, and zinc with D2EHPA were 20%, 100%, and 90%, respectively (pH 4.3), while those with PC-88A were 1%, 100%, and 95% (pH 4.6). Thus, both extractants exhibit a high extraction ability for iron and zinc without pH adjustment. Since the extraction percentage of nickel with PC-88A is lower than that with D2EHPA, PC-88A is more suitable for the selective extraction of iron and zinc.

## **CONCLUSIONS**

LIX84I is capable of extracting nickel from spent electroless nickel plating baths with good selectivity at pH values greater than 6. Nickel extracted by LIX84I can be stripped with  $1 \text{ kmol/m}^3$  sulfuric acid solution. When nickel sulfate ( $50 \text{ kg/m}^3$  nickel) is added to the stripping reagent, it is possible to obtain a concentrated nickel sulfate solution ( $> 100 \text{ kg/m}^3$  nickel) containing a very low amount of free sulfuric acid by countercurrent contact with 2 stages. This nickel sulfate solution could be reused in the electroless nickel plating process.

Iron and zinc as impurities in the spent baths can be removed with an organophosphorus acid extractant such as D2EHPA and PC-88A before the nickel extraction with LIX84I. The pH adjustment is not necessary in this case. PC-88A is more suitable for this purpose than D2EHPA because the co-extraction of nickel is lower. This process will simplify the treatment of the raffinate after nickel extraction and will contribute to produce higher purity nickel sulfate.

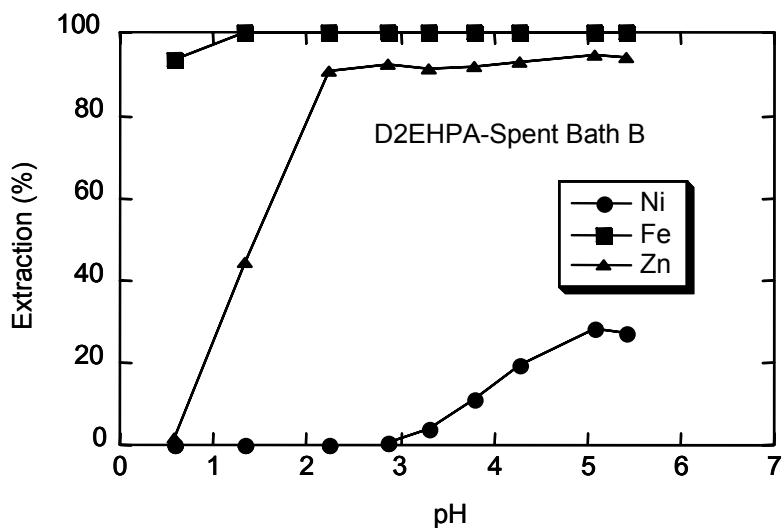

Figure 5. The effect of equilibrium pH on the extraction of metals from spent bath B with 10 vol% D2EHPA dissolved in Shellsol D70 at 298K.

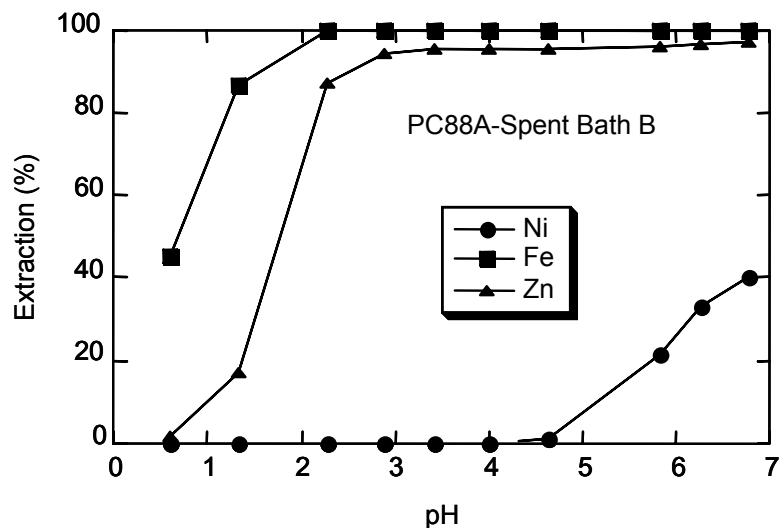

Figure 6. The effect of equilibrium pH on the extraction of metals from spent bath B with 10 vol% PC-88A dissolved in Shellsol D70 at 298K.

## RECOVERY OF COBALT AND NICKEL FROM SPENT CATALYSTS USING CYANEX 923

Bina Gupta, S. N. Tandon and Akash Deep

Department of Chemistry, University of Roorkee, Roorkee, India

The present communication reports the extraction behaviour of Co(II) and Ni(II) along with Cr(VI), Mo(VI), Al(III), Fe(III), Mn(II), Cu(II), Zn(II) and Pb(II) from HCl medium in Cyanex 923. Co(II) is quantitatively extracted while Ni(II) remains in the aqueous phase. The effect of extractant and metal ion concentration on the partition of Co(II) is investigated and the recycling capacity of Cyanex 923 determined. Based on the extraction data it has been possible to achieve some topical separations involving Co(II) and Ni(II). The commercial utility of the extractant is demonstrated by recovering high purity cobalt and nickel from spent catalysts.

### INTRODUCTION

Cobalt and nickel are two very vital metals because of their diverse industrial applications. There has been a rapid depletion in their mineral reserves resulting in to increasing interest in their recovery from the secondary sector. Liquid-liquid extraction has been commonly used for the said purpose and from time to time a variety of commercial extractants have been explored. Carboxylic acids, high molecular weight amines, oximes,  $\beta$ -diketones and aromatic hydroxyoximes suffer from the problem of solvent loss or require a strict control of aqueous-phase parameters for attaining the separations involving these metals. Among the alkylphosphorus extractants, D2EHPA [1,2] has been more frequently employed for recovering these metals but its use is limited because of emulsion formation at a higher pH and its hydrolytic stability. Of organophosphines of the Cyanex series, Cyanex 272 [3] and Cyanex 301 [4] have been applied for the mutual separation of Co(II) and Ni(II) and their isolation from commonly associated metal ions. The authors found that Cyanex 923 (a mixture of four trialkylphosphine oxides namely  $R_3P=O$ ,  $R_2R'P=O$ ,  $RR'_2P=O$ ,  $R'_3P=O$ , where R and R' represent *n*-octyl and *n*-hexyl groups, respectively) offers a convenient alternative for separations involving cobalt and nickel. The present communication embodies the extraction behaviour of Co(II) and Ni(II) in a toluene solution of Cyanex 923 from hydrochloric acid medium. The stoichiometry of the extracted Co(II) species is assessed and loading capacity of Cyanex 923 determined. The extraction of a number of commonly associated metal ions, namely Cr(VI), Mo(VI), Al(III), Fe(III), Mn(II), Cu(II), Zn(II) and Pb(II), has also been investigated. Based on the distribution data, the conditions for some important binary separations involving Co(II) and Ni(II) are optimized. This background has been used for the recovery of high purity cobalt from spent Co-Mn and Co-Mo catalysts and nickel from hydrogenation catalyst. The extractant can be recycled for use.

## EXPERIMENTAL

Stock solutions of metal ions were prepared by dissolving their salts of analytical purity in double-distilled water containing a minimum amount of the acid. The chemicals and organic solvents were analytical reagent grade materials from E.Merck/Thomas Baker, Mumbai, India. Cyanex 923 was received as a gift sample from Cytec Inc., Canada, and used without further purification. The spent catalysts were procured from the concerned industries in India.

Atomic absorption spectrometry (Perkin Elmer, 3100 USA) or inductively coupled plasma atomic emission spectrometry (Plasmalab, 8440 Australia) were used for the determination of metal ion concentrations.

For the partition studies, equal volumes of aqueous (metal ion solution in mineral acid) and organic phases were shaken for five minutes to ensure complete equilibration. After separation the two layers were isolated and the concentration of metal in the aqueous phase was assayed. The experimental conditions for the various studies are mentioned along with the corresponding data. The value of percent extraction of Co(II) at about 60% exhibits a coefficient of variance  $\pm 3\%$ .

About 1 g of powdered material was treated with  $2 \times 40$  mL of 8 mol/L HCl. The contents were heated, cooled and filtered. The final volume of the solution was made up to 100 mL keeping the overall acidity to 8 mol/L. The initial solutions of spent Co-Mn, Co-Mo and Ni hydrogenation catalysts were marked as Ai, Bi and Ci, respectively. In order to get a representative value three different samples of each matrix were processed by following the proposed extraction steps. The different results reported are an average of a minimum of two determinations.

## RESULTS AND DISCUSSION

### Extraction Behaviour of Metal Ions ( $1 \times 10^{-3}$ mol/L) from 1-10 mol/L HCl using 0.5 mol/L Cyanex 923

The variation in the percent extraction of Co(II) and Ni(II) along with Cr(VI), Mo(VI), Al(III), Fe(III), Mn(II), Cu(II), Zn(II) and Pb(II) with varying HCl concentration is shown in Figure 1. Co(II) shows an increasing trend in its extraction with an increasing HCl molarity whereas the extraction of Ni(II) is negligible (<3%) over the entire range of acidity investigated. Cu(II) and Pb(II) also show an increasing extraction with increasing acidity. A quantitative extraction (>95%) of Mo(VI), Fe(III) and Zn(II) is observed over a fairly wide range of acidity. The percent extraction of Cr(VI) decreases with increasing HCl molarity. Al(III) and Mn(II) show negligible (<3%) extraction in Cyanex 923 and their behaviour is not shown in the plot. The studies on the extraction behaviour of Co(II) and Ni(II) from 1-10 mol/L H<sub>2</sub>SO<sub>4</sub> and HNO<sub>3</sub> revealed that both of these metal ions are very poorly extracted (<3%) from these media. The subsequent studies were carried out using a  $1 \times 10^{-3}$  mol/L solution of Co(II) in 5 mol/L HCl using 0.5 mol/L Cyanex 923, unless stated otherwise.

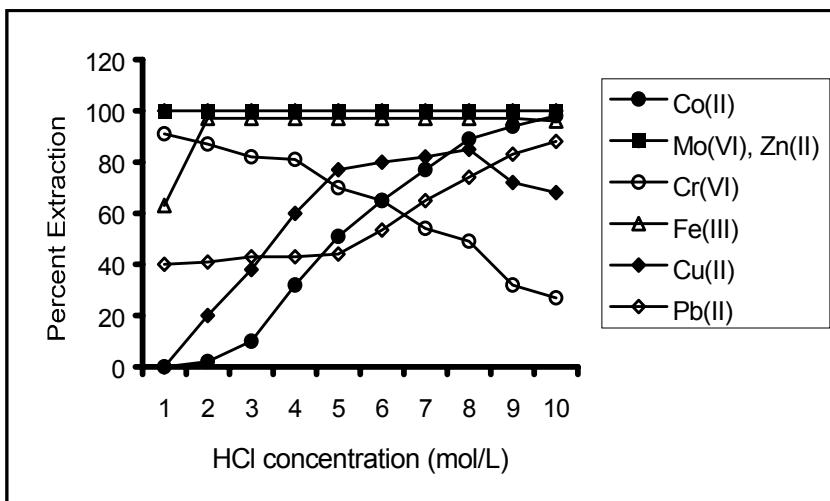

Figure 1. Extraction behaviour of metal ions.

#### Effect of Cyanex 923 Concentration

The effect of Cyanex 923 concentration (0.05-0.5 mol/L) on the partition of Co(II) was investigated. The results are shown in Figure 2. This gives a straight line with the slope around 2, thus suggesting the involvement of two Cyanex 923 molecules in the formation of the extracted Co(II) species.

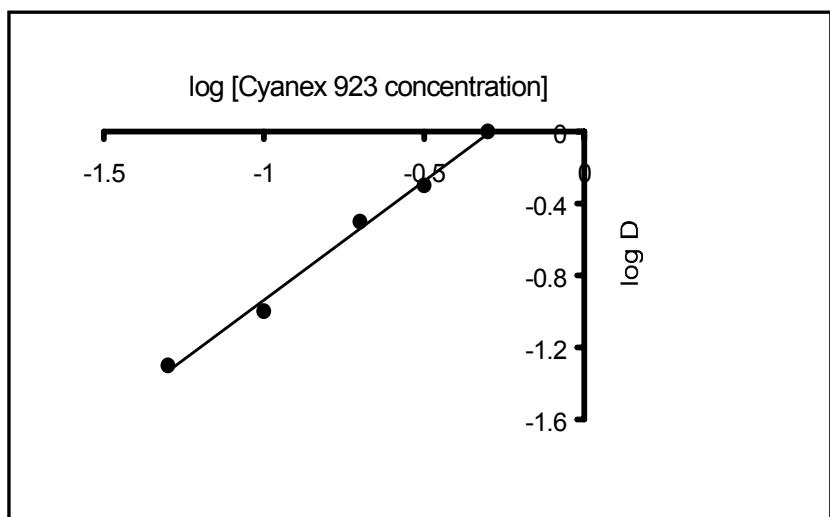

Figure 2. Effect of Cyanex 923 concentration on the extraction of Co(II).

#### Effect of Metal Ion Concentration

The effect of variation in the metal ion concentration ( $1 \times 10^{-5}$  – 0.6 mol/L) on the distribution of Co(II) from 6 mol/L HCl employing 0.4 mol/L Cyanex 923 gives a linear relation in the concentration range  $1 \times 10^{-5}$  – 0.2 mol/L Co(II). This indicates that the partitioning species of Co(II) does not change in this range of metal ion molarity. Beyond 0.2 mol/L, loading conditions start setting in. The percent extraction of Co(II) at the loading conditions is around 60% and therefore the metal concentration in the organic phase is calculated to be around 0.12 mol/L. It may be proposed that Cyanex 923 molecule can hold Co(II) up to a maximum of one half of its molar concentration.

### Stripping

A number of aqueous solutions were employed for the quantitative recovery of Co(II) from the organic layer. A minimum of four volumes of water, 1 mol/L HCl / H<sub>2</sub>SO<sub>4</sub> / HNO<sub>3</sub>, 8 mol/L H<sub>2</sub>SO<sub>4</sub> / HNO<sub>3</sub>, 0.3 mol/L EDTA and 0.2 mol/L oxalic / citric / tartaric acid can be used for the quantitative stripping of Co(II). Mo(VI) is stripped by employing 5% (NH<sub>4</sub>)<sub>2</sub>CO<sub>3</sub> solution in 10% NH<sub>3</sub>.

### Recycling Capacity of Cyanex 923

Successive extraction-stripping cycles were carried out to study the recycling power of Cyanex 923. Co(II) was extracted using 0.5 mol/L Cyanex 923 followed by stripping employing 8 mol/L H<sub>2</sub>SO<sub>4</sub>. The organic phase after stripping was washed with water until the washings were neutral. The recovery of each step was calculated from the amount of Co(II) was extracted in the organic phase in that particular cycle. It was observed that there was no significant decrease in the percent extraction (62-60%) / stripping (99-98%) of Co(II) up to fifteen cycles.

### Separtions

The partition data have been utilized to assess the separation of Co(II) and Ni(II) from other associated metals. The experimental conditions and recovery of metal ions are given in Table 1. Co(II) was separated from Ni(II) / Mn(II) by extracting the former at 8 mol/L HCl. Cr(VI) / Mo(VI) / Fe(III) / Zn(II) was separated from Co(II) / Ni(II) by extracting the first metal ion selectively over Co(II) / Ni(II) from 2 mol/L HCl. The extracted metal ions except Mo(VI) were recovered using 0.2 mol/L oxalic acid. The stripping of Mo(VI) was carried out by using 5% (NH<sub>4</sub>)<sub>2</sub>CO<sub>3</sub> in 10% NH<sub>3</sub>. The isolation of Ni(II) from Cu(II) was attained by achieving the selective extraction of Cu(II) from 8 mol/L HCl.

Table 1. Separation of Co(II) and Ni(II) ( $1 \times 10^{-3}$  mol/L) from Cr(VI) / Mo(VI) / Al(III) / Fe(III) / Mn(II) / Cu(II) / Pb(II) using (2 x vol) 0.5 mol/L Cyanex 923.

Metal ions	HCl conc. (mol/L)	Recovery of Co(II) <sup>a</sup> (%)	Ni(II) / Co(II) / Al(III) / Mn(II) remaining in aqueous phase (%)	Recovery of Cr(VI) <sup>b</sup> / Mo(VI) <sup>c</sup> / Fe(III) <sup>b</sup> / Cu(II) <sup>b</sup> / Zn(II) <sup>b</sup> (%)
Co(II)-Cr(VI)	2		97	95
Co(II)-Mo(VI)	2		96	96

a Recovered using 4(vol) x 1 mol/L H<sub>2</sub>SO<sub>4</sub>

b Recovered using 4(vol) x 0.2 mol/L oxalic acid

c Recovered using 4(vol) x 5% (NH<sub>4</sub>)<sub>2</sub>CO<sub>3</sub> in 10% NH<sub>3</sub>

### Recovery of Cobalt and Nickel from Spent Catalyst

10 mL of Ai, Bi and Ci were separately equilibrated with two volumes of 0.5 mol/L Cyanex 923. It quantitatively extracted Co(II) along with other metal ions, namely Mo(VI), Cr(VI), Fe(III) and Zn(II). In case of spent Ni hydrogenation catalyst solution (Ci), the above operation leaves pure Ni(II) in the aqueous solution and this was labeled as (Cf). The Co(II) content present in the organic layers of (Ai) and (Bi) was stripped by using 8 mol/L H<sub>2</sub>SO<sub>4</sub> and 2 mol/L HCl, respectively. The final recovered cobalt solutions were labeled as (Af) and (Bf). For recycling, the organic phase was washed with water, 0.5 mol/L oxalic acid, 5% (NH<sub>4</sub>)<sub>2</sub>CO<sub>3</sub> in 10% NH<sub>3</sub> (to recover pure Mo, if present) and water. Table 2 gives the compositions of (A), (B) and (C) before and after extraction.

*Table 2. Composition of spent Co-Mn (A), Co-Mo (B), and Ni hydrogenation (C) catalysts before and after extraction steps.*

Sample	Metal ions present	Concentration in initial solution (mg/L)	Concentration in final solution (mg/L)	Co purity (%)	Co recovery (%)
Spent Co-Mn catalyst	Co	497	469	$99.7 \pm 0.1$	$94 \pm 3$
	Al	32.2	< 0.01		
	Ni	13.3	< 0.01		
	Cr	5.53	0.25		
	Cu	5.8	1.14		
Spent Co-Mn catalyst	Co	155	147	$99.7 \pm 0.1$	$95 \pm 3$
	Mo	331	0.34		
	Al	291	< 0.01		
	Fe	35.2	0.13		
	Zn	8.52	0.04		
Spent Ni catalyst	Ni	2656	2598	$99.5 \pm 0.2$	$98 \pm 1$
	Fe	802	3.56		
	Cu	57.2	4.71		
	Zn	5.67	< 0.01		
	Cr	2.74	0.12		
	Mn	1.78	1.82		
	Co	1.32	0.03		

## CONCLUSIONS

The present investigations highlight the potential of Cyanex 923 for achieving a number of topical separations involving cobalt and nickel. The methods are convenient and require no strict control on phase variables. The extractant is easy to recycle and offers quicker phase separation. The loading capacity of Cyanex 923 for Co(II) is also good. The recovery process is simple and a fewer number of counter-current extraction steps will be sufficient to obtain high purity metals.

## ACKNOWLEDGMENTS

The authors are thankful to Cytec Canada, Inc. for providing the Cyanex 923 extractant. Financial support of Council of Scientific and Industrial Research and University Grant Commission, India, is gratefully appreciated.

## CYANIDE RECOVERY BY SOLVENT EXTRACTION

David Dreisinger, Berend Wassink, Keren Ship\*, James King\*,  
Marilyn Hames\* and Ralph Hackl\*

The University of British Columbia, Vancouver, Canada  
\*Placer Dome Technical Services, Vancouver, Canada

Cyanide is the preferred reagent for gold extraction from ores and concentrates. Cyanide is used in dilute concentration in solution so as to minimize cost and potential environmental impact. Residual cyanide in waste slurries or solutions is conveniently destroyed using either a chemical or biological process. Some ores and concentrates require higher concentrations of cyanide for leaching due to the presence of cyanide soluble copper or other species in solution. For these ores, it may be desirable to introduce cyanide recovery to reduce the net cost of gold extraction. Many of the current cyanide recovery processes (e.g., acidification/volatilization/re-neutralization (AVR) or sulfidization/acidification/ recycle/ thickening (SART)) produce acidic solutions containing soluble HCN. Soluble HCN can be recycled by direct neutralization or by volatilization/re-neutralization. The volatilization of HCN with air is undesirable due to the potential safety hazard of handling gaseous HCN and the high cost of air stripping/scrubbing columns. In this work, a solvent extraction alternative to HCN volatilization has been studied. The organophosphorus solvating extractants Cyanex 923, di-butyl-butyl-phosphonate and tri-butyl phosphate strongly extract HCN from aqueous solution. HCN may be conveniently stripped with any suitable alkali to reconstitute a strong cyanide solution for recycle.

### INTRODUCTION

The cyanidation of copper-gold ores containing the common oxide and secondary sulfide copper minerals results in irreversible cyanide degradation (to  $\text{CNO}^-$  and  $\text{CNS}^-$ ) and copper solubilization as cuprous cyanide complexes. Some of the possible reactions are shown below.

In conventional gold processing, the copper and complexed cyanide are not recovered after the gold is removed from solution (for example by carbon adsorption). This results in a significant economic penalty in excess cyanide consumption (beyond that converted to

cyanate and thiocyanate or to other metal cyanide complexes) and loss of a potentially valuable copper by-product. A variety of approaches have been investigated for copper and cyanide recovery including solvent extraction of copper cyanide, ion exchange methods and electrowinning of copper [1-5]. Unfortunately none of these processes have found commercial application.

The SART process is often selected for cyanide recovery. The SART process has basically two chemical steps – sulfidization/acidification and re-neutralization. The re-neutralization may be performed directly on the acidified solution (after copper sulfide filtration) or may be linked to a volatilization step. In either case, the chemistry of re-neutralization is identical.

#### Step 1. Acidification in the presence of NaSH

#### Step 2. Volatilization/Re-neutralization

The SART process is inherently very simple and effective. Unfortunately, volatilization and re-neutralization of HCN is potentially dangerous and expensive. In this study [6], the use of solvent extraction for HCN recovery was investigated. The organophosphorus extractants were selected for investigation.

## EXPERIMENTAL

Cyanex 923, di-butyl-butyl-phosphonate (DBBP) and tri-butyl phosphate (TBP) were used in this study. Cytec Inc. (Niagara Falls, Canada) and Albright and Wilson (USA) provided the extractant samples. The extractants were used at full strength or diluted with a kerosene diluent (Exxsol D-80 from Exxon Chemicals Canada). Organic liquids containing TBP, DBBP and Cyanex 923 were prepared at 100%, 50% and 25% extractant strength.

Synthetic solutions containing HCN were prepared. Aqueous cyanide solutions for treatment were prepared to contain about 0.0077 M NaCN (0.377 g/L NaCN and 0.200 g/L CN) and 0.001 M NaOH. A known sample volume was titrated with 0.125 M H<sub>2</sub>SO<sub>4</sub> to pH 4.00+/-0.05 to determine the required amount of acid to add to convert NaCN to HCN. A mildly acid pH is preferably maintained to improve the equilibrium of extraction of the neutral HCN species into the organic solvent, and to avoid polymerization of HCN in the presence of CN<sup>-</sup>. Upon acidification the solution contained about 200 mg/L HCN and 600 mg/L Na<sub>2</sub>SO<sub>4</sub>.

Various phase ratios of aqueous and organic solutions were tested, using flasks or separatory funnels. Acid was added to the solutions for extraction to maintain an acid pH in the aqueous media. In the examples, the vessels were sealed and the mixtures were shaken or stirred vigorously for 20 minutes and then allowed to settle. To assay samples for cyanide content, aqueous phase samples were added to a NaOH solution and titrated with a known AgNO<sub>3</sub> solution (about 0.018 M) using rhodamine as the titration end-point indicator. Loaded organic solution samples (*i.e.*, the organic phase loaded with HCN following extraction) were stripped with 1 M NaOH, usually at an aqueous to organic (A/O) ratio of 1. Samples of the stripped aqueous solutions were titrated with AgNO<sub>3</sub>. Blank tests were also performed in which the aqueous phases were deionized water.

## RESULTS AND DISCUSSION

The equilibrium loading results are shown in Figures 1 to 4 and summarized in Table 1.

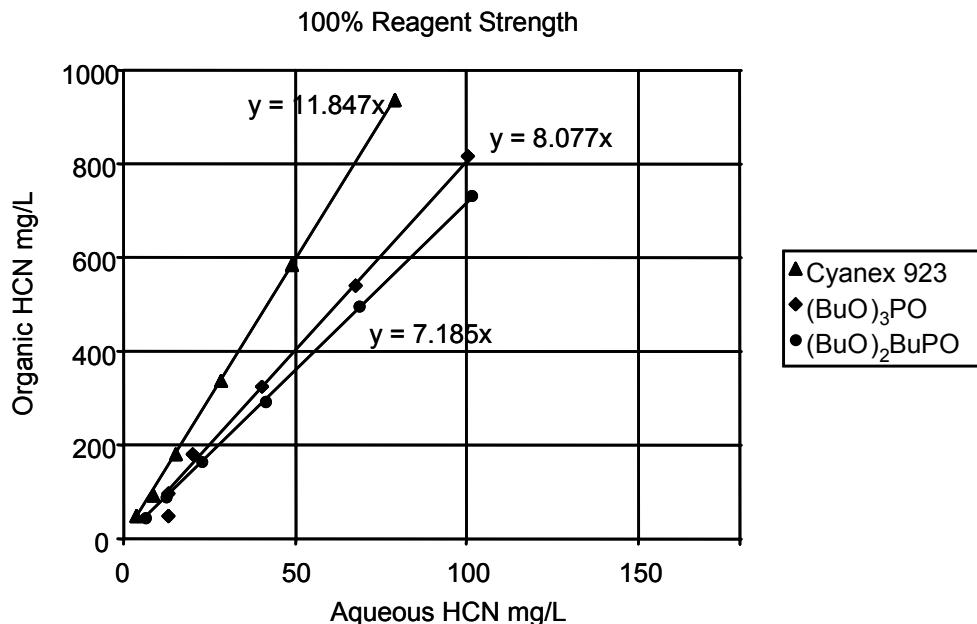

Figure 1. Cyanide extraction with 100% extractant solutions.

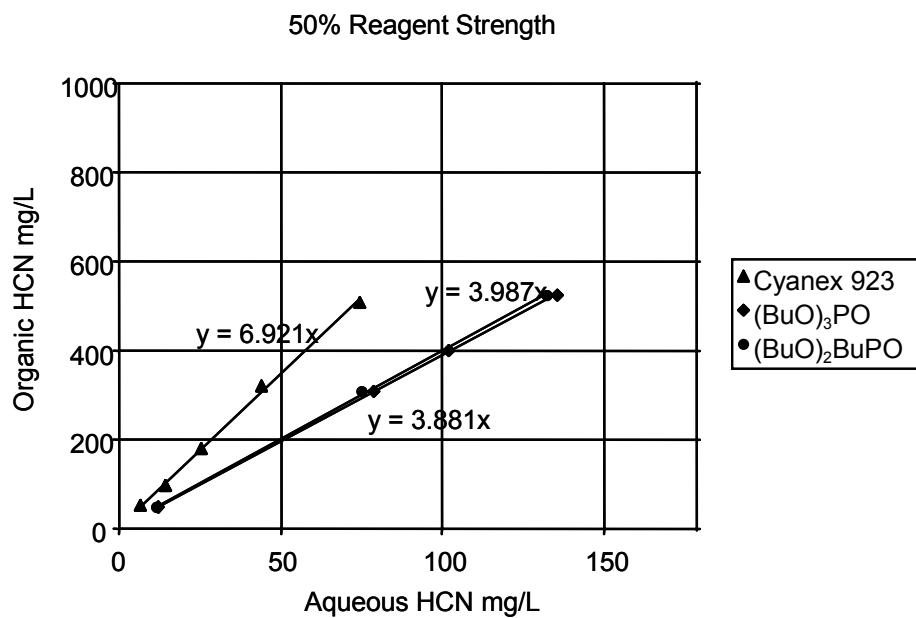

Figure 2. Cyanide extraction with 50% extractant solutions with Exxsol D-80 diluent.

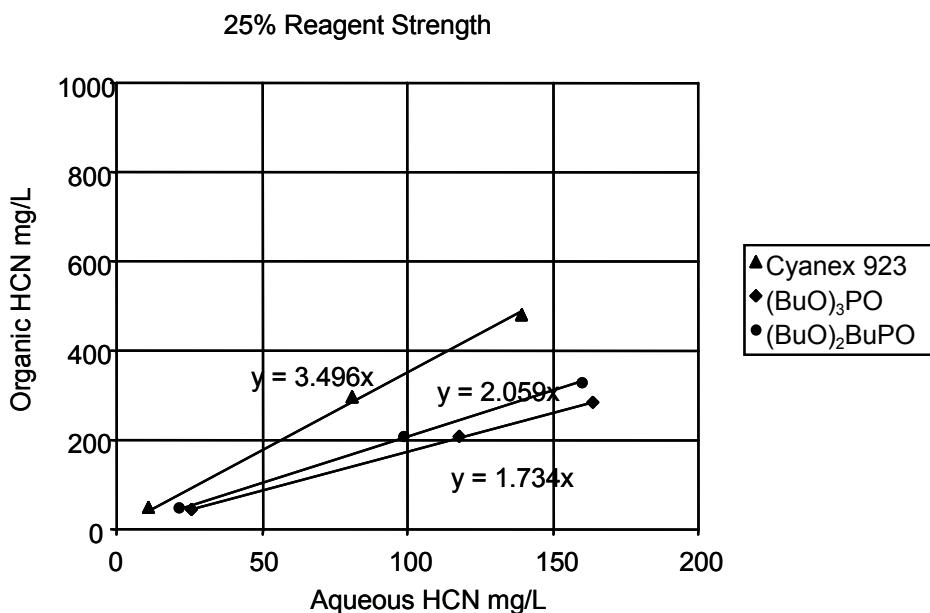

Figure 3. Cyanide extraction with 25% extractant solutions with Exxsol D-80 diluent.

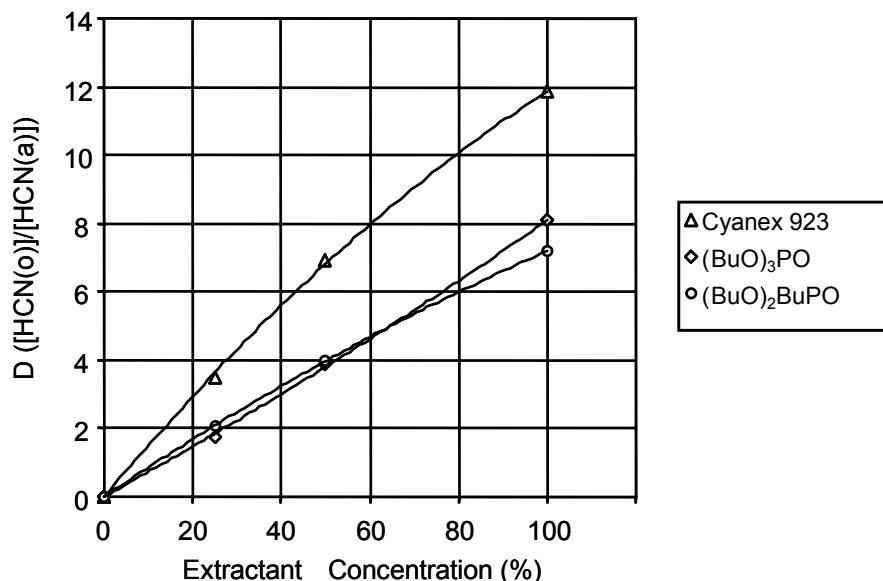

Figure 4. Comparison of the distribution values for various extractants as a function of extractant concentration.

Each of the solvents extracts HCN strongly from solution. Cyanex 923 is the strongest extractant in the series followed by DBBP and TBP. Dilution of the extractant with Exxsol D-80 weakens extraction of HCN in direct proportion to the dilution.

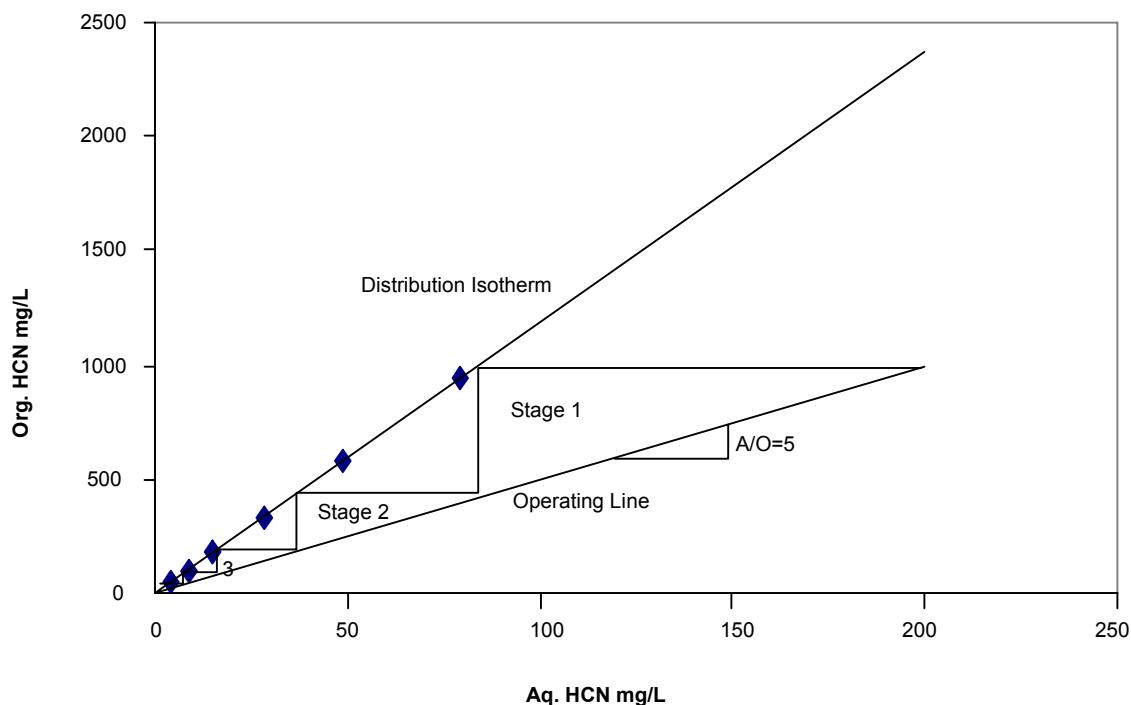

In the case of 100% TBP, the aqueous phases after loading were clear. These were analyzed without further clarification. A test was done to confirm that there was no interference from organic entrainment. In all other tests, the aqueous phases were centrifuged prior to analysis.

*Table 1. Distribution values for extraction.*

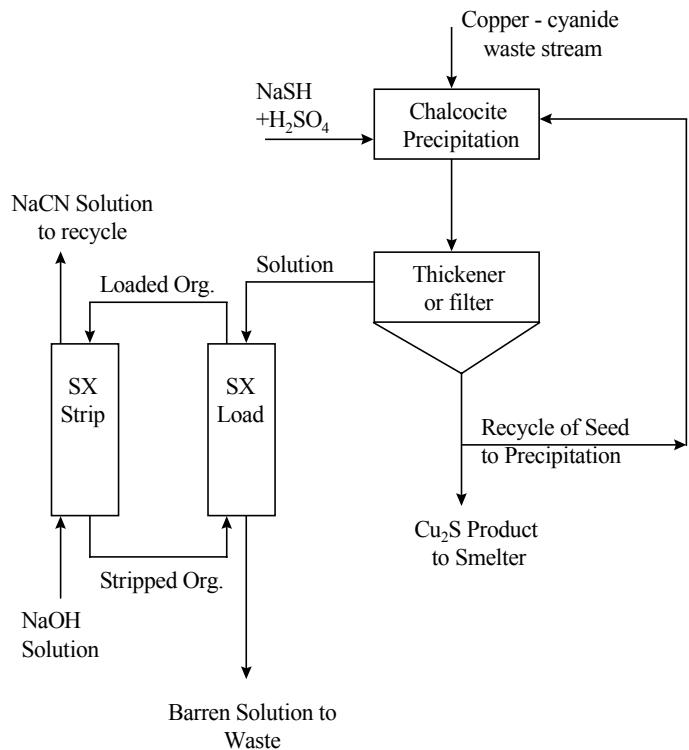

Organic reagent	Concentration (%)	$D_{HCN}$
Cyanex 923	25	3.5
	50	6.92
	100	11.85
$(BuO)_2P(O)Bu$	25	2.06
	50	3.99
	100	7.19
$(BuO)_3P(O)$	25	1.73
	50	3.88
	100	8.08

The lowest aqueous HCN levels detected (for single contact) were found for tests at A/O 0.25. For Cyanex 923 this was 4 mg/L, for dibutylbutylphosphonate, 7 mg/L and for tributylphosphate, 13 mg/L. These results indicate the tremendous potential of the solvent extraction system to remove HCN from solution and decontaminate discharge solutions from gold mine sites.

Figure 5 shows a simple McCabe-Thiele construction for HCN extraction. This diagram indicates that about 4 stages of extraction would be sufficient to recover cyanide to less than 10 mg/L residual cyanide from a starting concentration of 200 mg/L cyanide at an A/O ratio of 5:1. Figure 6 shows the potential integration of cyanide solvent extraction into a cyanide recovery circuit.

*Figure 5. McCabe – Thiele diagram for HCN extraction. 100% Cyanex 923.*

*Figure 6. Process flow diagram for cyanide recovery using solvent extraction.*

The extraction kinetics of HCN are fast and at least 4 stages of extraction are required for effective cyanide removal from solution. In this case, a column contactor such as the Bateman Pulsed Column system is ideal for application. The Bateman Pulsed Column system allows for high flow, low stage height contact of aqueous and organic solutions to effectively recover cyanide. Pilot scale testing of this system using a Bateman Pulsed Column will be the subject of a future publication.

## CONCLUSIONS

The solvent extraction recovery of cyanide from acidified solutions using organophosphorus solvating extractants has been demonstrated. Distribution factors for cyanide loading increase in the series TBP – DBBP – Cyanex 923 and even with dilution with Exxsol D-80 are favourable for effective HCN loading. Stripping of the organic loaded solvent can be accomplished by organic phase “neutralization” with an alkali solution (e.g., NaOH). The solvent extraction process for HCN appears to be a viable alternative to conventional volatilization/reneutralization in which air is the transfer medium.

## MERCURY RECOVERY FROM DENTAL AMALGAMS USING SOLVENT EXTRACTION

L. A. Silva De Lima, C. Pereira De Souza, J. Y. Pereira Leite and A. I. Curbelo Garnica\*

\*Universidade Federal do Rio Grande do Norte, Natal, Brasil

This paper presents the study of a leaching process of dental amalgam as well the solvent extraction of Hg ions from this waste. HCl, HNO<sub>3</sub> and HCl / HNO<sub>3</sub> (3:1) were used in the digestion process and the temperature, concentration of the solution and the time of contact between the phases were investigated. In the solvent extraction process tri-ethanoamine and tri-isooctilamine were used as extractant agent. The pH, mass ratio of the organic and aqueous phases and the time of contact between the phases were optimized. The tri-isooctilamine is more efficient than the tri-ethanoamine at lower pH at 25 °C.

### INTRODUCTION

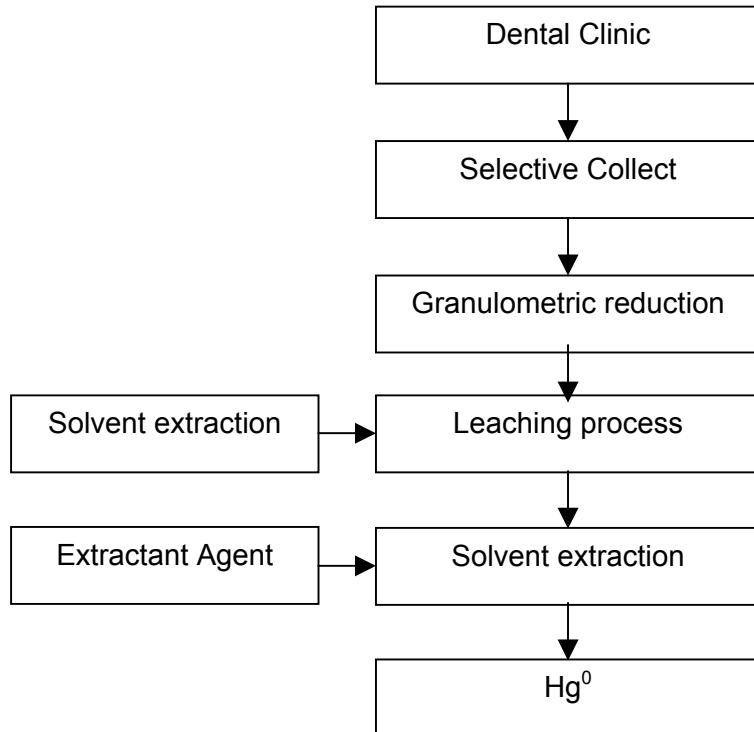

Environmental pollution in the form of heavy metals at high concentrations generates a series of problems that can affect biological natural cycles. A source of this pollution is the dental amalgam from clinics that is discharged into sewer streams. The average composition used by dentists in the amalgam preparation is 50-55% Hg, 32.5-35% Ag, 12-14.5% Sn, 0-3% Cu and 0-1% Zn. Contamination by mercury represents a danger to the environment as the discharge enters the natural aquatic environment that in turn provides a food source (fish and mollusks) for the local population.

Statistical studies show that the amount of amalgam can reach approximately 150 kg/year in the State of Rio Grande do Norte [5,6] and this material is discharged in the sewer stream of the Potengi River in Natal city. The Hg is present in the inorganic form and the digestion process takes place in the organic form as methyl mercury. This process occurs by the action of the microorganisms contained in the flora of the river that are consumed by fish and mollusks. The toxicity of this metal can affect the nervous system and promotes other diseases. According to Klaassen [1,3], it can also change the genetic code of the humans.

The study of technical routes to solve this problem requires the investigation of new processes of recycling and recovery of the mercury contained in the dental amalgams collected from the clinics. In the present work various conditions of the digestion process have been optimized. These include the type and concentration of the leaching agent, contact time and temperature of the system [7,8]. In the second stage, two types of extractant agents, tri-ethanoamine (TEA) and tri-isooctilamine (TIOA) and the pH of the solution containing the Hg [2,4,9] were investigated.

## EXPERIMENTAL PROCEDURES

The experimental procedure developed in this work is shown in Figure 1.

*Figure 1. Process flowsheet for the recovery and recycling of dental amalgams.*

Samples were collected from the Odontology Clinic of the CEFET – RN and then subjected to granulometric reduction using special ball mills (8'x 8') with balls that were coated with refractory ceramic to avoid the contamination of the material. The milling process reduced the particle size of the waste to lower than 105 µm. The samples were dissolved in HCl, HNO<sub>3</sub> and HCl/HNO<sub>3</sub> (3:1) using the following concentrations (vol.-%): 20%, 25%, 30% and 35%. The time of digestion was 2, 4 and 5 hours and the temperature was 25 and 50°C. The temperature of the system was controlled using a thermostatic bath.

In the solvent extraction process, the experiments were carried out using a synthetic solution of HgCl<sub>2</sub> containing 400ppm of Hg. The influence of the pH on the extraction process was studied for the mass relation between the Organic phase (OP)/Aqueous phase (AP) of 1:1. The composition of the organic phase was 95% kerosene, 4% octanol and 1% amine. The solution was stirred for 5 minutes using a glass extractor at 25°C. When the equilibrium was reached, the aqueous phase was separated and the Hg concentration was determined using an atomic absorption spectrophotometer. The efficiency of the process was calculated using equation 1:

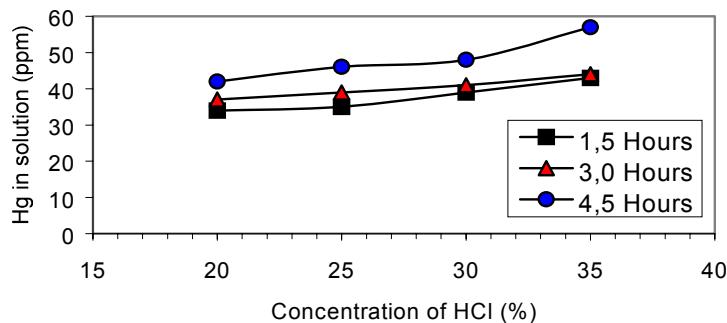

$$\% E = \frac{[Hg]_E}{[Hg]_E + [Hg]_R} \times 100 \quad (1)$$

where [Hg]<sub>E</sub> and [Hg]<sub>R</sub> were the concentration of mercury in the extract and raffinate phases, respectively.

## RESULTS

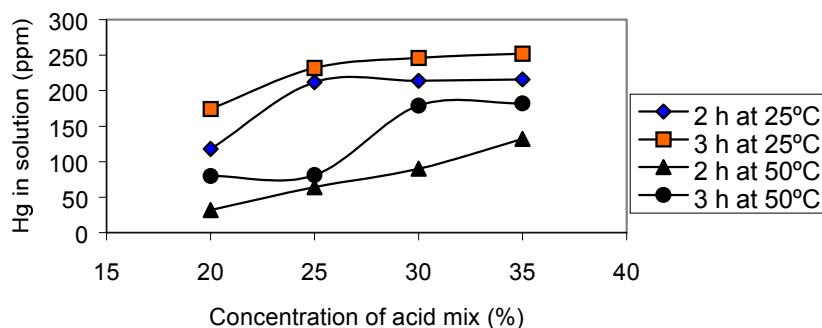

### Dissolution

In the digestion process of the dental amalgam three different types of acids were used: HCl,  $\text{HNO}_3$  and HCl/ $\text{HNO}_3$  (3:1). The phases were shaken for 1.5, 3.0 and 4.5 hours and the temperature of the system was maintained at 25 and 50°C. The results are shown in Figures 2 to 4.

*Figure 2. Dissolution of Hg from amalgam waste using HCl at 25°C.*

Dissolution efficiency with HCl was low and increasing the time of contact and the concentration of acid did not improve the dissolution significantly.

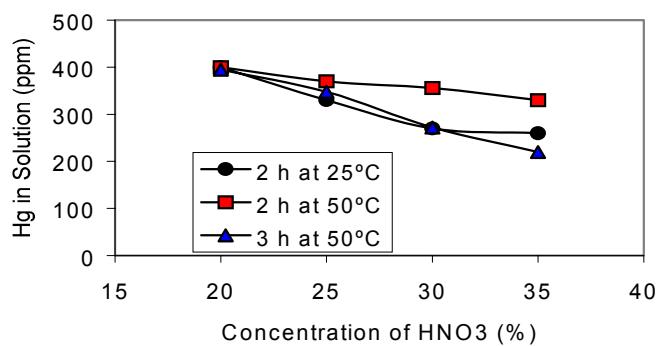

*Figure 3. Dissolution of Hg from amalgam waste using HCl / $\text{HNO}_3$  (3:1) mixture.*

Figure 3 shows that, for the acid mixture, an increasing amount of amalgam dissolved when the time of contact increased and a larger quantity of the amalgam dissolved for a temperature of 25°C than for 50°C.

The experiments using  $\text{HNO}_3$ , presented in Figure 4, show the total dissolution (400 ppm) of the Hg for a low concentration of  $\text{HNO}_3$  at 25°C. The HCl/ $\text{HNO}_3$  (3:1) mixture dissolves 250 ppm, while the HCl dissolves only 60 ppm at the same temperature, according to the Figures 3 and 2, respectively.

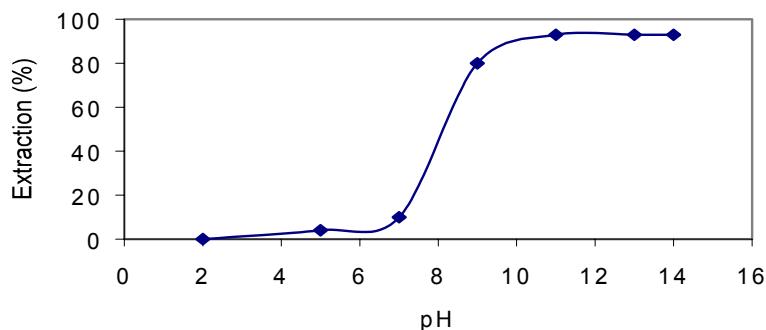

In summary, HCl is an inefficient lixiviant, while the HCl/ $\text{HNO}_3$  (3:1) mix gives better results at 25°C. This phenomenon can be explained by the gathering of the ions of  $\text{Hg}^{2+}$  as a function of the heat of solvation. When the temperature increases the increased solvation heat promotes the agglomeration of these ions that can therefore not be read by the molecular absorption instrument. Dissolution efficiencies were high for low concentrations of  $\text{HNO}_3$  that promotes the total dissolution of the amalgam. The temperature changing did not influence the process. The efficiency of the digestion process using the three different acids follows the sequence: [HCl] < [HCl/ $\text{HNO}_3$  (3:1)] < [ $\text{HNO}_3$ ].

*Figure 4. Dissolution of Hg from amalgam waste using HNO<sub>3</sub>.*

### Solvent Extraction

In the study of the pH of the aqueous phase of the solvent extraction process, the experiments were carried out using TEA. The results are presented in Figure 5.

*Figure 5. Influence of pH on the solvent extraction of Hg using TEA.*

The curve presented in Figure 5 shows that the extraction reaches equilibrium with approximately 93% Hg extracted at the pH = 11.07. This phenomenon is explained by the saturation of the TEA with Hg.

Experiments varying contact time were carried out using TIOA. The pH was 2.55 and the mass ratio AP/OP of the phases was 1. The phases were stirred at 25 °C and samples were removed every 5 minutes for analysis. The results of the effect of contact time on the extraction efficiency are shown in Figure 6.

Figure 6 shows that extraction efficiency with TIOA at 25 °C increases with increasing time of contact. After 35 minutes of contact between the phases 74.44% of Hg was extracted from the solution.

The relative extraction efficiency of the two solvents can be compared using data from Figures 5 and 6. For the same pH (pH = 2) and 5 minutes of stirring, TIOA extracted 20% while TEA never extracted Hg ions.

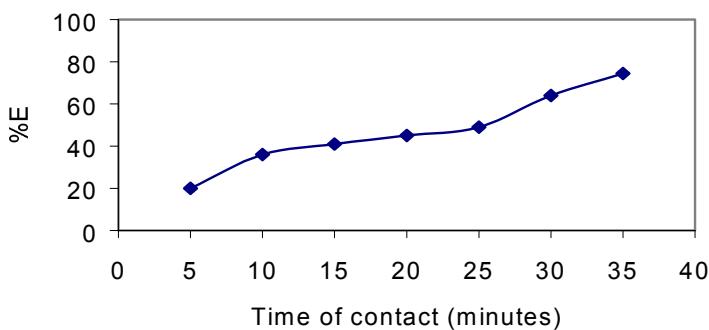

Figure 6. Influence of contact time on extraction efficiency of Hg using TIOA.

## CONCLUSIONS

The efficiency of the digestion process for the three acids used increased in the order: [HCl] < [HCl/HNO<sub>3</sub> (3:1)] < [HNO<sub>3</sub>]. The use of the nitric acid (20 vol.%) allows the total dissolution of the amalgam residues resulting in a solution containing 400 ppm of Hg at 25°C or 50 °C. In the next step of this work, the influence of the other species present in dental amalgam on the leaching process will be investigated.

Solvent extraction with TEA as the extractant presented better results as the pH increased (93% extraction at pH = 11) for a mass ratio between the phases of 1:1. The solution was stirred for 5 minutes at 25°C. For the same conditions of pH (pH = 2) and contact time (5 minutes) TIOA extracted 20% Hg while TEA extracted no metal. TIOA is therefore a more efficient extractant than TEA under these conditions. Further studies will be performed using the solution generated from the leaching of amalgam as will experimental studies of the phase diagram of the ternary system: Hg<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub> – TIOA – Water at 25°C.

## ACKNOWLEDGEMENTS

The authors thankfully acknowledge the financial support provided by CNPq (National Council for Scientific and technological Development) for this work and the scholarships given to the student.

## SUPERCritical FLUID EXTRACTION-OXIDATION TECHNOLOGY TO REMEDIATE PCB CONTAMINATED SOILS/SEDIMENTS

Wu Zhou, Gheorghe Anitescu and Lawrence L. Tavlarides

Syracuse University, Syracuse, USA

Systematic studies conducted on PCB contaminated site samples to investigate both the technical and economic feasibilities of supercritical fluid extraction technology for remediation of soil/sediments are discussed. In support of the extraction process, partition equilibrium data of targeted solutes between contaminated samples and supercritical CO<sub>2</sub> with and without 5 mol % methanol are reported. Laboratory scale desorption experiments reveal that PCB concentrations in sediments can be reduced from ~2200 ppm to <5 ppm (99.7% extraction efficiency) in 60 minutes when CO<sub>2</sub> - MeOH (5 mol %) is used. Follow-up experiments conducted with a 2-liter fixed bed bench scale unit confirm the laboratory scale findings. A linear driving force model, developed on the laboratory scale desorption data, predicts the bench scale results well. An economic analysis of a two-stage process of supercritical fluid extraction and supercritical water oxidation of the sediment extracts shows that the cost range of 142-175 USD/m<sup>3</sup> is competitive with other remediation technologies.

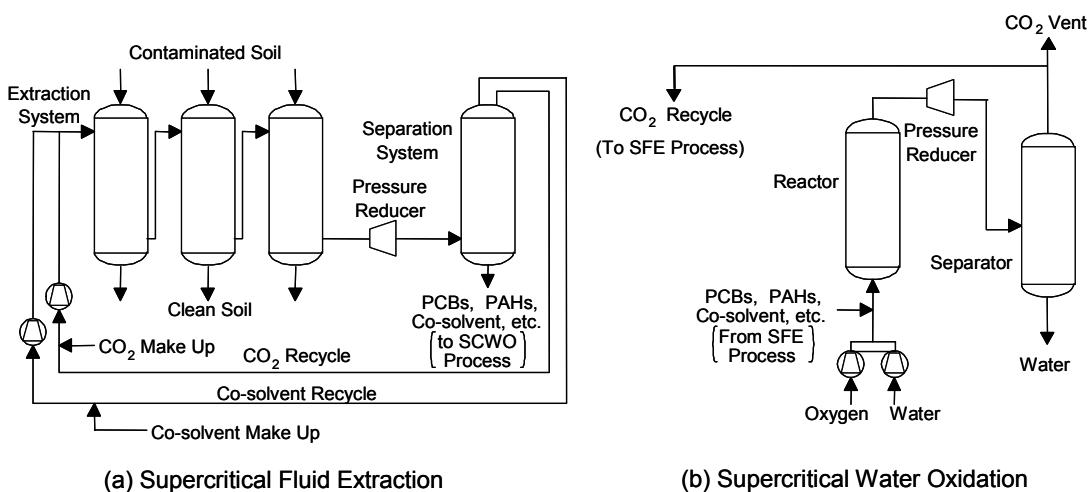

### INTRODUCTION

It has been estimated that about 175 million kg of polychlorinated biphenyls (PCBs) exist in landfill and other storage, and another 11 million kg exist in sediments, soil, and biosystems [1]. The environmental threat of the large amount of PCBs has called for the development of effective PCB cleanup techniques. However, methods to extract and destroy PCBs from contaminated soils/sediments (S/S) are facing unusual challenging problems due to the wide spreading areas, strong molecular interactions with S/S pores, very high chemical stability, low water solubility, and slow kinetics. Extraction and destruction methods include *in situ* thermal desorption, liquid solvent extraction, supercritical fluid extraction (SFE) and incineration and chemical reduction/oxidation, respectively.

Studies regarding a two-stage supercritical fluid technology (SFT) for S/S remediation process consisting of SFE of PCBs and supercritical water oxidation (SCWO) of the extracted pollutants are in progress at Syracuse University [2-3]. SFE is seen as an appropriate method to remove both organics [4] and metals (through chelating agents) [5] from different solid matrices. The unique property of supercritical fluids (SCFs) that makes them technically enticing is that they show enhanced ability to dissolve organic compounds which can be easily tuned by changing temperature and/or pressure [6], leading to simple solute-solvent separation. Further, low viscosity and high diffusivity of SCFs are essential to reduce mass transfer resistance during the desorption process. The most popular SCF is the non-toxic, non-flammable, readily available, and inexpensive CO<sub>2</sub>. Using this “green” solvent to replace liquid organic solvents offers important health and environmental advantages and the cleaned, unaltered S/S are returned to the site.

## PROCESS DESCRIPTION

The two-stage SFT process we advance at Syracuse University consists of SFE of PCBs/PAHs from the contaminated S/S and SCWO of the extracts (Figure 1) [2-3]. In the first step, the contaminated materials are contacted in a multistage SFE system and the extracted pollutants are separated from the supercritical fluids by pressure letdown and can be concentrated by distillation. Residual methanol can be stripped from the clean S/S by switching to pure CO<sub>2</sub>. Different options of the technology propose different levels of methanol recovery and recycle. The cleaned S/S are returned to the site. In the second stage, the extracted solutions are oxidized in a SCWO unit to mineral products such as CO<sub>2</sub>, H<sub>2</sub>O, and HCl, which can be easily transformed in NaCl. The oxidation can occur at the end or at intermediate points in the separation step to recover high pressure CO<sub>2</sub>. Both steps of the technology are contained processes and use recycle loops. The methanol in the second step is fully reacted and contributes to the PCB rate reaction enhancement and acts as fuel for the SCWO process.

## SCREENING, SOLUBILITY, SORPTION, AND DESORPTION STUDIES

Three real world St. Lawrence River sediment (SLRS) samples obtained from a contaminated site near Massena, NY, exhibit similar properties and PCB congener distribution patterns but different PCB concentration levels. These requirements are needed to conduct cohesive studies for a comprehensive and systematic evaluation of the SFE process. The three sediments were prepared by air-drying and sieving. Mineral properties, total organic carbon (TOC), and initial PCB concentrations of the three sediments given in Table 1 indicate that the three samples have similar properties yet different levels of PCB concentrations.

### Screening Desorption Rate Studies

Effects of pressure, temperature, cosolvent, soil moisture, initial PCB concentration, and soil type on PCB desorption efficiencies have been investigated to determine proper desorption conditions [7]. Table 2 summarizes the results of the systems studied and shows that sub 5 ppm PCB residual concentration can be achieved in approximately 60 minutes of desorption of 2200 ppm real world SLRS. Contact time for desired levels of desorption is seen to depend upon these conditions and vary between 15 to 60 minutes.

*Table 1. Properties of real world St. Lawrence River sediments.*

Sediment samples	Composition (%)			TOC (%)	PCB Conc. (ppm)
	Sand	Clay	Silt		
St. L. R. Sediment #1	37.67	32.72	29.60	1.34	130
St. L. R. Sediment #2	55.73	23.21	21.06	1.21	710
St. L. R. Sediment #3	58.38	22.1	19.53	1.76	2200

*Table 2. Laboratory scale desorption data with spiked soils and contaminated sediments.*

Sample	Initial Conc. (ppm)	P (atm)	T (°C)	Cosolvent (mol.%)	Moisture (wt.%)	Contact Time (min)	Residual Conc. (ppm)
Till <sup>a</sup>	1150	200	40	5	10	45	3.2
Sediment <sup>b</sup>	370	200	40	5	10	60	15.1
Sediment <sup>c</sup>	71	100	40	5	20	45	5.7
Surficial <sup>a</sup>	4257	200	40	5	10	30	6.7
Sand <sup>a</sup>	950	100	40	5	10	15	1.2
Sediment <sup>b</sup>	2200	116	50	5	0	60	<5

<sup>a</sup>Laboratory spiked samples;

<sup>b</sup>Real world contaminated St. Lawrence River sediment;

<sup>c</sup>Real world contaminated Hudson River sediment.

Initial PCB concentration effects indicate that, even though there exist more than three fold differences of initial concentrations, the desorption rates of PCBs are essentially identical for the same sample. Regarding the effects of S/S moisture content and cosolvent on PCB desorption rates from two different samples, experimental data show that the presence of 10 - 20 wt % water retards the initial PCB extraction rate sharply. In contrast, the addition of methanol in SC-CO<sub>2</sub> enhances PCB desorption rates and reduces the ultimate PCB residual levels in S/S. Among all the cosolvents studied (methanol, *n*-butane, *n*-propanol, and hexane) [7], the polar and water-soluble methanol is the most effective for the extraction of PCBs from S/S. Other factors studied show the system pressure effects on PCB desorption efficiencies. It is found that pressure affects PCB desorption much more significantly for wet samples than for air-dried samples, and that for extraction from wet samples the enhancement of PCB desorption rate was not proportional to pressure increment [7]. Also comparisons between real world contaminated and spiked sediments show that laboratory prepared samples have more rapid PCB desorption rates and lower final residual concentrations than real world samples. These results underscore the need to conduct laboratory tests with samples from the site to be remediated.

### Thermodynamic Solubility Studies

These data permit one to assess the most desirable SCF from a capacity and selectivity standpoint. Research efforts at Syracuse University have resulted in the generation of a substantial database of PCB solubilities in SC-CO<sub>2</sub> and SC-CO<sub>2</sub> modified with *n*-butane and methanol over a range of conditions [8]. Solubility data of PCBs are correlated by semiempirical equations over the experimental ranges of pressure and temperatures. Both *n*-butane and methanol were found to enhance the solubilities of PCB congeners compared to those in pure SC-CO<sub>2</sub>. For the entire data set, an enhancement of 5-91% of the solubilities is observed.

### **Partition Equilibrium Studies**

During extraction processes, the PCB concentrations in SC phase are less than their saturation solubilities due to the interactions between PCBs and soil matrices and relatively long contact time needed to reach equilibrium. For a SCF to effectively remove PCBs from soil, it must have high PCB dissolving capacities and proper interaction properties with the soil matrices and PCBs, such as competing with solute for active sites and swelling the soil matrices to improve solute accessibility. Therefore, to select a proper cosolvent and to provide information for desorption data modeling, the equilibrium partition behavior of PCBs between SCFs and S/S needs to be studied. PCB partitioning equilibrium studies between SLRSs and both SC-CO<sub>2</sub> and CO<sub>2</sub> - MeOH (5 mol %) were conducted at 40, 50, and 60 °C and different SCF density levels (5.5, 8.0, 10.5, 13, and 15.5 mol/L) requiring a pressure range of 76.3-177.5 bar. These results are used to model PCB desorption rates.

The partition equilibrium data were analyzed for both totals PCBs and 12 major individual congeners detected in the sediments. All the isotherms show good linearity except for those at lower density (5.5 and 8.0 mol/L) in pure CO<sub>2</sub> system. Preferential desorption was found among the PCB congeners analyzed. The partition coefficients increase roughly in the order of molar weight increase of PCB congeners. The increase of either temperature or density while one of them is kept constant results in the decrease of partition coefficients (favor PCB desorption) for both SCFs. Temperature and density effects appear to be more significant for the CO<sub>2</sub>-MeOH system than for pure CO<sub>2</sub>. All the isotherms are fitted with a linear model. The correlation between the partition coefficients (*K*) and system temperature and pressure is established for each PCB-sediment-SCF system. The AARD values of the models are in the range of 10-14% for all PCBs in the CO<sub>2</sub> system and 14-20% for CO<sub>2</sub>/MeOH. These models have been used in the analysis of PCB desorption data. The model analysis reveals that PCB adsorptions onto sediments from both SCFs are exothermic and physical processes with the adsorption energy of ~4 kcal/mol in pure CO<sub>2</sub> and ~8 kcal/mol in CO<sub>2</sub>/MeOH system. The larger adsorption energy in CO<sub>2</sub>/MeOH system suggests stronger interactions between sediment active sites, PCB molecules, and this SCF.

### **Desorption Studies from Real World St. Lawrence River Sediments**

These studies were conducted to develop a consistent set of data with real world samples at laboratory scale. The air-dried SLRS #3 samples (Table 1) are extracted 60 minutes at 50 °C and 117.8 bar (corresponding to a CO<sub>2</sub> density of 10.5 mole/L) to determine flow-rate effects. Both pure CO<sub>2</sub> and CO<sub>2</sub> with 5 mole % MeOH were used as SCFs. With the former, larger CO<sub>2</sub> flow rate (1.35 versus 0.76 g/min) increases the desorption rate and reduces the final PCB residual concentration. With the latter, it is found that PCB concentration in sediment can be reduced from approximately 2200 ppm to less than 10 ppm (+99.5% extraction efficiency) in 25 minutes of extraction time and to less than 5 ppm (99.77% extraction efficiency) in 60 minutes. These flow rate effects are not significant after ~7.5 minutes of extraction time in the presence of 5 mole % methanol in the SCF. These results demonstrate that the use of methanol as cosolvent induces more rapid desorption rates and lower PCB residual concentrations compared to SC-CO<sub>2</sub> alone.

PCB desorption from a fixed bed of sediments was modeled employing the transient desorption material balance and assuming negligible axial dispersion effects. The governing equation can be given as:

$$\varepsilon \frac{\partial C}{\partial t} + u \frac{\partial C}{\partial z} + (1-\varepsilon) \rho_p \frac{\partial q}{\partial t} = 0 \quad (1)$$

where  $\varepsilon$  is void fraction of the soil bed; C is PCB concentration in the SCF phase; t is processing time;  $u$  is SCF superficial velocity; z is axial dimension of the bed;  $\rho_p$  is the density of S/S; and q is solid phase PCB concentration. A linear relationship can relate the partition equilibrium of PCBs between SCF and solid phase,

$$q = KC \quad (2)$$

and the PCB diffusion rate is governed by a linear driving force,

$$\frac{\partial q}{\partial t} = \frac{15D_s}{R_p^2}(KC - q) \quad (3)$$

where  $R_p$  is the soil particle radius and  $D_s$  is a “lumped” diffusion coefficient for PCBs. Combined with equations (2) and (3) and a set of initial and boundary conditions, equation (1) is solved and the two parameters,  $D_s$  and K, are determined by regression analysis on the experimental desorption data when partition equilibrium data are not available for K values. This model is used to fit PCB desorption data from spiked till under various conditions [9].

Bench-scale desorption experiments have been conducted on SLRS #3 (Table 1). Based on the results of laboratory desorption and partition equilibrium studies, the conditions of bench-scale desorption studies are determined as: CO<sub>2</sub> and CO<sub>2</sub>/5 mol % MeOH as SCFs; sample size of ~1500 g; CO<sub>2</sub> flow rates of 450 and 250 g/min (2.11 and 4.22 mol CO<sub>2</sub>/min); temperature of 50 °C; pressure of 118 bar; SCF densities of 10.5-15.0 mol/L. Bench-scale desorption experiments show that PCB concentration in SLRSs can be reduced from ~1840 ppm to less than 5 ppm (more than 99.73% extraction efficiency) in 40 minutes. The final PCB concentrations after 60 minutes of extraction are around 3 ppm which is comparable with the final PCB concentrations of ~4 ppm for the laboratory-scale experiments when CO<sub>2</sub>-MeOH are used as SCF, suggesting that the scale-up effect is not significant on the desorption processes. The modeling analysis produces comparable parameters with those obtained from the laboratory-scale studies. The parameters obtained from laboratory-scale desorption data predict the bench-scale data and give reasonably good results, validating the linear driving force model.

## ECONOMIC ANALYSIS

The base case of the proposed remediation process for PCB contaminated S/S using SFT consists of three 2.5 m<sup>3</sup> extractors operated in a 30-minute cycle time (the time for each extractor to be exposed to fresh SCF) and in a 60-minute processing time (cycle- plus exposing-time of PCB/SCF from a previous extractor). It can treat 36,000 m<sup>3</sup> contaminated S/S each year. The total processing cost for the SFE-SCWO process includes the cost for S/S handling, SFE of the PCBs from the S/S, and the cost of oxidizing the extracted PCBs using SCWO. The excavation costs are estimated to be \$50/m<sup>3</sup> and the SCWO costs for the extracts are estimated to be \$15/m<sup>3</sup>-sediment. Purchase costs are estimated for all of the major process units. The total operating cost is estimated from the costs of operating labor, utilities, raw materials, the fixed capital investment, S/S processing, and SCWO. The total processing cost consists of the total operating cost plus the depreciation of the plant over 10 years. Capital cost factors are used for each process unit to account for installation, engineering and construction expenses, and contingency funds and the contractor's fee. The utilities costs used are \$0.06/kwh, \$31.00/kwh for cooling at -18 °C cooling and \$6.62/1000 kg of low pressure steam (160 °C steam). Raw materials costs are \$0.30/gal for methanol and \$65/ton for CO<sub>2</sub>. Allowance of \$54/hr was made for the replacement and treatment of the carbon in the filter unit. Using the costs outlined above, the total treatment cost including depreciation is \$175/m<sup>3</sup> of S/S for the base case.

Two alternatives to the base process were also evaluated. In the first alternative, the cycle time for the extraction of the soil is decreased from 30 minutes to 20 minutes. Another extraction unit is added and each canister is exposed to CO<sub>2</sub> and methanol for three cycles instead of two, increasing the rate of S/S treatment from 5 m<sup>3</sup>/hr to 7.5 m<sup>3</sup>/hr. For this alternative, the capital cost is increased by the cost of the extra unit, but labor and other operating costs for the process are essentially the same. The estimated total treatment cost for this alternative is \$142/m<sup>3</sup>. In the second alternative, the CO<sub>2</sub> and methanol stream used to extract the S/S is assumed to leave the extraction units at 70 % of the equilibrium PCB concentration. To assure this higher PCB concentration an additional extraction unit is also added and the cycle time is kept at 30 minutes. This concentration ( $\sim 2.9 \times 10^5$  µg/mol-SCF) is approximately four times the average concentration of PCBs ( $6.7 \times 10^4$  µg/mol-SCF) leaving the extractor units in the base case. Accordingly, the capacities of all the operation units, except the extractors and the PCB storage tank, are reduced by a factor of four. The resulting capital costs of these equipments are scaled down using a factor of 4<sup>0.6</sup>. The utilities and raw materials costs are also reduced by a factor of 4<sup>0.6</sup> while the labor costs are kept as constant. The estimated total treatment cost for this alternative is \$144/m<sup>3</sup>.

Economic analysis of these processes reveals that the operation costs for the proposed process are in the range of \$142-175/m<sup>3</sup> of S/S. Comparison of these costs with the costs of other alternative technologies shown in the introduction section, suggests that the SFE-SCWO process is economically promising and attractive for the remediation of PCB contaminated S/S.

## CONCLUSIONS

A new PCB remediation process using supercritical fluid technology has been systematically evaluated based on real world PCB contaminated St. Lawrence River sediments. Major research areas include the PCB partition equilibrium, both laboratory and bench scale PCB desorption experiments, and the economic analysis of the proposed process. The results show that the proposed process is both technically and economically feasible for the remediation of PCB contaminated soil/sediment. The significance of our work is that we have demonstrated that the SFE of CO<sub>2</sub> – MeOH (5 mol %) can achieve <5 ppm residual PCBs in real St. Lawrence River sediments and soils from initial concentrations of ~2200 ppm (4300 ppm with lab spiked soils) in 45-60 minutes processing time for 99.8% removal.

An updated preliminary economic analysis indicates this SCF technology costs of \$142-175/m<sup>3</sup> soil processed is economically competitive.

These studies suggest that a multistage semi-batch process with CO<sub>2</sub> and methanol recycle and SCWO of the PCB extract is an efficient process configuration. Other downstream process configurations may prove more effective. Additional process information is needed to define an operable and economic process configuration to implement this technology.

# SUPERCritical CO<sub>2</sub> EXTRACTION OF HALOGENATED FLAME RETARDANTS FROM POLYMER MATERIALS USING DIFFERENT MODIFIERS

T. Gamse and R. Marr

Institute of Thermal Process and Environmental Engineering,  
Graz University of Technology, Graz, Austria

Electronic waste materials contain flame retardants to protect the plastic material in case of fire. These compounds cause problems during incineration because of the formation of dioxines. Solubility measurements and calculations were performed for two widely used flame retardants, hexabromocyclododecane (HBCD) and tetrabromobisphenyl-A (TBBA). Supercritical CO<sub>2</sub> extraction experiments were carried out for the polymer polybutylene-terephthalate (PBT) containing either TBBA or HBCD. With pure CO<sub>2</sub>, extraction yields up to 100 % could be achieved at the highest conditions of 500 bar and 100°C. Using CO<sub>2</sub>-modifier mixtures (methanol, isopropyl alcohol, toluene, water-methanol mixturea) reduces the necessary extraction pressure for complete separation to 200 bar. For TBBA, a small amount of water positively influences the extraction results.

## INTRODUCTION

New techniques are urgently required in the field of polymer recycling and/or disposal, especially for polymer composites of mass consumer products like electronic waste which contain flame retardants in concentrations up to 30%. As flame retardants, special inorganic compounds, halogenated organic compounds, organophosphorus and halogenated organic phosphorus compounds are used. One main recycling process for plastics is the incineration and there the formation of halogenated dibenzodioxines and dibenzofurans due to the halogenated compounds cannot be avoided.

One promising way to separate the halogenated flame retardants from polymer matrices is the extraction by supercritical fluids like supercritical carbon dioxide (SC-CO<sub>2</sub>). The advantage of this process is that the polymer as well as the flame retardant can be recycled. This gives an economic benefit because flame retardants are relatively high price products.

Before starting extraction experiments, the solubility behaviour has to be known. To date, only limited data on flame retardants in combination with supercritical CO<sub>2</sub> are available in literature [1, 2]. For this reason, solubility data in supercritical CO<sub>2</sub> for two widely used flame retardants, hexabromocyclododecane (HBCD) and tetrabromobisphenyl-A (TBBA), were performed for a wide range of pressure and temperature. The experimental data and the fitted parameters for the Chrastil equation are published [3, 4].

Based on these solubility data, supercritical CO<sub>2</sub> extraction experiments were carried out for different polymers (ABS, PS, PBT) containing either TBBA or HBCD. Preliminary tests showed that the polymers ABS and PS are not suitable for CO<sub>2</sub> extraction. They have a relatively low melting point (below 60°C) under CO<sub>2</sub> pressure, so the removal from the vessel after extraction is difficult to handle because the polymer is then a sticky material. Furthermore, the polymers ABS and PS are partly soluble in CO<sub>2</sub> and therefore a separation of flame retardant and polymer is not possible. The extractions were therefore performed with PBT + TBBA and PBT + HBCD using firstly pure CO<sub>2</sub> and then adding different modifiers (methanol, isopropyl alcohol, toluene and water-methanol mixtures).

## MATERIALS AND METHODS

### High Pressure Apparatus

A Speed-SFE apparatus from Applied Separations Co. with a 300 ml extractor designed for 690 bar and of 250°C was used for all extraction tests. The apparatus and procedure are described in [6-9].

### Gas Chromatographic Method

The flame retardant-solvent mixture of the CO<sub>2</sub> sample was analysed in a gas chromatograph (HP 5890 Series II) with electron capture detector (GC-ECD) using a capillary column (type HP-1, 12 m x 0.2 mm x 0.2 µm). The injector temperature was held constant at 290°C, the detector temperature at 300°C and oven temperature constant at 290°C.

### CO<sub>2</sub> Density Calculation

The dependence of the density of pure CO<sub>2</sub> on pressure and temperature was calculated using the equation of Bender [4, 5].

### Materials

HBCD with a purity of 97% was purchased from Sigma Aldrich and TBBA with a purity of 98% from Riedel de Haen. Methanol, isopropyl alcohol and toluene were purchased from Merck. The CO<sub>2</sub> with a purity > 99.94% and a dew point lower than -60°C was purchased from Linde (Graz) and stored in a tank with 3200 L capacity. The polymers ABS, PS and PBT spiked with HBCD and TBBA were purchased from Celabor, Belgium. The polymer particle size had to be reduced before extraction which was performed by cryogenic milling adding CO<sub>2</sub> snow to the polymer to avoid melting of the material and to give better size reduction. After milling the polymer was separated by sieving in three fractions (< 500 µm, 500 – 1000 µm and 1000 – 2000 µm).

## RESULTS

### Solubility of TBBA and HBCD in CO<sub>2</sub>

Detailed results of the determined solubility data are already published [6, 7].

### CO<sub>2</sub> Extraction With Pure CO<sub>2</sub>

Preliminary CO<sub>2</sub> extraction tests showed that the polymers ABS and PS are partly soluble in CO<sub>2</sub> so insufficient separation of the flame retardants can be achieved as these polymers melt in the presence of CO<sub>2</sub> below 60°C, giving a sticky product at the end of extraction. Therefore only the polymer polybutyleneterephthalate PBT spiked with 20 wt% TBBA or 26 wt% HBCD was used for the extraction tests. Extraction time was set constant at 4 hours for extracting 4 g polymer material with a CO<sub>2</sub> flow rate of 4.6 l/min. The best extraction yields result at the highest pressure (500 bar), highest temperature (100°C) and smallest particle size (< 500 µm) tested [8, 9].

## CO<sub>2</sub> Extractions Using Different Modifiers

To reduce the necessary extraction pressure and temperature for a complete extraction, different modifiers (methanol, isopropyl alcohol and toluene) and different modifier amount were added to the CO<sub>2</sub> stream.

Figure 1 shows the influence of different methanol concentrations on the extraction yield of TBBA. It is obvious that increasing modifier amount increases the extraction yield. With a modifier content of 10 % methanol the same efficiency can be reached at 200 bar as with pure CO<sub>2</sub> at 500 bar. The other modifiers tested also increased the efficiency but not to the extent that methanol does (see Figure 2).

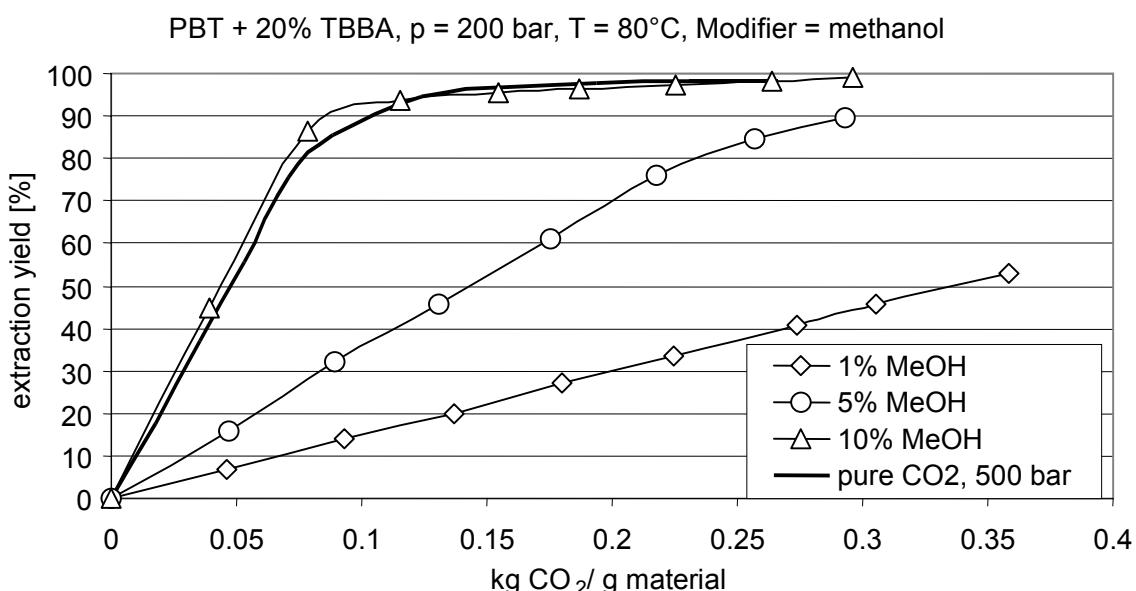

Figure 1. Influence of methanol concentration on extraction yield of TBBA.

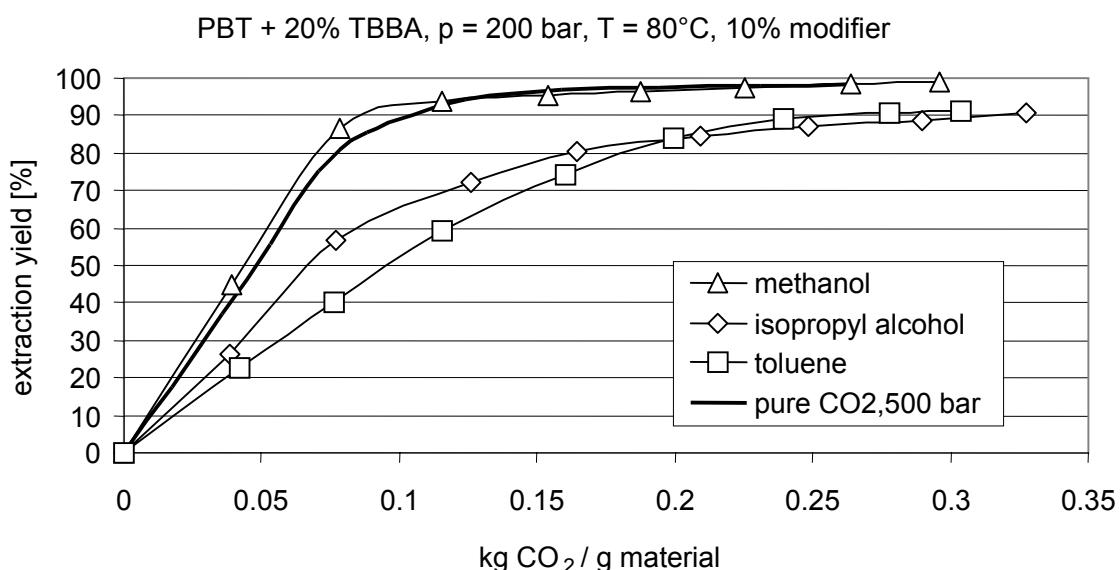

Figure 2. Influence of different modifiers on extraction yield of TBBA.

For the extraction of HBCD, methanol also gives the best results as shown in Figure 3. It is obvious that with a concentration of 10% methanol nearly the same extraction efficiency arises at 200 bar as with pure CO<sub>2</sub> at 500 bar.

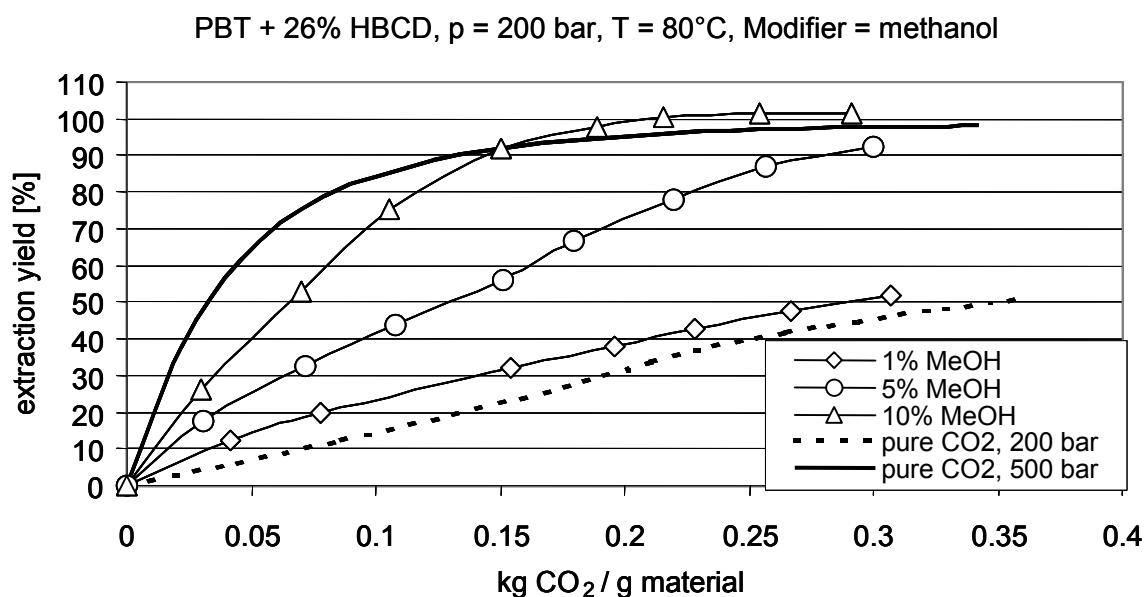

Figure 3. Influence of methanol content on extraction yield of HBCD.

The results at 40°C and 80°C are nearly the same but normally an increase in temperature results in better extraction yield. For this reason, the influence of temperature on the extraction yield using 10% methanol as modifier was determined. From Figure 4 it can be seen that a temperature increase starting at 40°C increases the extraction yield and at 70°C an optimum exists. Higher temperatures result in a decrease of the extraction yield.

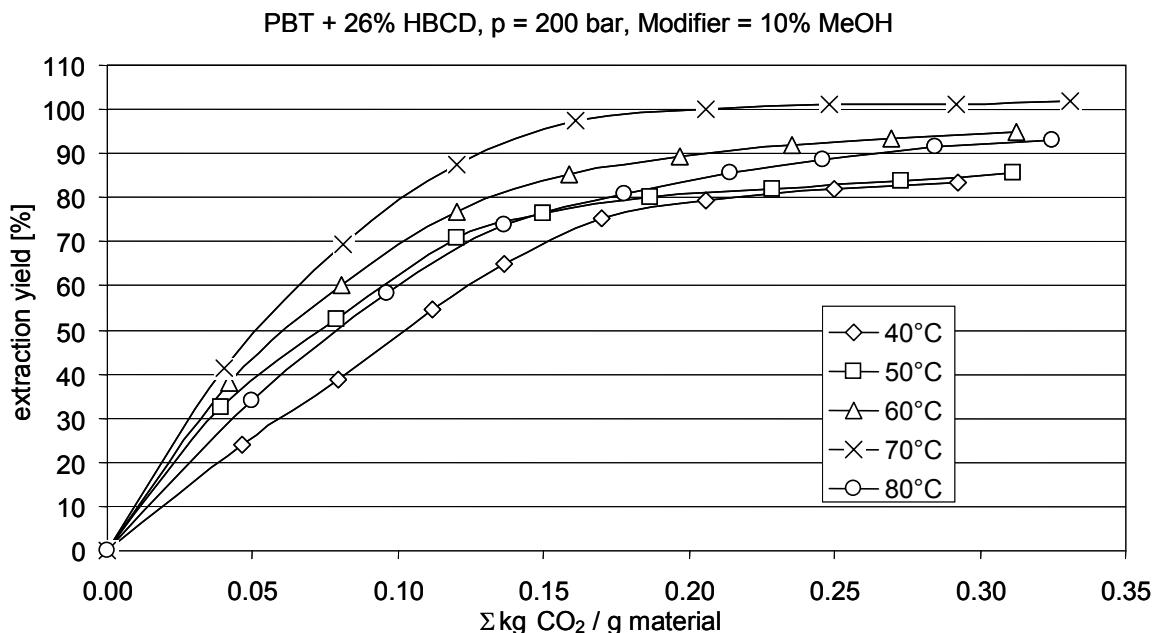

Figure 4. Temperature influence on extraction of HBCD using 10% methanol as modifier.

### CO<sub>2</sub>-Extractions Using Water-Methanol Mixtures As Modifier

To increase the polarity of the modifier, different amounts of water were added to the methanol. Figure 5 shows the influence of water concentration on the extraction yield of TBBA, where a modifier mixture of 5% water and 95% methanol gives the best extraction. Pure water was also used as modifier and it is obvious that this has a negative effect on the extraction rate.

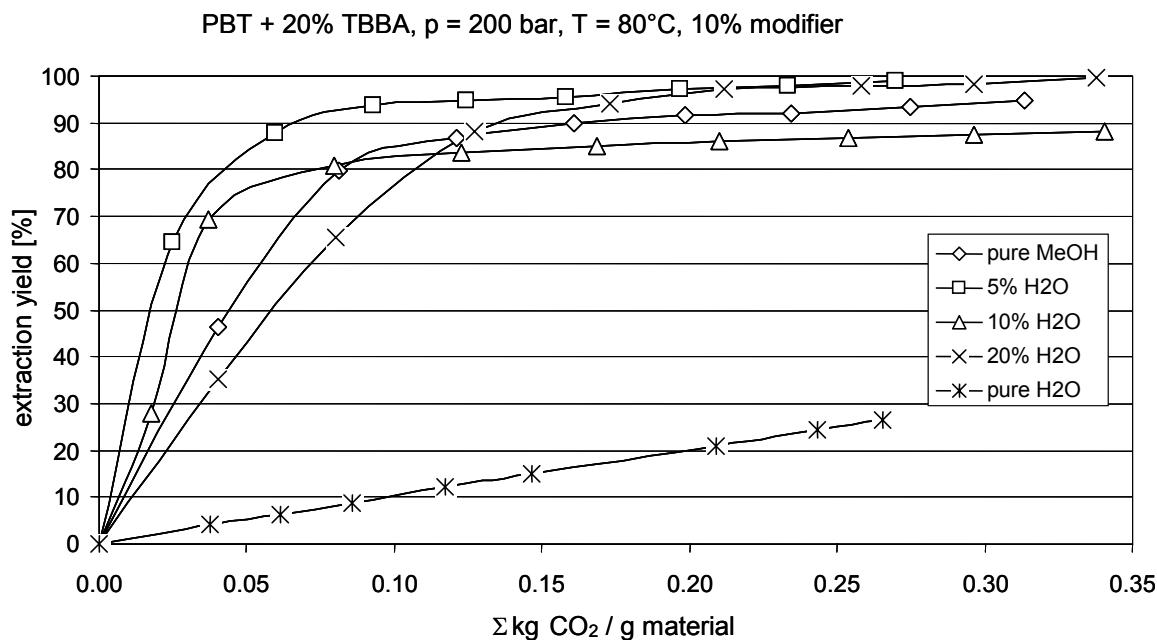

Figure 5. Influence of water-methanol mixture on extraction rate of TBBA.

In contrast to the extraction of TBBA, a water-methanol mixture has no positive influence for the removal of HBCD, as shown in Figure 6. For HBCD, pure methanol is the best modifier at an optimal extraction temperature of 70°C.

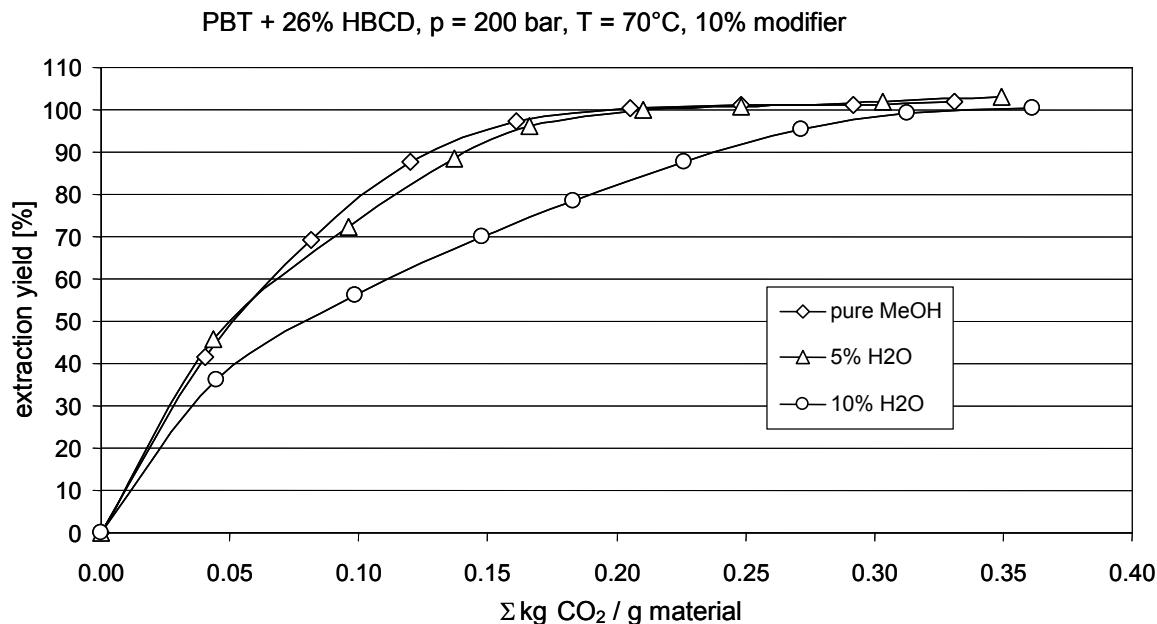

Figure 6. Influence of water-methanol mixture on extraction yield of HBCD.

## CONCLUSION

Supercritical CO<sub>2</sub> extraction is a promising process to get rid of the problem of flame retardants in polymers. A complete removal of TBBA and HBCD from the PBT polymer is possible, especially if higher temperatures, small particle sizes and modifiers are used. Best results for TBBA could be achieved using methanol with small amounts of water as a modifier. For HBCD, pure methanol as modifier gives the best results and the optimal temperature is 70°C at 200 bar.

To develop an economic process, the separation step has to be taken into account because a great amount of CO<sub>2</sub> is necessary for a complete removal of the flame retardants. Using absorption or adsorption as separation method will give the advantage of running this process isobarically or using only a small pressure decrease and therefore reducing investment and running costs for the CO<sub>2</sub> pump. Furthermore, a separation by absorption in a stripping column will result in modifier-saturated CO<sub>2</sub> entering the extraction vessel and the saturation concentration is much higher than the concentrations determined in these experiments. With increasing amount of modifier, the extraction yield also increases at shorter extraction times, so an industrial plant will run under much better conditions.

## METAL ION AND DYE EXTRACTION FROM TEXTILE WASTEWATER BY MICROEMULSIONS

L. T. Cordeiro Beltrame, E. L. Barros Neto, A. A. Dantas Neto, T. N. Castro Dantas

Universidade Federal do Rio Grande do Norte-Natal, Rio Grande do Norte, Brazil

The coloration resulting after conventional wastewater treatment in textile industries has been spurring the development of processes of color removal. This study presents a new extraction method to remove colors, dyes and metals by microemulsion. The wastewater used in this study was obtained by a real disperse dye bath containing the dyes Dianix Rubine S-2G (CI Disperse Red 167:1), Palanil Dark Blue 3RT (CI Disperse Blue 148) and Dianix Yellow Brown SE-R (CI Disperse Orange 29) and a real reactive dye bath containing the dyes Procion Yellow H-E4R (CI Reactive Yellow 84), Procion Blue H-ERD (CI Reactive Blue 160) and Procion Red H-E3B (CI Reactive Red 120). The optimized method was very efficient in removing all dyes and metals contained in the effluent.

### INTRODUCTION

Modern textile dyes are required to have a high degree of chemical and photolytic stability in order to maintain their structure and color. The stability and resistance of dyes to degradation have made color removal from textile wastewater difficult by biological treatment plants [1].

Many studies have been accomplished trying to help the textile industry to eliminate this problem [2-7]. Nowadays, the processes employed are few and the installation and operational costs are very high, making its utilization economically unviable.

The aim of this study was to develop a new method that is economically viable and observes the toxicological and environmental aspects, to remove the color present in textile effluent.

In recent years, attention has been given to the development of novel surfactant-mediated separation processes. Among the various new methods, the application of microemulsions for the separation, concentration and purification of proteins, for the extraction of metals, as drug-delivery systems, etc. seems to be one of the most exciting and promising techniques [8].

A microemulsion is a liquid-liquid dispersion, formed by two liquids of different polarities (most commonly water and oil) and a mixture of surfactant agents (surfactant and/or co-surfactant). Macroscopically it exhibits a monophase liquid (homogeneous), which has a translucent and isotropic appearance. Within the known proportions of its constituents this liquid is able to equilibrate with other phases, either aqueous or organic. In the case of extraction by microemulsions, one can work with the equilibrium between the microemulsion and the aqueous phase, which is called the Winsor II system.

Characteristic solvent effects of microemulsions, as reported in the stability of acids and bases and the reactivity of metal ions, are beneficial to various separation methods using microemulsions as media [9].

Metals have been found in textile wastewater [10] and some dyes are formed by chemical bonds between the metal and the organic molecule of the dye. Utilization of microemulsion systems in metallic cations extraction has been a good alternative [11-14], because they have some characteristics which make them profitable and safe, when compared to the conventional techniques.

This work presents the first application of microemulsion in color extraction from textile wastewater.

## EXPERIMENTAL METHODOLOGY

### **Composition and Preservation of the Samples**

The wastewater used in this study was obtained from a dyeing house, from the first discharge after dyeing with reactive dyes (hydrolyzed dyes) and from the first discharge after dyeing with disperse dyes. As simulating a real final wastewater, the mix of these baths together in the proportion of 1:1 was studied.

The dye baths had all the auxiliaries normally used, and the dyes are presented in Tables 1 and 2. All the extractions were carried out at room temperature (26°C) and after extraction the samples were preserved at 10°C.

*Table 1. Disperse dyes.*

Dye	Color Index	Chemical Characteristic	Concentration in the bath (g/L)
Dianix Rubine 2-2G	Disperse Red 167:1	Azoic	0.1805
Dianix Yellow Brown SE-R	Disperse Orange 29	Azoic	0.3888
Palanil Dark Blue 3RT	Disperse Blue 148	Azo	0.8333

*Table 2. Reactive dyes.*

Dye	Color Index	Chemical Characteristic	Concentration in the bath (g/L)
Procion Yellow H-E4R	Reactive Blue 84	Azoic - bismonochlortriazin	0.5902
Procion Blue H-ERD	Reactive Blue 160	Copper formazan bismonochlortriazin	0.4721
Procion Red H-E3B	Reactive Red 120	Azo - bismonochlortriazin	0.1062

### **Extraction Method**

A microemulsified system composed of a long chain amine (as surfactant), *n*-butanol (as co-surfactant), kerosene (as oil) and water was used as an extractor agent. This system was mixed in a 1:1 proportion with the disperse dye bath, the reactive dye bath and the mix of reactive and disperse baths, as it occurs in the effluent. The process was carried out in one stage by magnetic agitation (5 – 10 minutes) and immediate decantation. The two phases formed were easily separated: the superior phase, formed by the oil phase of the microemulsion, which is strongly colored and the colorless aqueous phase, formed by the water from the microemulsion and from the bath.

## **Methods of Analysis**

The samples from the dyes baths and the aqueous phases obtained after extraction were analyzed. The presence of metals was determined according to APHA [15], by flame atomic absorption spectrometry. The metals analyzed were Cd, Cu, Cr and Fe. The equipment used was a VARIAN SpectrAA – PLUS.

Color determination used the spectrophotometric method. In this method, absorbance was determined and the measures were compared to the Typical Color Consent [1]. The equipment used for color measurement was a molecular absorption spectrophotometer UV – Visible VARIAN CARY-1 E.

## **RESULTS AND DISCUSSION**

### **Choosing the Extraction Point**

Using a pseudo ternary diagram, three points were chosen from the microemulsion region. The initial chosen points were: w (rich in oil), z (rich in water) and k (same quantities of water and oil) as shown in Figure 1.

Extraction tests at these points with the disperse bath, reactive bath and disperse and reactive bath were realized. The best results were obtained at point z.

### **Study of the Best Concentration of Cosurfactant/Surfactant (C/S)**

With the objective of knowing the best concentration of the active matter, the points a, b and c, in which the same amounts of oil used in the point z were maintained, were tested (Figure 1). The points b and c presented better results but, as point b used smaller amounts of active matter, it was the chosen point. At this point, 20% of C/S, 79% of water and 1% of kerosene were used.

### **Study of the Optimum pH of Extraction**

The pH of the samples were 10.97 (reactive bath), 10.97 (disperse and reactive bath) and 5.25 (disperse bath). At these pH values, no extraction on the disperse bath, a good color extraction on the reactive bath and an excellent color extraction on the disperse and reactive bath, were observed.

It was observed that by varying pH, color extraction could be improved. The reactive dyes bath has better extraction when the sample is acidified at pH 9 or less, before extraction. In this case, aqueous phase is completely colorless. It is due to the high salinity of this kind of bath, in which Winsor II microemulsion formation is favored. The disperse dyes bath has an excellent extraction at pH 13., with colorless aqueous phase; above this pH the extraction still happens, but the aqueous phase becomes more colored as the pH increases. The mix of reactive and disperse dyes baths has the best extraction at pH 10 – 12. It is due to the high salinity of the mix (from the reactive bath) and the facility of extraction at high pH (from the disperse bath).

### **Dyes Baths Concentration**

The concentrations of the reactive bath and disperse bath are not possible to determine due to different exhaustion curves of the dyes used to dye. According to O'Neill *et al.* [1], the description of textile effluent in terms of absorbance is more useful in terms of describing a pollutant than its dye concentration, as different dyes give rise to different intensities and colors. As absorbance changes with the types of dye used, there is not a direct relationship between these values and dye concentrations.

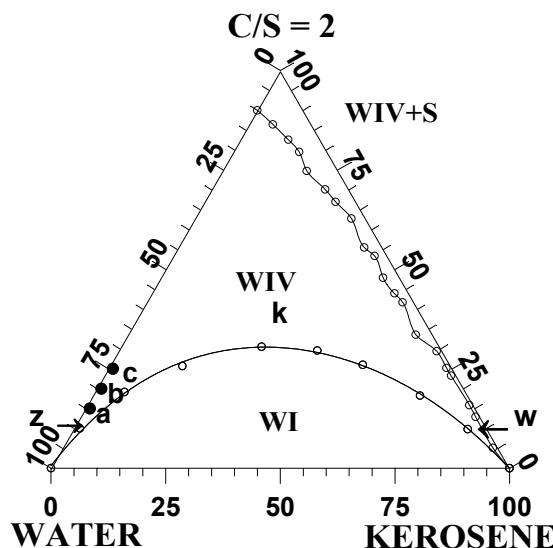

Figure 1. Ternary pseudo diagram with the chosen points for extraction tests.

#### Determination of COD (Chemical Oxygen Demand)

The determination of COD from the samples was not possible due to the high chloride concentration, over than 2000 mg Cl/L [15].

#### Extraction of Metals

Cd, Cu, Cr and Fe have been found in the wastewater from the industry where samples were collected [10]. In the samples of disperse and reactive baths, Cd, Cr and Fe quantities were under the detection limits of the equipment used. But copper was found in the reactive bath and in the mix of reactive and disperse baths. The quantities are shown in Table 3.

Table 3. Metals in the dyeing bath and in the extracted aqueous phase.

Metals	Dyeing bath			Extracted aqueous phase		
	Reactive	Disperse / reactive	Disperse	Reactive	Disperse / reactive	Disperse
Cu (mg/l)	1.34	0.58	-	0.05	0.02	-
Cr (mg/l)	-	-	-	-	-	-
Fe (mg/l)	-	-	-	-	-	-
Cd (mg/l)	-	-	-	-	-	-

According to the results obtained, the extraction of copper was 96.27% from the reactive bath and 96.55% from the mixture of reactive and disperse baths. It is important to say that these values were obtained without any correction of pH, which would improve the extraction and that the extraction was carried out in a single stage of agitation and decantation.

#### Color Removal

To date there is no environmental quality standard (EQS) for color, and therefore the practice is to determine an acceptable color for the river to which effluent is to be discharged by taking samples of the river and assessing which samples are acceptable to the eye [1]. Consent limits are usually expressed as absolute limits for the wavelength within a particular range. Consent limits [1] are expressed in Table 4, for comparing the results obtained after color extraction from the baths.

With the samples from reactive bath and from the mix of disperse and reactive baths, pH correction wasn't used. For the sample from disperse bath the pH was correct to 13.2.

*Table 4. Color consent standard for Sewage Treatment Works comparing to the dyeing bath absorbance and extracted aqueous phase absorbance.*

Color wavelength (nm)	Dyeing bath			Extracted aqueous phase			Typical color consent *
	Reactive	Disperse / reactive	Disperse	Reactive	Disperse / reactive	Disperse	
400	0.5356	1.4125	2.3875	0.0350	0.0422	0.0353	0.115
450	0.5494	0.9010	1.6250	0.0379	0.0239	0.0153	0.085
500	0.5765	0.9702	2.4501	0.0291	0.0133	0.0128	0.065
550	0.5000	0.8958	2.5998	0.0166	0.0076	0.0116	0.055
600	0.1482	0.4375	0.6875	0.0018	0.0031	0.0080	0.040
650	0.1053	0.2754	0.3750	0.0004	0.0001	0.0066	0.028
700	0.0333	0.0993	0.0113	0.0000	0.0000	0.0064	0.013

\* Environmental Agency in: O'Neill *et al.* [1]

These results show that aqueous phases obtained after extraction present very low absorbance and the new method used to color removal from textile effluent was very efficient.

## CONCLUSIONS

The system used was very efficient in color removal. Disperse dyes should be extracted in a strongly alkaline medium (pH 13.2). Reactive dyes and the mix of disperse and reactive dyes can be extracted at the normal pH of the samples. The extraction of reactive dyes is optimized as the sample is acidified and under pH 9, the aqueous phase is completely colorless. The mix of disperse and reactive dyes presents best extraction at pH 10 – 12.

The extraction of metals, in the case of copper, was 96.27% in the reactive dye bath and 96.53% in the mix of reactive and disperse dyes baths. For the extraction, simple agitation (magnetic agitation) was used, followed by decantation. In this determination, pH correction was not used.

Looking to verify possible interference from the dyeing auxiliaries, a real effluent was studied. The system was shown to be indifferent to any interference.

## RECOVERY OF POLYPHENOLS FROM OLIVE MILL WASTE-WATERS BY PRECIPITATION AND LIQUID-LIQUID EXTRACTION

Jorge Rodrigues de Carvalho, Celina Santos, Rosinda Ismael, Licínio Ferreira

Departamento de Engenharia Química, Instituto Superior Técnico, Lisboa, Portugal

Olive mill waste-waters (OMWW) are rich in polyphenols. In order to remove polyphenols from OMWW, an integrated process including precipitation and polyphenol removal by liquid-liquid extraction is proposed. The precipitation was required to avoid crud formation during liquid-liquid extraction. Different concentrations of  $\text{FeCl}_3$  and lime were tested, with or without a flocculant. Several commercial extractants were tested to remove polyphenols from pre-treated OMWW. The raffinates were analysed by HPLC. None of extractants were selective for polyphenols. However, combination of two extractants, in a sequential extraction resulted in the recovery of an organic solution rich in hydroxytyrosol, which could be stripped with caustic soda. Synthetic polyphenol solutions extractions were also experimented.

### INTRODUCTION

The extraction of olive oil, accomplished in small, seasonally operated agro-industrial units, results in the production of high-density waste water. Their high levels of organic substances and, consequently, their highly pollutant nature pose a serious environmental problem. Such effluents have established low commercial values. Olive mill waste waters (OMWW), however, may also be a possible source of substances of possible technological interest, such as polyphenols. Polyphenol levels in OMWW are in the range of 453 ppm up to 7624 ppm [1]. Hydroxytyrosol, tyrosol, catechol, 4-methylcatechol and caffeic acid are the main polyphenols in OMWW [2]. Because of their high antioxidant effect, polyphenols are increasingly being used by pharmaceutical industries. As a recovery process, liquid extraction should be considered an attractive process to recover polyphenols from OMWW. However, the high turbidity of OMWW presents considerable liquid extraction problems, mainly due to crud formation. To avoid this crud formation, turbidity removal must be accomplished by coagulation and precipitation as a pre-treatment prior to liquid-liquid extraction. The purpose of the present work was to explore the different selectivities of four extractants for polyphenol extraction. Pre-treatment prior to the liquid-liquid extraction process was also studied by coagulation and precipitation processes. The efficacy of this pre-treatment was demonstrated.

## MATERIALS AND METHODS

### Chemicals

Ferric chloride, lime and other common reagents were analytical grade. Aliquat 336 and Alamine 336 were purchased from Cognis, tri-*n*-butylphosphate (TBP) and Primene JMT were from BDH Chemicals, Ltd. and Rohm and Haas Company, respectively. Cyanex 923 and TOPO were purchased from Cytec Canada Inc. Hostarex 327 was from Hoechst. ShellSol T (SST) and ShellSol A (SSA) were purchased from a local market. Flocculants non-ionic Praestol 2500, anionic polyacrylamide A100 (Cyanamide Superfloc) and cationic polyacrylamide C472 (Cyanamide Superfloc) were purchased from a local market. JMT and Hostarex 327 were sulphated as in [3]

### Effluent Characterization

OMWW in this study has a total polyphenol content of about 3300 ppm and a pH value of 4.9. Total solids and turbidity levels are 86 g/l and 16100 NTU, respectively. COD and BOD levels are 130 g O<sub>2</sub>/l and 13 g O<sub>2</sub>/l, respectively.

### Analytical Method

Total polyphenols were determined according to the method proposed in Standard Methods, which is based on the Folin-Ciocalteau reagent [4]. HPLC has been used to analyse aqueous phase for polyphenols. A Dionex system was used, equipped with a GINA auto sampler, a P 580A LPG gradient pump and a UV-Vis diode array UVD340S detector. A RP18 column from Merck was used. Turbidity was measured on a LP 2000 turbidity meter, from Hanna Instruments, and calibrated against formazin standards. COD and BOD concentrations were measured on a Aqualytic® Pcompact COD/CSB photometer and on a BOD-Sensor and Aqualytic inductive stirring system, respectively.

## RESULTS AND DISCUSSION

### Solvent Extraction Applied to OMWW

The following extractants were mixed with diluent (50% SST, 50% SSA): Cyanex 923, TOPO, Aliquat 336, TBP, sulphated JMT and sulphated Hostarex. These extractants represent different characteristics and therefore interact by a different mechanism with polyphenols. The results of these experiments, expressed as removal percentage, are given in Table 1, for pH 2 and pH 12. These results were obtained using the Folin-Ciocalteau method to analyse total polyphenols removal.

*Table 1. Removal of polyphenols from OMWW by liquid-liquid extraction by several extractants (%).*

pH	Cyanex 923	TOPO	Aliquat 336	TBP	sulphated JMT	sulphated Hostarex
2	26	8	44	12	8	20
12	-	0	53	8*	-	-

\* pH 11.

(10% v/v) in a 40% (v/v) SST + 40% (v/v) SSA diluent.

Volume of aqueous phase = Volume of organic phase.

The chromatographic determination of polyphenols, after their extraction with those extractants was also performed. These results showed no selectivity for all the extractants. Aliquat 336 extracted all the compounds existing in the range of retention time 35 to 75 min.

Solvent extraction applied directly to OMWW produced crud. Precipitation was, therefore, applied to OMWW in order to clarify this effluent.

### **Coagulation/Precipitation**

The experimental results, were carried out in terms of the effect of effluent dilution, iron(III) and CaO concentration on residual COD and turbidity, during the coagulation process. Furthermore, the use of different flocculants was experimented. This precipitation, as already was referred, is essential before applying liquid-liquid extraction because it can substantially reduce the turbidity and at the same time reduce the COD, as presented below.

#### **Effect of iron(III) concentration on turbidity and COD residual**

The addition of ferric chloride resulted in a black mass that tended to form amorphous aggregates. Above the poorly settling flocs, the supernatant was very dark brown in colour.

For undiluted effluent, 2000 ppm of iron(III) is required to reduce almost 60% of the initial COD and almost 97% of the turbidity. This concentration decreases with increasing effluent dilution (Figures 1 and 2).

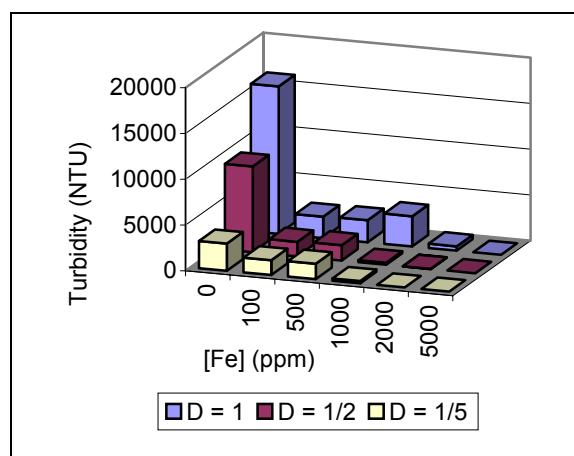

Figure 1. Residual turbidity (after 24 h) after addition of ferric chloride for different effluent dilutions (D). pH 5.5.

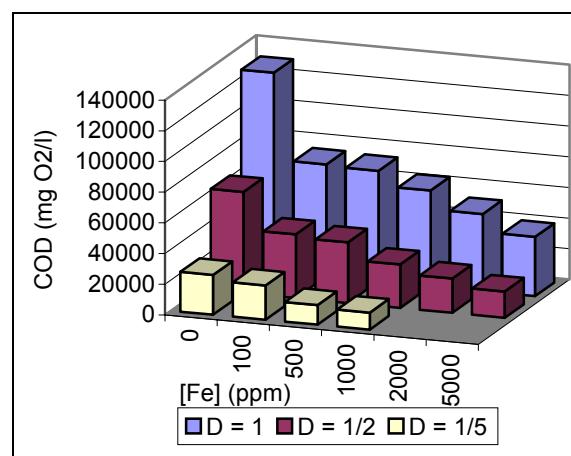

Figure 2. Residual COD (after 24 h) after addition of ferric chloride for different effluent dilutions (D). pH 5.5.

#### **Effect of lime concentration on turbidity and COD removal**

Lime coagulation led to an orange-yellow supernatant and a fine brown floc, which settled very slowly. To elucidate the effect of lime on OMWW, pure calcium oxide was used. When hydrated, it generated calcium hydroxide. It was shown that removal efficiency increased with increasing lime concentration. With lime treatment, 70% of COD and 99% of turbidity removal may be reached using 28 g/l of calcium oxide, but, for economical considerations, treatment with 10 g.dm<sup>-3</sup> calcium oxide was sufficient. For ½ effluent dilution, the calcium oxide concentration required to remove about 94% of turbidity and about 50% of COD was only 5 g/l.

#### **Effect of flocculant**

To further agglomerate coagulated particles, forming larger flocs and thus accelerating the sedimentation process, addition of a flocculant (synthetic polymer) is needed to decrease the amount of salt required and to improve the precipitation with trivalent salts.

The best result of flocculation was obtained with the flocculant Cyanamid C472 at a concentration value of 50 ppm.

### Solvent Extraction applied to Clarified OMWW

Before a solvent extraction process is applied, a pre-treatment with 5g/l CaO must be used. To remove the excess of calcium, an ion exchange process, using a Dowex 50W-X8 ion exchange resin, was used. During ionic exchange fouling was not detected. After these two steps, the polyphenol content of the effluent was 486 ppm hydroxytyrosol, 19 ppm protocatechuic acid, 473 ppm tyrosol, 11 ppm caffeic acid, 13 ppm of p-coumaric acid, 10 ppm of rutine, being the total polyphenols content of 758 ppm. For solvent extraction of OMWW, four extractants were assayed for polyphenols removal. The chromatographic determination of polyphenols, after their extraction with those extractants was also performed. The results in Table 2 show the percentage of removals of the main polyphenols with 0.18 M of different extractants in 50% SSA/SST.

*Table 2. Removal of polyphenols by liquid-liquid extraction by several extractants (%).*

Extractants	Hydroxy-tyrosol	Protocatechucic acid	Tyrosol	Caffeic acid	p-coumaric acid	Sinapinic acid	Rutine	Total
Initial aqueous phase at pH 1								
Cyanex 923	57	100	2	100	100	100	91	42
Aliquat 336	60	100	18	99	100	94	100	52
Alamine 336	49	100	0	99	98	89	100	42
TBP	4	50	0	73	90	61	20	24
Initial aqueous phase at pH 8								
Cyanex 923	52	68	7	90	93	29	91	37
Aliquat 336	62	100	30	96	96	80	100	64
Alamine 336	9	0	10	7	15	18	68	24
TBP	11	0	11	14	13	42	39	24

Aqueous phase/Organic phase (v/v) = 1.

Aqueous phase pre-treated with 5 g/l CaO and through a cation exchange resin.

As can be seen, neither of the extractants could selectively remove any polyphenols. Only Aliquat 336 was capable of extracting polyphenols better at pH 8 than at pH 1. Nearly equal removals were obtained with Cyanex and Alamine 336. Both of them showed poor extraction of tyrosol from the effluent. The best results were obtained with the quaternary ammonium compound Aliquat 336, which had a total polyphenol removal of about 51% and 64% at pH 1 and pH 8, respectively.

The combination of several consecutive extraction stages will result in the recovery of hydroxytyrosol. In the first extraction stage, Cyanex 923 can remove, at pH 1, almost all the polyphenols leading a raffinate rich in tyrosol and with 48% of hydroxytyrosol. This aqueous solution can again be extracted with fresh Cyanex 923 to remove the remaining hydroxytyrosol. This organic phase can then be stripped by caustic soda leading a solution rich in hydroxytyrosol.

Other studies of solvent extraction of p-coumaric acid with Aliquat 336 were performed. In order to reduce the amount of SSA in the diluent. Since aromatic compounds are toxic and soluble in aqueous phase, several diluent compositions were studied. Composition selection or rejection was based on third phase formation when the organic phase is loaded with the solute. The results are presented in Table 3 using p-coumaric acid as the solute.

Three systems are successful for liquid-liquid extraction of p-coumaric acid without third phase formation. The system with the solvent composition Aliquat 336 10% + 1-decanol 10% + SST 80% must be the best due to environmental considerations. Stripping was also studied for Aliquat 336. Only basic solutions in the presence of sodium chloride could strip the organic phase. However, it was observed that significant polyphenol dissociation or

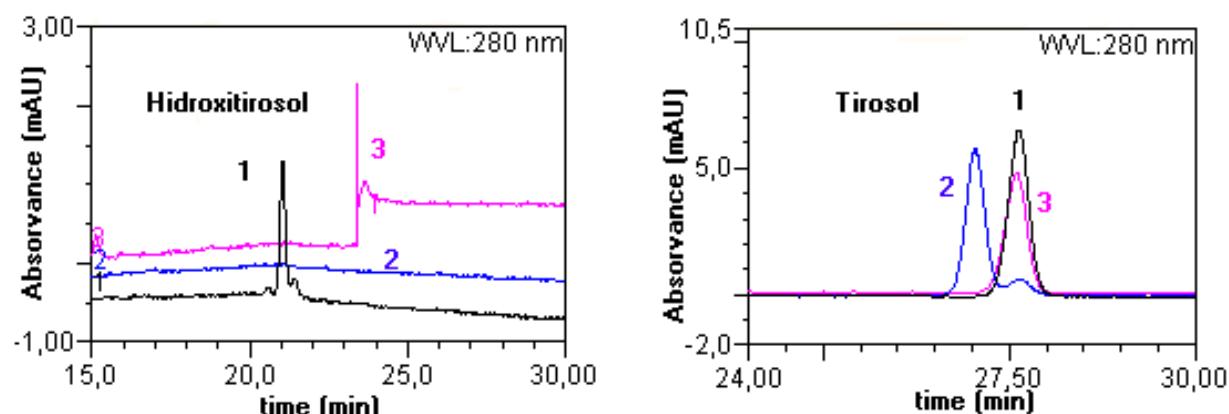

degradation occur with this basic solution. This was shown by the disappearance of almost all polyphenols when the pH solution was increased to 10 and to 13. However, when the pH was readjusted to the initial value with concentrated H<sub>2</sub>SO<sub>4</sub> some polyphenols (hydroxytyrosol, tyrosol, p-coumaric acid and p-hydroxybenzoic acid) reappear, indicating that the reaction with NaOH is reversible for these four compounds. In Figure 3, spectra for hydroxytyrosol and tyrosol are overlaid to accentuate spectral changes.

*Table 3. Different compositions for organic phase and respective p-coumaric concentration attained after several contacts of organic and aqueous phases.*

Organic phase	[p-coumaric acid] in organic phase (not saturated) (ppm)	Third phase formation
Aliquat 336 1% + (SST+SSA) 99%	5337	Yes
Aliquat 336 10% + (SST+SSA) 90%	9959	Yes
Aliquat 336 10% + SST 30% + SSA 60%	9917	Yes
Aliquat 336 10% +1-decanol 10%+SST 40%+SSA 40%	13683	No
Aliquat 336 10% +1-decanol 10%+SST 80%	10530	No
Aliquat 336 10% +1-decanol 10%+SSA 10%+SST 70%	13477	No
Aliquat 336 10% +1-decanol 5%+SSA 10%+SST 75%	8537	Yes
Aliquat 336 10% +1-decanol 5%+ SST 85%	8324	Yes
Aliquat 336 5% +1-decanol 5%+ SST 90%	7976	Yes

Aqueous phase feed: P-coumaric concentration 700 ppm.

Phase ratio of 2/1.

*Figure 3. Overlay of chromatographic spectra for hydroxytyrosol and tyrosol at different pH values; 1- Solution of 10 ppm of the compound at natural acidic pH, 2- Solution 1 after addition of NaOH, 3- Solution 2 after readjusting the pH for initial value of solution 1.*

These results led us to consider the stripping with basic solution efficient for tyrosol, hydroxytyrosol, p-coumaric acid and p-hydroxybenzoic acid. However, for the other polyphenols, degradation products will be obtained, leading to their poor recovery. Several basic stripping solutions were assayed for p-coumaric acid (Table 4).

*Table 4. Efficiency of different strip solution compositions for stripping of p-coumaric acid.  
Aqueous phase/Organic phase of 1 (v/v).*

Strip liquor	Strip efficiency (%)	Strip liquor	Strip efficiency (%)
NaCl 1 M, pH 2	1	NaOH 2 M, pH14	13
NaCl 1 M, pH 10	4	NaOH 0.5 M + NaCl 0.1 M	31
NaCl 3 M + NaOH 2 M, pH 14	94	NaOH 0.5 M + NaCl 0.3 M	59
NaOH 0.01 M, pH 12	2	NaOH 0.5 M + NaCl 0.5 M	75
NaOH 0.5 M, pH 14	7	NaOH 0.5 M + NaCl 1 M	91
NaOH 1 M, pH 14	11	NaOH 0.5 M + NaCl 3 M	95

## CONCLUSIONS

COD and turbidity from OMWW were efficiently removed by a precipitation/coagulation process with iron(III) or lime, followed by sedimentation. Dilution is needed to decrease the amount of ferric chloride or lime added to the effluent. Also, flocculant improved the coagulation performance. From the results reported above, it is possible to conclude that addition of about 5g/l of lime, to the ½ diluted effluent, are sufficient to produce a treated effluent with very low turbidity and suspended solids contents. This supernatant is suitable for solvent extraction application. Consecutive extraction steps resulted in the recovery of a solution rich in hydroxytyrosol.

If Aliquat 336 was used for a synthetic solution of p-coumaric acid extraction, the system Aliquat 336 10%+ 1-decanol 10% + SST 80% allow a concentration of p-coumaric acid in organic phase above 10g/l without third phase formation. Stripping with NaOH 0.5 M + NaCl 0.5 M was efficient for tyrosol, hydroxytyrosol, p-coumaric acid and p-hydroxybenzoic acid without polyphenol degradation. However, for the other polyphenols, degradation products were obtained, leading to their poor apparent recovery, in spite of the solvent being stripped.

## METHYL TERT-BUTYL ETHER - A NEW SOLVENT FOR PHENOL AND ACETIC ACID EXTRACTION FROM WASTEWATER

Costică Strătulă, Florin Oprea, Casen Panaiteșcu, Mihaela Petre and Gheorghe Botoc\*

Universitatea Petrol-Gaze Ploiești, Romania

\*S. C. Carom S.A., Onești, Romania

In order to remove phenol from wastewater several solvents are used: aromatics, butyl acetate, and diisopropylether. Liquid-liquid experimental data in the system water-phenol-methyl *t*-butyl ether (MTBE) shows a much higher distribution coefficient for this solvent than other solvents. Similarly, the liquid-liquid experimental data show the same high distribution coefficient for this solvent in the water-acetic acid-MTBE system. Based on these experimental data, industrial plants for phenol and acetic acid extraction with MTBE have been designed. The industrial plants have two parts: the liquid-liquid extraction column and solvent recovery from the two phases: the extract phase (MTBE phase) and the water phase. Solvent recovery from water phase is necessary as the solubility of MTBE in water is nearly 4% by mass. Economic calculations show that in the case of phenol, the annual operating cost is under the value of the recovered phenol and a profit is obtained. In the case of acetic acid, even with two recovery columns, the process is much more advantageous than ordinary distillation or azeotropic distillation with butyl acetate.

### INTRODUCTION

In the phenol production process (cumene hydroperoxide method) wastewater with a phenol content of 0.5-2% by mass is produced. Such waters also result from NOVOLAC fabrication, wood distillation and in the thermocatalytic process in refineries, in which the phenol concentration is much lower (600-1000 ppm by mass). To avoid river and underground water pollution it is necessary to remove phenol from this water. For this is necessary to: (1) design and construct the wastewater treatment plant at the same time as the phenol production plant and, (2) choose a process with minimum phenol content in wastewater and with a minimum flow rate of such water. For existing processes, the flow rate of wastewater with phenol can be reduced by water recycling (totally or partially) after treatment and conditioning.

There are several processes for phenol removal from waste water, depending on the initial and final phenol contents required: (1) liquid-liquid extraction with several solvents, (2) distillation in presence of electrolytes, (3) adsorption on active carbon, and (4) biochemical process. In order to remove phenol from waste water using liquid-liquid extraction it is necessary to solve two problems: (1) proper liquid-liquid extraction using different solvents, and (2) solvent regeneration and phenol recovery.

## PHENOL EXTRACTION FROM WASTEWATER WITH MTBE

### Experimental Concerning Liquid-Liquid Extraction Data

In the liquid-liquid extraction of the phenol, different solvents are used: aromatics (benzene, toluene, xylenes, cumene), diisopropylether, butylacetate, and methyl *t*-butyl ether (MTBE). The most important property of a solvent is its solving power (capacity) for the component that is extracted, in our case phenol. This power can be expressed by the distribution coefficient, K, defined as the ratio of solute concentrations in both liquid phases:

$$K = \frac{Y}{X}, \quad (1)$$

where Y represents the phenol concentration in solvent (kg phenol/kg solvent or kg phenol/m<sup>3</sup> solvent);

X is the phenol concentration in wastewater (kg phenol/kg water or kg phenol/m<sup>3</sup> water).

As the distribution coefficient increases, the solving power of the solvent improves, and the performance of the process is better, requiring fewer equilibrium stages, a lower solvent ratio, and giving a higher degree of extraction. From this point of view, the solvents like diisopropyl ether butyl acetate and MTBE, having higher distribution coefficients, are better than aromatics.

In the case of phenol extraction with MTBE, liquid-liquid equilibrium data are presented in Figure 1. Experimental values were fitted and resulted in the fit of a Nerst-Shilov equation:

$$Y = a \cdot X^b, \quad (2)$$

where a has the value 1547.23411 and b = 1.39004.

The distribution coefficient of phenol in MTBE (80 to 110) is greater than the distribution coefficient of phenol in benzene, which has the value 3, and is comparable with those of butyl acetate and diisopropyl ether. On the other hand, the price of MTBE is much lower than that of the latter solvents (around US\$ 200 per tonne).

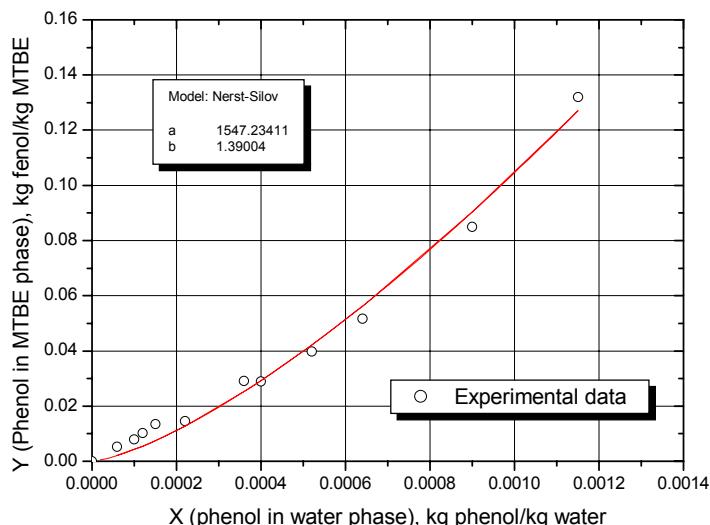

Figure 1. Liquid-liquid equilibrium data for the water-phenol-MTBE system.

### The Design of the Liquid-Liquid Phenol Extraction Column

With these data the principal parameters of the phenol extraction column can be calculated (number of theoretical trays and solvent ratio). In the extraction column presented in Figure 2,  $S_1$  represents water flow rate (kg/h);  $S_2$  – MTBE flow rate (kg/h);  $X_i$ ,  $X_e$  – phenol content in aqueous solution, input and output from the column (kg phenol/kg water);  $Y_i$ ,  $Y_e$  – phenol content in MTBE stream, input and output from the column (kg phenol/kg MTBE).

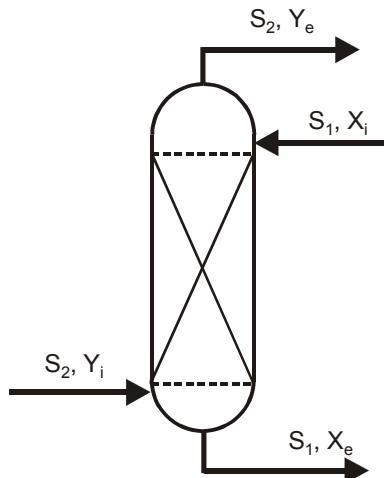

Figure 2. Extraction column configuration.

For a practical example it can be considered that in order to reduce phenol content in stream  $S_1$  from an input value  $X_i = 0.031$  kg phenol/kg water to an output value  $X_e = 0.0003$  kg phenol/kg water, the MTBE stream  $S_2$  enriches from the input concentration  $Y_i = 0.005$  kg phenol/kg MTBE (see next section) to several output concentrations  $Y_e$ . Using a simplified graphical method in rectangular diagram [1] the solvent ratios,  $S_2/S_1$ , were calculated for different numbers of necessary equilibria (number of theoretical trays),  $N_{tt}$ . The pairs ( $S_2/S_1$ ,  $N_{tt}$ ) are presented in Figure 3.

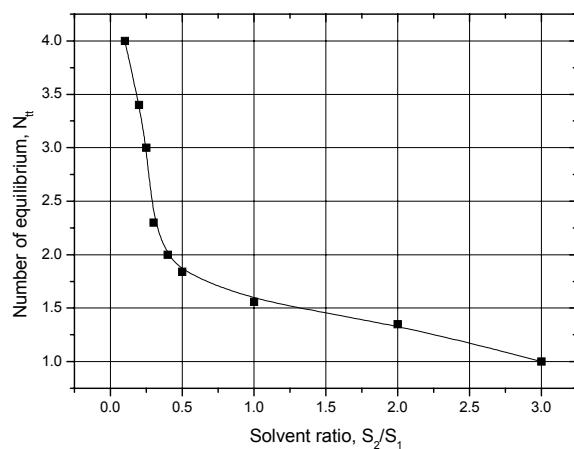

Figure 3. Number of theoretical trays versus solvent ratio for phenol extraction.

### Design of the Recovery Solvent System (Phenol Case)

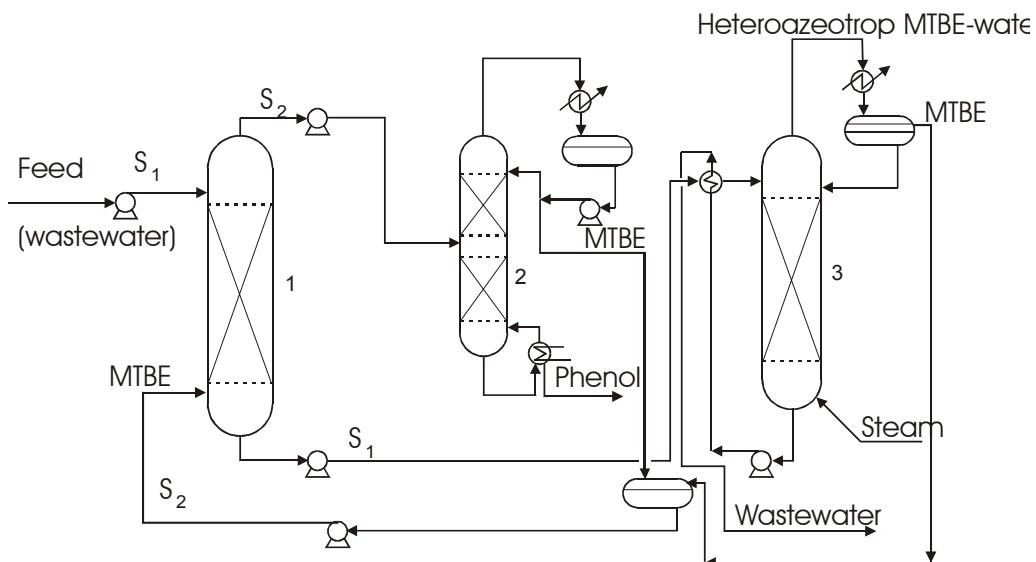

In order to design a continuous phenol extraction system, with the correct number of extraction stages, it is necessary to include a solvent regeneration stage, simultaneously with extracted phenol recovery. In this way, the solvent can be recycled to the extraction stage. For these reasons, the regeneration stage has the same importance as the extraction

stages, and the design of this stage often is more difficult. In the case of phenol extraction with MTBE, because of the mutual solubility of water and MTBE, water stream  $S_1$  from the bottom of extraction column will contain MTBE at the solubility limit, and MTBE stream  $S_2$  from the top of extraction column will contain some water at the solubility limit. Therefore, the regeneration system for the solvent, MTBE (see Figure 4), will have two stages: one stage (column 2) for phenol separation from MTBE stream  $S_2$ ; and one stage (column 3) for MTBE separation from water stream  $S_1$ . Using this installation, the MTBE losses are substantially reduced.

The analysis of such a process leads to the utilities consumption presented in Table 1 for a feed flow rate (wastewater) of 1500 kg/h and for 20 ppm by mass maximum MTBE content in the wastewater [2, 3].

*Table 1. Main utilities consumption.*

Utility	Annual consumption	Cost (US\$)
Steam (tonne)	2776	15.6
Cooling water ( $m^3$ )	43 120	0.024
Electric power (kWh)	6160	0.042

*Figure 4. Phenol extraction with MTBE installation.*

Considering the utilities prices in Table 1, this process results an annual total utilities cost of US\$25089. This process recovered 353.6 t/a phenol at a phenol price of US\$800/t, resulting in an operational cost of this process of only 8% of the value of the recovered phenol, even if the main goal of this process is cleaning wastewater with high phenol content.

## ACETIC ACID EXTRACTION FROM WASTEWATER WITH MTBE

### Experimental Concerning Liquid-Liquid Extraction Data

In order to recover acetic acid from wastewater streams (resulting from production of acetic acid, dimethyl terephthalate, etc.) different processes can be used: (1) liquid-liquid extraction with different solvents, (2) distillation, and (3) azeotropic distillation. There are two conditions for the use of solvents: (1) high distribution coefficient, and (2) a high enough boiling

temperature to ensure easy solute separation. The good results obtained for phenol extraction with MTBE led to the idea of using MTBE as a solvent for acetic acid extraction. Experimental data in this case are presented in Figure 5.

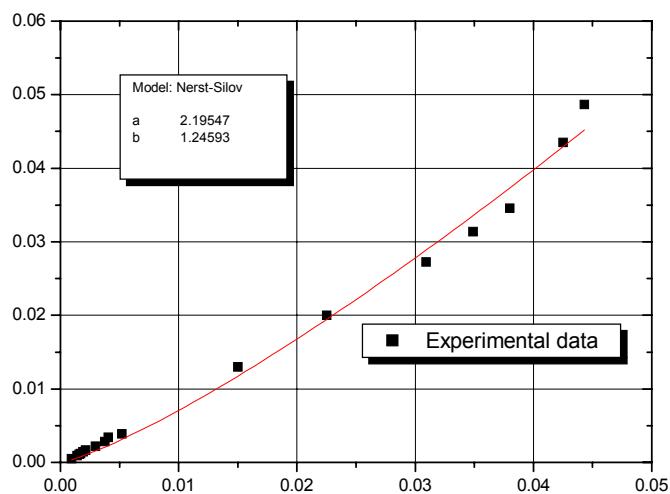

Figure 5. Liquid-liquid equilibrium data for the water- acetic acid - MTBE system.

The experimental values were fitted and a Nerst-Shilov equation obtained similar to Equation (2), where  $a$  has the value 2.19547 and  $b = 1.24593$ .

#### The Design of the Liquid-Liquid Extraction Column and Solvent Recovery System (Acetic Acid Case)

The same analysis as for the phenol case phenol was carried out in order to determine  $S_1/S_2$  for different numbers of theoretical trays,  $N_{tt}$ . The results are presented in the Figure 6.

The flowsheet of the process, with the recovery solvent system is the same as that presented for the phenol case. An economic comparison between this system and acetic acid removal using ordinary distillation was done in the case of a wastewater flow rate of 1500 kg/h with 9% weight acetic acid (Table 2).

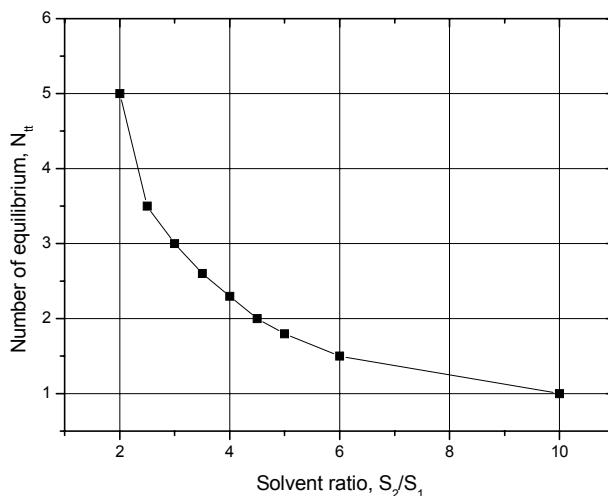

Figure 6. Number of theoretical trays versus solvent ratio for acetic acid extraction.

*Table 2. Economic comparison between two acetic acid removal processes: extraction and ordinary distillation. (Acetic acid product flow rate = 140 kg/h.)*

	Solvent ratio	$N_{tt}$	Steam consumption (t/h)	Water consumption (t/h)
Extraction followed by solvent recovery	2	5	1.2	35.4
	3	3	1.86	50.4
	4.5	2	3.54	93
Ordinary distillation	Reflux ratio: 2:1		5.52	142.8

## CONCLUSIONS

The liquid-liquid equilibrium data for system water-phenol-MTBE and for the system water-acetic acid-MTBE were experimentally obtained. These data were fitted to an equilibrium curve corresponding to the Nerst-Shilov equation.

Commercial processes for phenol and acetic acid removal were proposed. These include an extraction column, a column to separate MTBE from phenol/acetic acid, and a column to separate MTBE from water.

Technical and economical viability of the proposed processes has been successfully demonstrated. In the case of phenol removal, the economic analysis shows that the operating costs of this process represent only 8% of the value of the recovered phenol. In the case of acetic acid removal, the economic analysis shows that the steam consumption is 4.6 times lower and the water consumption 4 times lower than for ordinary distillation.

## POINT SOURCE RECOVERY OF HYDROCARBONS FROM WASTEWATERS BY SOLVENT EXTRACTION

Marc Halevy and Peter Jones

Universite de Sherbrooke, Quebec, Canada

An industrial liquid-liquid extraction process prototype is under development for the recovery of selected industrial solvents that are characterized by a limited but non-negligible aqueous miscibility, including phenol, and low molecular weight chlorinated organics and petroleum hydrocarbons. Process development activities presented in this paper were pursued on industrial wastewaters generated during routine aircraft maintenance operations. Aircraft coatings removal and application operations were targeted in order to recover solvents used in painting/paint stripping operations. Process development activities are pursued on an extraction process that relies on phosphine chemistry, on the use of a multi stage internal centrifugal mixer separator for phase contacting and separation, and on distillation/solvent washing for product and extractant separation and recovery.

### INTRODUCTION

Aircrafts are constantly subjected to hostile environments. Corrosion control operations ensure safety and lifespan. Wastewaters generated during coatings removal and/or application operations to aircraft surfaces are characterized by high concentrations of hazardous organics and inorganics that originate from the:

- usage of complex, maintenance formulations, based on petroleum-based and synthetic solvents, including dichloromethane, phenol, ketones, and benzoyl alcohol.
- paints, primers, and conversion coatings being removed from aircraft surfaces.
- aircraft metal and/or composite surfaces.

The majority of aircraft maintenance facilities surveyed or audited throughout Canada, United States, and Western Europe, generate wastewaters very similar in characteristics. Typical characterization data is summarized in Table 1 for organic parameters pertinent to this process development segment. This data is typical of a wastewater that was collected in a maintenance hangar where good housekeeping practices and waste segregation measures were implemented.

The wastewater was pre-treated to remove contaminants detrimental to the cyclic performance of the extraction process under development. These contaminants were shown, in earlier process development extraction runs, to have a noticeable impact on coalescence rates, solutes partitioning, hydration and free (entrained) water content in the loaded extractant, on crud formation in the solvent extraction and washing circuits, and on solvent poisoning.

*Table 1. Analytical characterization data highlights.*

Parameter Type	Concentration (mg/L)
Biochemical Oxygen Demand (BOD)	59
Chemical Oxygen Demand (COD)	15 100
Total Organic Carbon (TOC)	3 760
Phenol	4 670
Total Petroleum Hydrocarbons (TPH)	318
Dichloromethane	67
(Other) Volatile Organics (VOC)	< 10
Alcohols (C <sub>1</sub> – C <sub>6</sub> )	97
(Other) Semi-Volatile Organics	< 10

## EXPERIMENTAL SET-UP AND WORKPLAN

Stringent protocols were established for sampling, shipment, storage, preparation, equipment clean up and set-up, materials preparation, treatability, and analytical characterization. Aircraft paint stripping wastewaters were collected from selected Canadian aircraft maintenance hangars. The extractant formulation was based on Cyanex 923™, manufactured by Cytec Canada. Throughout the pursuit of the bench and pilot scale process development studies, phenol was selected as the main monitoring parameter. Occasional monitoring of organics by GC/MS, TOC, TPH (dichloromethane-extractables) and O&G (n-hexane extractables) was also conducted. The 4-amino-antipyrine Standard Method 5530 was retained for the spectrophotometric determination of phenol concentrations.

All chemicals used were reagent-grade. High detergency solutions and hot caustic solutions were used for the cleaning of equipment and peripherals. Hot tap water was used for rinsing. Treatability was conducted at 20–25°C. Solution pH for the wastewater was adjusted to a neutral to slightly acidic range (5<pH<7) that was previously shown to optimize the extraction process.

Bench scale experimentation was initially pursued to assess phenol partitioning in the extractant formulation. Aqueous and solvent phases were contacted until equilibrium conditions were reached. Reaction kinetics were studied to assess the:

- kinetics of the complexing reaction.
- rates of diffusion of the specie(s) that control the chemistry of the process.
- effect of reaction temperature and ionic strength on extraction performance.

Bench scale runs were either pursued in one litre, high shear (20000 rpm) mixer/homogenizer, for the thermodynamic studies, or in a two litre baffled vessel equipped with a variable shear mixer (600–2750 rpm) for the kinetic studies. Proper agitation was consistently realized to ensure that spatial composition gradients were minimized. Absolute liquid-liquid phase separation was achieved by using a phase separation inert microfiltration membrane.

In order to capture kinetic data, additional phenol needed to be added to the wastewater to increase the 4–7 g/L concentration range typically observed to 17–20 g/L. Very high aqueous-to-organic ratios (A:O) were retained, typically 100:1.0 (100) to 100:0.5 (200). A time lapse of five seconds was set to turn off the mixer, transfer the solution to the microfiltration unit, and collect the filtrate. In cases where an insufficient volume of filtrate was collected, the run was discarded, and repeated.

The bench scale treatability studies included the simulation of an ideal countercurrent process for several phase ratios. The following procedure was retained to simulate an ideal two-stage countercurrent process:

1. Feed, F, was contacted with virgin extractant, E. Extract, E2', was discarded. Raffinate, R1', was kept.
2. R1' was contacted with virgin extractant, E. Raffinate, R2', was discarded. Extract, E1', was kept.
3. E1' was contacted with Feed, F. Extract, E2', was discarded. Raffinate, R1', was kept.
4. R1' was contacted with virgin extractant. Raffinate, R2', was sent for analysis and discarded. Extract, E1', was kept.
5. Feed, F, was contacted with E1', and the cycle was repeated two additional times, to reach steady state.

## BENCH SCALE RESULTS AND DISCUSSION

Table 2 presents the distribution data for all five different 200 L batches collected for the conduct of the bench scale treatability program. Partition coefficients showed a strong concentration dependency: a range of 260 to 1457 was observed for phase ratios, A:O, of 100 to 1, and corresponding equilibrium phenol concentrations in the extract of 5 g/L to 372 g/L, respectively. In addition to the concentration dependency observed for phenol, the non-linear data collected suggests that other solute(s) might also be competing. From earlier trials on pure phenol systems where similar behavior was observed, water is known to be one of the competing solute. The partition data were retained for subsequent graphical and numerical analysis.

*Table 2. Partitioning data summary.*

A : O	Individual Distribution Coefficients	Mean and Standard Variation
100:1.0	255; 262; 263	260 and 4.7
100:2.0	474; 454; 441	456 and 16.6
100:2.5	350; 357; 222; 282	303 and 63.6
100:5.0	926; 901; 901; 955; 940; 792; 784	886 and 69.5
100:10	1162; 1136; 1136; 1160; 1142; 1208; 1196	1163 and 28.9
100:50	685; 685; 605	658 and 46.2
100:100	1718; 1718; 1169; 1151; 1718; 1217; 1507	1457 and 271.1

Initial Phenol Conc. Range 5.156 g/L - 6.030 g/L.

Table 3 presents the partitioning data generated for an ideal two-stage countercurrent extraction process. The empirically derived data confirms that a raffinate phenol concentration of 5 mg/L (and a corresponding 99.9 % phenol reduction) can be met for a A:O phase ratio of 20, resulting in a phenol loading in the extractant of 114 g/L. It should be noted that this treatability segment was pursued not to maximize phenol concentration in the extract, which was shown to be as high as 364 g/L under some of the higher A:O phase ratio runs presented, but to empirically derive ideal phase contacting/separating distribution data for a countercurrent, multi-phase process.

Tables 4 to 7 present extraction rate regime data. This kinetic study was conceived to distinguish the effect of the chemical reactions involved in solute partitioning from the effect of rate limiting diffusional processes. No temperature effect was noted in the range of 20 C to 70 C. When sodium chloride was retained to modify the aqueous ionic strength of the wastewater, no impact on partitioning values was observed for a range up to 100 g (NaCl)/L.

*Table 3. Ideal two stage countercurrent process performance summary.*

A:O	Mean (Standard Variation) Aqueous Phenol Conc. in Feed (g/L)	Mean (Standard Variation) Aqueous Phenol Conc. @ Stage 1 (g/L)	Mean (Standard Variation) Aqueous Phenol Conc. @ Stage 2 (g/L)
100 :1.0	5.156	4.21 (0.17)	1.56 (0.06)
100:2.0	5.156	1.69 (0.09)	0.19 (0.00)
100:2.5	5.59 (0.12)	0.87 (0.08)	0.030 (0.00)
100 : 5.0	5.45 (0.24)	0.144 (0.001)	0.005 (0.00)

Initial phenol conc. range 5.156 g/L - 5.687 g/L.

*Table 4. Effect of temperature on partitioning data.*

Temperature (K)	Phenol Concentration (mg/L) @ Reaction Time (min)				
	@ 0.5	@ 1.0	@ 2.0	@ 3.0	@ 5.0
322	140	131	128	126	138
331	147	127	120	127	129
343	140	134	129	121	138

Initial Phenol Conc. = 5.889 g/L; A:O = 100:5.

*Table 5. Impact of ionic strength on partitioning data.*

$\text{Na}^+\text{Cl}^-$ Concentration (g/L)	Phenol Conc. (g/L) @ reaction time (sec)				
	@ 5	@ 10	@ 15	@ 30	@ 150
3 g/L	3.09	3.11	3.03	3.19	3.23
100 g/L	3.06	3.14	3.01	3.06	-

Initial Phenol Conc. = 5.460 g/L; A:O = 100:0.5.

*Table 6. Kinetic regime extraction data.*

Phenol Conc. (g/L)	Reaction time (s)							
	2	2	3	4	5	10	60	120
	12.82	12.83	12.08	11.78	11.76	11.78	11.71	11.76

Initial Phenol Conc. = 19.430 g/L; A:O = 100:1.

*Table 7. Diffusional regime extraction data.*

Reaction Time (sec/min)	Aqueous Phenol Conc. (g/L) @ Stirring Rate (rpm)					
	@ 600	@ 800	@ 1 000	@ 1 500	@ 2 000	@ 2 750
0 (initial)	18.7	18.8	17.2	19.2	19.1	20.0
2 s	-	-	-	-	15.8	15.9
5 s	-	-	16.1	15.6	14.1	14.7
15 s	17.1	-	15.5	14.3	13.3	13.4
30 s	16.5	16.7	14.8	13.1	12.8	13.0
1 min	15.4	15.5	14.0	12.1	12.6	12.8
2 min	-	14.2	12.6	12.7	-	-
5 min	12.8	12.4	11.1	12.4	-	-
10 min	12.2	-	-	-	-	-

The kinetic data showed very fast reaction kinetics, and the following linear regression was derived:

$$\ln(C - C_{eq}) = -1.36(t) - 1.66$$

Next, diffusion-controlled kinetic data as a function of stirring rate was analysed. A linear regression was undertaken for each set of stirring rate data set. First order reaction rate constants were derived, and the following regression analysis relating individual reaction rate constants to the corresponding stirring rates is presented:

$$\ln(k) = 1.53 \ln(\text{rpm}) - 14.51$$

The kinetic data clearly shows the notable increase in kinetic rate constant values with increasing mixing energies. A significant increase in the rate constant by two orders of magnitude was observed when the system was operated in a kinetic regime (at 20000 rpm).

Based on the bench scale treatability data generated, a pilot scale program was undertaken with the wastewater as the continuous phase, as it is mass transfer controlling. Very high A:O phase ratios were experimented with, without any extract recycle. A kinetic operating regime operation and short residence time for partitioning and phase disengagement and separation were investigated.

The extractant-based formulation had already been modified in earlier trials to provide effective droplet coalescence in order to achieve rapid and clean phase separation even at high phenol loading in the extract when using a static settler/decanter. Consequently, short phase-separation times of the order of only a few seconds under several hundred g-force factors could conceivably be sufficient to simulate near ideal plug flow dynamics in a discrete multi-stage contactor. For those reasons, the use of an industrial multistage internal centrifugal mixer-separator contactor was chosen for the upcoming pilot scale development activities (to be presented in the oral or poster presentation). Figure 1 presents the schematics for the solvent extraction process under development.

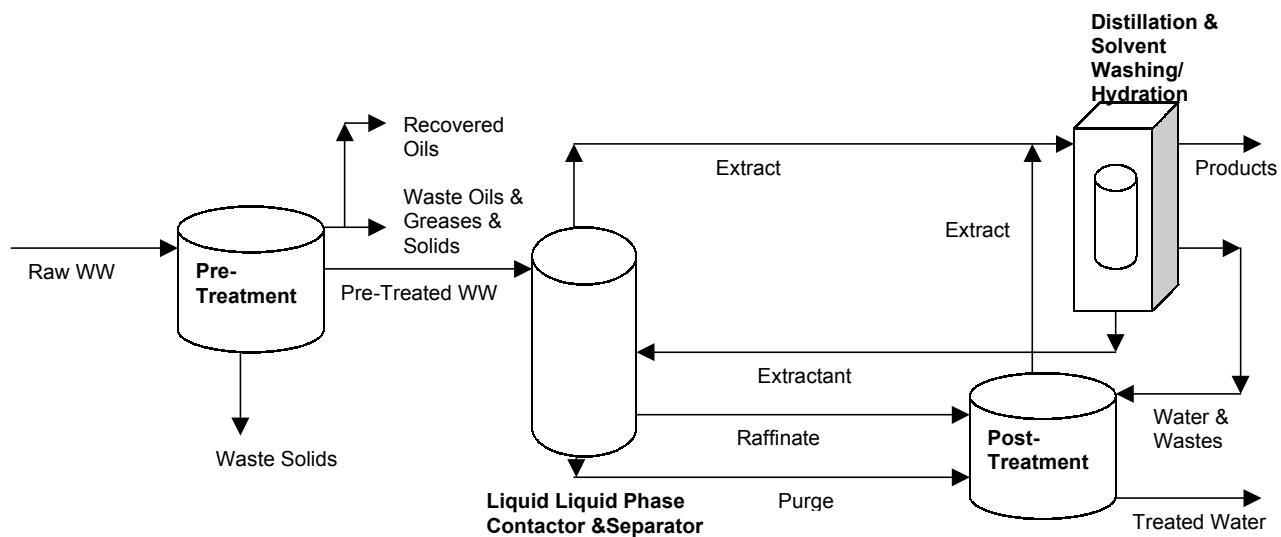

Figure 1. Solvent extraction circuit.

## **SUMMARY AND CONCLUSIONS**

Process development studies pursued at bench scale confirmed the strong affinity between Cyanex 923 and the targeted solvents and hydrocarbons in the wastewaters, including phenol, dichloromethane,  $\geq 4$ -C linear aliphatic alcohols, and residual concentrations of dissolved petroleum-based hydrocarbons. Phenol partitioning coefficients were observed to show a strong concentration dependency over the concentration range studied. Very high phenol loading in the extract was achievable and could exceed 370 g/L. Reaction kinetics were very fast. This almost instantaneous chemical reaction and/or partitioning confirm the possibility of conceiving the operation of a commercial process under a kinetic regime.

## CATALYST RECOVERY FROM THE WET PEROXIDE OXIDATION PROCESS BY MEANS OF NON-DISPERSIVE SOLVENT EXTRACTION

A. M. Urtiaga, C. Muela and I. Ortiz

Departamento de Ingeniería Química y Química Inorgánica, Universidad de Cantabria,  
Santander, Spain

In this work we analyse the recovery of a mixture of Fe(III), Cu(II) and Mn(II) used as a catalyst in the Wet Peroxide Oxidation Process by means of non-dispersive solvent extraction. The performance of different solvent extraction reagents was tested: D2EHPA, LIX 622N and Cyanex 272. LIX 622N was selected as a selective extractant for Cu(II) recovery, and Cyanex 272 for the selective recovery of Fe(III) and Mn(II). Extraction selectivity was achieved by working at different pH values in the feed solution. The three metals were stripped using sulphuric acid.

### INTRODUCTION

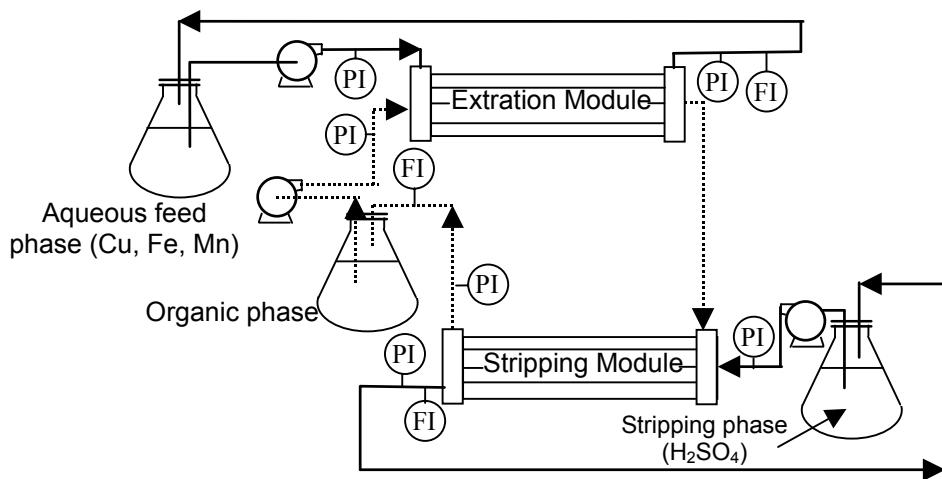

Chemical oxidation of refractory organic pollutants is an attractive method for industrial waste reduction because of its high efficiency and simplicity. Of these methods, hydrogen peroxide treatment has emerged as a viable alternative. It does not form harmful by-products and H<sub>2</sub>O<sub>2</sub> is a non-toxic chemical [1]. However the methods for oxidation of wastewaters with hydrogen peroxide are mostly based on homogeneous catalysis by metal ions. In the novel Wet Peroxide Oxidation (WPO) process a catalytic mixture of Cu(II), Mn(II) and Fe(II) is used [2]. But the use of metallic salts as catalysts induces additional pollution. When the oxidation is complete the metal catalysts are precipitated to form a sludge that must be managed as a toxic waste.

In this work, the viability of the recovery by means of membrane-based non-dispersive solvent extraction (NDSX) of Fe(III), Cu(II) and Mn(II) from the oxidised wastewater stream is analysed, as an alternative to the metals precipitation step.

### EXPERIMENTAL

The schematic representation of the experimental system that has been used for individual metal recovery is shown in Figure 1. The NDSX experimental set-up consisted of two hollow fibre contactors, having the following characteristics: 10,000 porous polypropylene fibres; internal diameter  $2.4 \times 10^{-4}$  m; wall thickness  $3.0 \times 10^{-5}$  m; mass transfer area  $1.4 \text{ m}^2$ .

As the feed phase, synthetic aqueous solutions of Fe<sub>2</sub>(SO<sub>4</sub>)<sub>3</sub>, CuSO<sub>4</sub> and MnSO<sub>4</sub> were used; initial metal concentrations simulated the average values in the aqueous stream after the Wet Peroxide Oxidation Process, *i.e.*, Cu, 250 mg/l; Fe, 170 mg/l and Mn, 170 mg/l. The performance of several extractants was studied: bis(2-ethylhexyl)phosphoric acid (D2EHPA) (Merck), LIX 622N (Cognis) and Cyanex 272 (Cytec). All the extractants were used as supplied. Experiments were performed at room temperature.

*Figure 1. Schematic diagram of the NDSX experimental system.*

## SELECTION OF EXTRACTANTS

The work started with selection of extractants for the removal and recovery of Fe, Cu and Mn from the oxidised aqueous stream. A review of the possibilities of solvent extraction in order to achieve metals separation from aqueous solutions containing iron is given by Ritcey [3]. Using the phosphinic acid Cyanex 272 together with tri-butyl phosphate (TBP) as the modifier, iron can be readily stripped from the loaded organic phase with sulphuric acid [3]. The solvent extraction of copper is a well-established hydrometallurgical process. The extractants with hydroxyoxime functional groups for chelation are in use in commercial solvent extraction-electrowinning plants. Chelating extractants are known to be selective for copper over Fe(III), the selectivity being based on the relative rates of extraction of copper and Fe(III).

In order to check the viability of the selective removal of copper from an aqueous solution containing Cu, Fe and Mn, the behaviour of LIX 622N was investigated. Results are given in Figure 2. It is observed that the concentration of Cu in the feed tank decreased with time while the concentrations of Fe and Mn remained at the initial value. According to these results it was thought that the separation of copper could be performed in a first step using LIX622N as a selective extractant.

A series of iron extraction/stripping experiments using D2EHPA and concentrated sulphuric acid and hydrochloric acid as stripping agents did not permit stripping efficiencies of Fe higher than 25% to be obtained. Thus the use of D2EHPA was discarded. Next the performance of Cyanex 272 was tested. As shown in Figure 3, Fe(III) is extracted and recovered in the stripping phase while Mn(II) remains in the feed phase. According to the information of the manufacturer (Cytec), the effect of the pH of the feed phase permits the selective separation of Fe and Mn from a sulphate media using Cyanex 272. Figure 4 shows the results of Mn extraction and stripping.

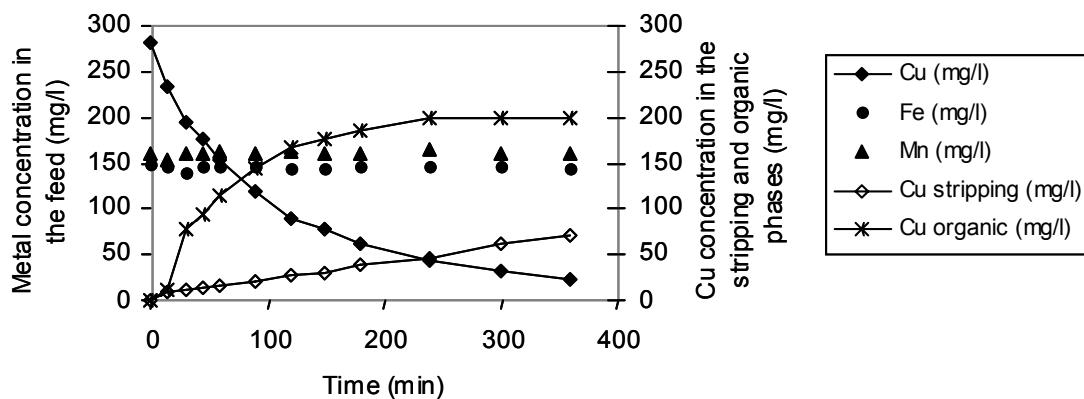

Figure 2. NDSX of Cu using LIX 622N. Organic phase: 10% v/v LIX 622N, 10% v/v TBP in kerosene. Initial pH of the feed phase pH=2. Stripping phase: sulphuric acid 2 M.

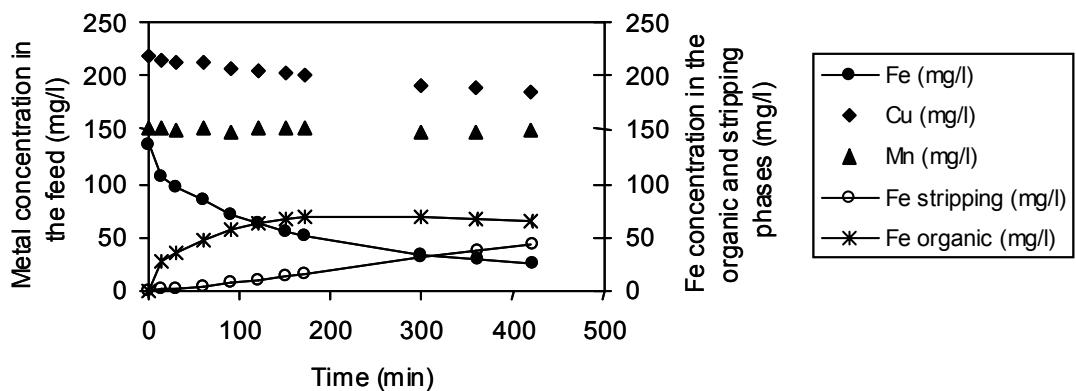

Figure 3. NDSX of Fe. Organic phase: 7.5% v/v Cyanex 272, 7.5% v/v TBP in kerosene. Initial pH of the feed phase pH=2.75. Stripping phase: sulphuric acid 2 M.

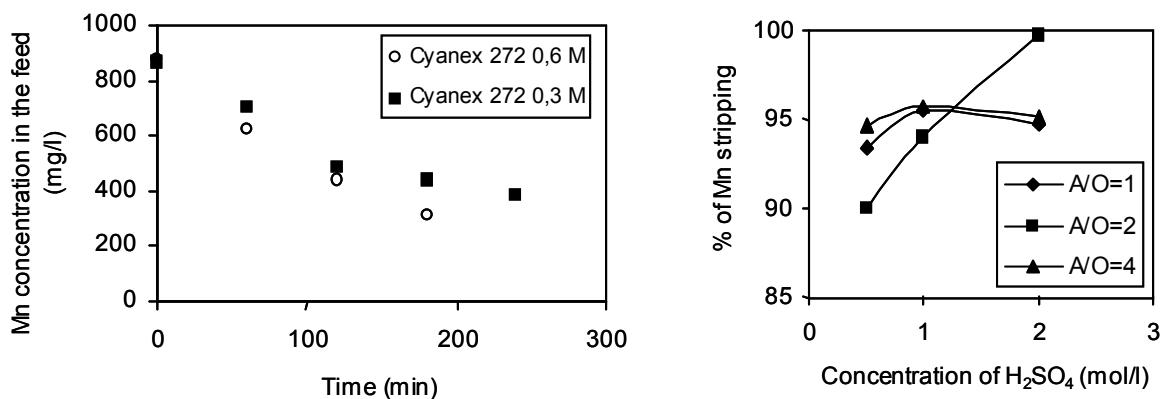

Figure 4. NDSX of Mn using Cyanex 272. Organic phase: Cyanex 272 0.3 M and 0.6 M, 10% v/v TBP in kerosene. pH of the feed phase pH=5.25. Stripping tests performed in perfect mixing experiments.

From the results obtained, the flowsheet proposed for the NDSX recovery of the WPO catalyst is shown in Figure 5.

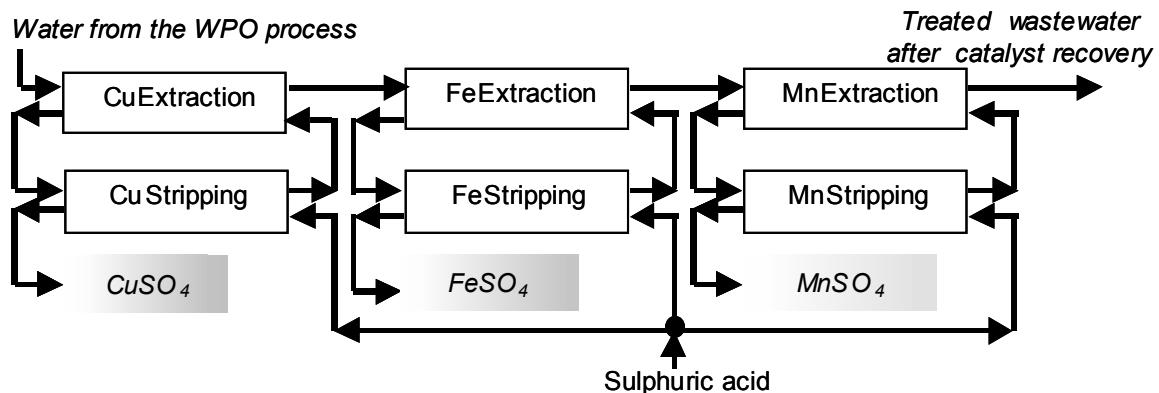

Figure 5. Flowsheet of the NDSX process for the recovery of the WPO catalyst.

### KINETICS OF COPPER EXTRACTION AND STRIPPING

Following the preliminary experiments for the selection of extractants, the NDSX process for the recovery of Cu was studied in detail. Kinetic experiments were performed working with a synthetic feed solution with an initial Cu concentration of 200 mg/l. Results are shown in Figure 6. In order to increase the concentration of Cu in the stripping solution, a set of experiments were carried out replacing the feed solution by a fresh one after 90 minutes running, while the organic and feed solutions were maintained the same.

It can be seen that the Cu concentration in the feed phase reaches values lower than 0.5 mg/l in the cycles 1, 2 and 3. In the stripping phase the Cu concentration increases linearly with time up to a value higher than 2 g/l. The concentration of Cu in the organic phase is maintained under 110 mg/l during all the experimental time. However, the rate of the extraction step is lower as time is increased, probably due to the influence of the loading of the stripping phase. Figure 7 shows the results of a similar experiment with two longer extraction cycles and using 10 litres of feed phase.

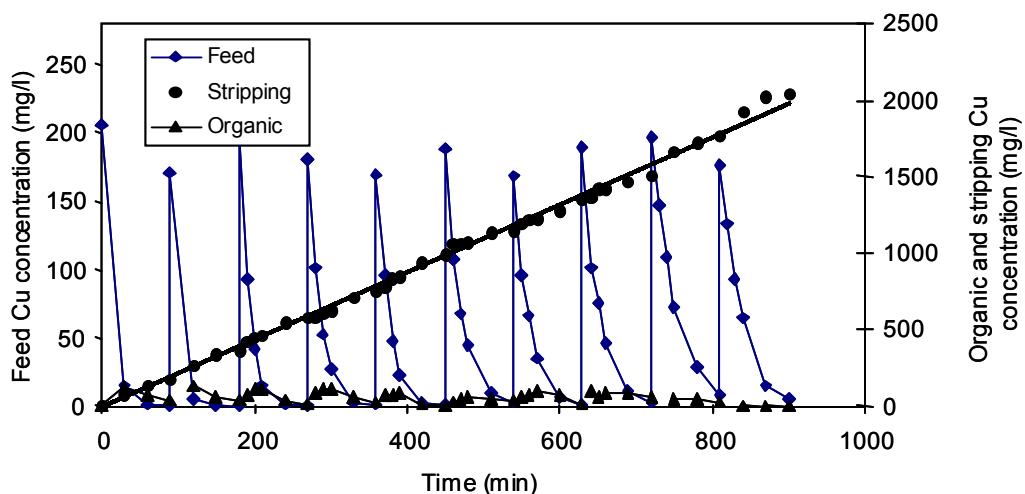

Figure 6. Evolution of the Cu concentration in the feed, stripping and organic tanks. Organic phase: 10% LIX 622N; 10% TBP in kerosene. Stripping phase:  $H_2SO_4$  1M. Constant feed pH = 2.5.  $V_{feed} = V_{org} = V_{stripping} = 1$  litre.

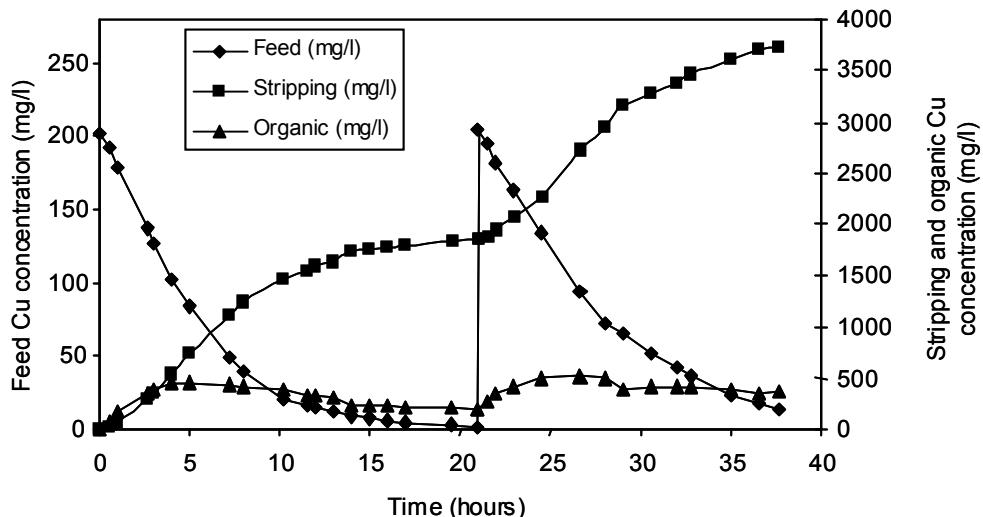

Figure 7. Evolution of the Cu concentration in the feed, stripping and organic tanks. Organic phase: 10% LIX 622N; 10% TBP in kerosene. Stripping phase:  $H_2SO_4$  1M. Constant feed pH = 2.5.  $V_{feed}$  = 10 litres.  $V_{org} = V_{stripping}$  = 1 litre.

### MATHEMATICAL SIMULATION OF THE NDSX OF Cu

The dynamic response of the process has been determined by the solution of the system of differential equations describing the evolution of the concentration of Cu in the feed, organic and stripping phases when flowing along the extraction and stripping modules together with the mass balances for the three tanks considered as ideal stirred vessels. This type of mathematical description has been previously employed to describe the NDSX separation of Cr(VI), Cd(II), and Ni-Cd mixtures [4].

Assuming that the mass transfer rate is limited by the transfer of the complex  $R_2Cu$  in the organic phase immobilised in the porous membrane, the parameters needed for the simulation are the diffusion coefficient of the complex  $R_2Cu$  in the organic phase and the equilibrium constant of the extraction reaction. The stoichiometry of the extraction of Cu with LIX 622N can be described by the expression:

As a first approximation, the values of the parameters were obtained from the literature [5] for the system LIX84-Cu(II):  $D_{CuR2} = 1.46 \times 10^{-10} \text{ m}^2/\text{s}$ ;  $K_{eq} = 1.7$ . Figure 8 shows the comparison of the experimental and simulated evolution of Cu concentration in the feed and stripping phases.

Further work will deal with the kinetic modelling of the selective recovery of Fe and Mn as necessary steps in process design; the methodology applied to the recovery of Cu will be applied to the rest of the metals.

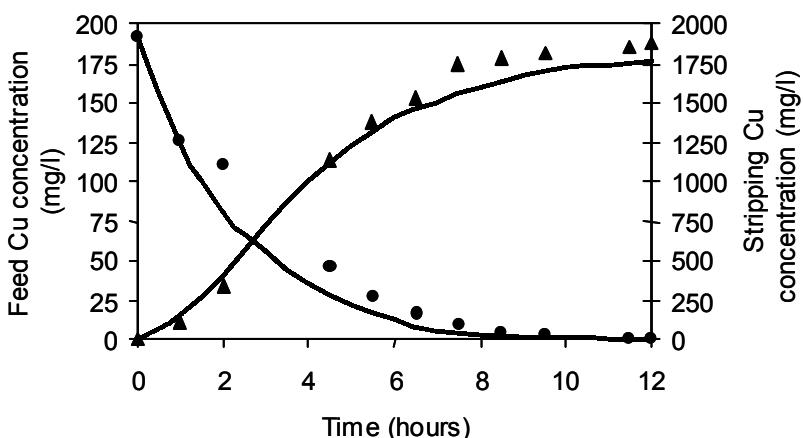

Figure 8. Experimental and simulated concentrations of Cu in the feed and stripping tanks.  
Organic phase: 10% LIX 622N; 10% TBP in kerosene. Stripping phase:  $H_2SO_4$  1M.

## CONCLUSIONS

This work focused on the recovery of the metallic catalyst used in wet peroxide oxidation processes constituted of mixtures of Fe(III), Cu(II) and Mn(II) by means of non-dispersive solvent extraction. It started with the selection of the suitable commercial extractants that would allow selective recovery of the three metals. Preliminary experiments led to the selection of LIX622N and Cyanex 272. Next, the development of the metal separation models and parameters was accomplished starting with the selective recovery of copper. Kinetic experiments were successfully described by means of a mathematical model previously developed for similar systems and using as characteristic parameters,  $D_{CuR2} = 1.46 \times 10^{-10} \text{ m}^2/\text{s}$ ;  $K_{eq} = 1.7$  [5]. Further work will deal with determination of the necessary parameters for the selective recovery of the three metals and definition of the integrated separation process.

## ACKNOWLEDGEMENTS

Financial support of the Ministry of Science and Technology (Spain) and European Commission under the project 1FD97-1189 is gratefully acknowledged. Cytec and Cognis are thanked for providing the extractants used in this work.

# COPPER RECOVERY USING LEACH / SOLVENT EXTRACTION / ELECTROWINNING TECHNOLOGY: FORTY YEARS OF INNOVATION, 2.2 MILLION TONNES OF COPPER ANNUALLY

Gary A. Kordosky

Cognis Corporation, Tucson, USA

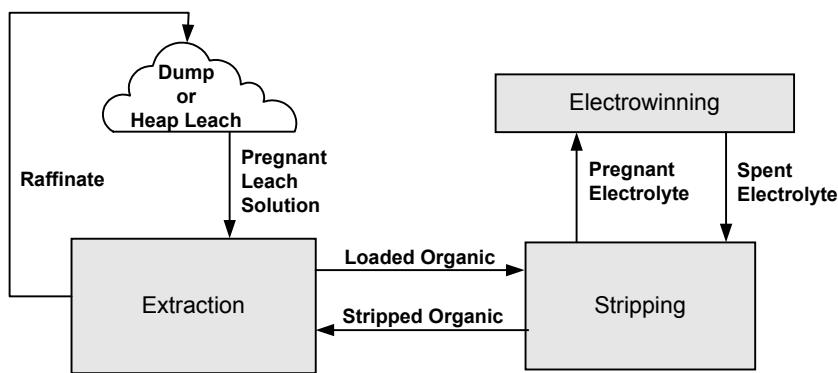

The concept of selectively extracting copper from a low grade dump leach solution followed by stripping the copper into an acid solution from which electrowon copper cathode could be produced occurred to the Minerals Group of General Mills in the early 1960s. This simple, elegant idea has resulted in a technology by which about 2.2 million tonnes of high quality copper cathode was produced in year 2000. The growth of this technology is traced over time with a discussion of the key plants, the key people and the important advances in leaching, plant design, reagents and electrowinning that have contributed to the growth of this technology. Some thoughts on potential further advances in the technology are also given.

## INTRODUCTION

A keynote paper for solvent extraction (SX) applications in hydrometallurgy should “set the stage” for the papers that follow by discussing a commercially successful application of SX in hydrometallurgy. In addition the paper needs to discuss a complete metal recovery process for the simple reason that an SX process for metal recovery does not stand alone, it is always part of an overall metal recovery process. The SX process must be compatible with, and complimentary to, the metal leaching process that precedes it and the metal recovery process that follows. The paper should acknowledge that most of the advances in a metal recovery technology are made for economic reasons. This discussion of the leach / solvent extraction / electrowinning (L/SX/EW) process for copper recovery, considered by some to be one of the great advances in copper recovery technology of the last 100 years [1], satisfies these criteria.

## HISTORICAL BACKGROUND

When the sulfuric acid copper L/SX/EW flow sheet (Figure 1) was put forth by the Minerals Development Group of General Mills in 1960 solvent extraction had been known for over 100 years [2]. It was used extensively on a very small scale in analytical chemistry [3] and on a large scale for the recovery of uranium from sulfuric acid leach solutions [4]. General Mills had already developed and commercialized Alamine® 336 as an SX reagent for the recovery of uranium from sulfuric acid leach liquors [5] and believed that a similar technology for copper recovery would be welcome. However, an extensive market survey showed that the industry reception for copper recovery by L/SX/EW technology was almost hostile. The R&D director of a large copper producer predicted at an AIME annual meeting that there would never be a pound of copper recovered using solvent extraction and his comment prompted applause [5].

*Figure 1. Conceptual Leach / Solvent Extraction / Electrowinning flow sheet.*

Fortunately, the Minerals Development Group of General Mills, in the person of Joe House, Don Agers and Ronald Swanson, believed so much in the copper L/SX/EW process that they kept the development of this technology alive as a “bootleg” project, that is, a project where the three individuals had other primary work duties and could only work on this project when they found time or on their own time. By late 1962 this group had identified and formulated an organic soluble molecule containing a hydroxy-oxime functionality as the reagent LIX® 63. While LIX 63 had many of the properties required for a reagent to be successful in the proposed L/SX/EW flow sheet, LIX 63 was not compatible with the copper leaching process because it did not extract copper below pH ~ 3 [6].

Technically this problem could be solved by neutralizing the acid leach liquor or by leaching oxide copper with ammonia, but neither solution was economical. A molecule that extracted copper well from typical dump leach liquors (pH ~1.8) had to be built. The reagent LIX 64, containing the ketoxime LIX 65 (Figure 2) and a catalytic amount of LIX 63, was introduced in 1965 [7] and in March 1968 the first commercial copper L/SX/EW operation, the Bluebird plant of Ranchers Exploration and Development Corporation, came on line [1].

REAGENT	R	A	TYPE
LIX 65	C <sub>12</sub> H <sub>25</sub>	C <sub>6</sub> H <sub>5</sub>	Ketoxime

### Copper Recovery by L/SX/EW in 1968

In 1968 there was only two widely practiced copper leaching processes using dilute sulfuric acid. The first process, vat leaching of high-grade copper oxide ore followed by EW of copper from the leach solution, produced low quality copper cathode at relatively high cost. In 1968 the tonnage of high-grade oxide ores was decreasing and vat leaching was on the decline.

The second process, heap and dump leaching of low-grade oxide and/or sulfide ore followed by precipitation of low quality copper from the leach solution on scrap iron, was practiced on oxide ore that was too low grade for vat leaching, or low grade sulfide ore that had to be mined in order to expose the underlying high grade sulfide ore. Copper recovered from leaching low grade copper ores was considered a bonus and little effort had been made to fully understand the leaching process or to maximize copper recovery. While some fundamental leaching studies had taken place [8, 9], on the whole leaching was a poorly practiced art and little had been done to make it a well-practiced science.

Solvent extraction for copper was not yet proven commercially so most copper companies were taking a wait and see attitude. Furthermore LIX 64, the only reagent available, had significant limitations with respect to extractive strength, metal transfer kinetics and copper/iron selectivity and it could only be used up to a maximum copper loading of about 3 g/l because of entrainment problems. These properties restricted copper leach solutions which could be effectively treated by SX using LIX 64 to  $\leq$  3 g/l Cu at a pH  $\geq$  1.8.

In 1968 the copper industry as a whole did not believe large quantities of high quality copper could be produced by hydrometallurgy and at the time the Ranchers plant came on line, expectations for the eventual success of copper L/SX/EW technology were rather modest.

#### **Ranchers' Bluebird Sulfuric Acid Leach / Solvent Extraction / Electrowinning Plant**

Ranchers leached run of mine copper oxide ore ( $> 0.5\%$  Cu) placed in a sealed canyon in 20 foot layers (heaps) by distributing dilute sulfuric acid over the fresh ore via spray emitted from needle valves with pipes and needle valves placed to ensure complete coverage of the ore. New heaps were built over old heaps. Pregnant leach solution flowing from the bottom of the heap was collected in a pond created by placing a dam downstream from the leach area. The Bluebird copper SX plant was built similar to existing uranium SX plants with tall, single baffled mixers and long narrow settlers. Dispersion exiting the mixer was pumped to the opposite end of the settler and the phases flowed back toward the mixers.

In electrowinning rich electrolyte with  $\sim$ 36 g/l Cu, 3 g/l Fe and 145 g/l H<sub>2</sub>SO<sub>4</sub> entered one end of the EW cells and spent electrolyte with  $\sim$ 32 g/l Cu and 151 g/l H<sub>2</sub>SO<sub>4</sub> exited the other end. Cathodes weighing 60 kilograms were grown on copper starter sheets at a current density of about 180 A/m<sup>2</sup> with a current efficiency of 80 to 85%. The anode was 6 % Sb in Pb.

Design production at Ranchers was 30,000 pounds of copper daily. In its first fiscal year of operation, July 1968 – June 1969, the Bluebird plant produced 9 million pounds of copper (82% of design), a remarkable achievement for a metallurgical plant using new technology. By later adding only rectifier capacity the plant often exceeded its design production by 50%.

Ranchers' Bluebird plant proved that L/SX/EW technology could produce large quantities of good quality cathode copper on a consistent day to day basis at a profit [1]. This raised the awareness and sparked the interest of the industry in copper L/SX/EW. Improvements in the technology quickly followed from many sources including consultants, copper producers, engineering companies, chemical companies and metallurgical testing laboratories.

## **IMPROVEMENTS IN COPPER L/SX/EW TECHNOLOGY**

#### **Solvent Extraction Reagents**

The first improvement in copper SX reagents came when LIX 64N was added as makeup to the Ranchers plant in late 1968. LIX 64N had greater extractive strength, faster kinetics, faster phase separation, lower entrainment, increased copper/iron selectivity and lower viscosity than

LIX 64 [10]. These improved reagent properties broadened the range of copper leach liquors which could be successfully treated by solvent extraction, allowed for less staging thereby reducing the capital cost of the SX plant, and lowered operating costs by decreasing organic losses and tankhouse bleeds. LIX 64N is LIX 65N (Figure 2) with a catalytic amount of LIX 63.

In 1968 Ashland Chemical introduced Kelex® Reagents along with the idea of using varying amounts of modifier, either nonylphenol or isodecanol, to facilitate the stripping of copper from the loaded reagent with normal tankhouse electrolytes [11,12]. Kelex reagents have not been used commercially for copper SX, but the use of modifiers to shift the extraction ↔ stripping equilibrium of copper extractants represents a significant, widely used advance in copper SX.

Shell International Chemicals brought the reagent SME®529 (Figure 2) to the market in the mid-1970s as an alternative to LIX 64N. This reagent found only limited commercial use because the poor properties of the side products from the manufacture of this reagent overrode the very good properties of the extractant molecule, a molecule in wide use today.

At ISEC '74 Birch reported the reagent P1 (Figure 2) from Acorga Ltd. had rapid kinetics, excellent Cu/Fe selectivity and fast phase separation [14]. However, P1 was such a strong copper extractant that efficient stripping required nearly 250 g/l sulfuric acid, an acid content not compatible with normal EW practice. In 1977 the Acorga P-5000® series of reagents was described [15,16]. These reagents combined P1 with various amounts of nonylphenol to give reagents having tailored extraction ↔ stripping properties. These modified aldoxime reagents brought a significant advance to copper SX because they allowed solutions with a high copper content and/or a low pH to be effectively treated in 2 instead of 3 or 4 extraction stages.

In 1979 the tridecanol modified aldoxime reagent LIX 622 (Figure 2), was made available by the Henkel Group which had purchased General Mills Chemicals in 1977. LIX 622 was the first tridecanol modified reagent to be commercialized when the Pinto Valley copper SX plant came on line in 1981. Tridecanol is still a widely used modifier in copper SX reagents.

Aldoxime/ketoxime blends were introduced in 1982 by Henkel as the LIX 860 reagent series. This reagent series combines the fast kinetics and extractive strength of the aldoximes with the stability and good physical performance of the ketoximes, without the detrimental properties of added modifier [17]. The addition of LIX 860-I (Figure 2) to existing plants using LIX 64N allowed these plants to quickly upgrade their plant performance and flexibility if needed or desired. Today aldoxime/ketoxime blends are widely used in copper SX.

Henkel purchased the SME 529 technology from Shell in late 1984 and 2 years later, using a new manufacturing process, began producing LIX 84-I, a much improved version of SME 529 (Figure 2). LIX 84-I replaced LIX 64N and LIX 65N in the LIX Reagent line and led to the LIX 900 Reagent series of LIX 84-I/LIX 860-I blends.

The use of hindered, high molecular weight alcohols and esters as modifiers was reported in 1986 with the claim that ester modifiers increase both Cu/Fe selectivity and oxime stability when compared to other modifiers [18]. Since then the ester modified reagents such as M5640 and LIX 664N have become the most popular of the modified reagents.

Improvements in reagent properties for the extraction of copper from dilute sulfuric acid leach solutions are summarized in Table I. These improvements have come about for 3 reasons:

1. New molecules: LIX 65N, SME 529, P-1 and LIX 860-I are examples.
2. Improved processes to produce cleaner reagents: LIX 65N and LIX 84-I are examples.
3. Manipulation of reagent properties: modified aldoximes and aldoxime/ketoxime blends are examples.

*Table 1. Trends in reagent properties.*

Property	1965	1970	Late 1970s	Today
Extractive Strength	Moderate	Moderate	Strong	Tailored
Cu/Fe Selectivity	Fair	Good	Good	Excellent
Kinetics	Slow	Moderate	Fast	Fast
Stability	Excellent	Excellent	Good	Very Good
Crud Generation	Moderate	Low	Moderate	Low
Versatility	Poor	Marginal	Good	Excellent

There are two distinct classes of modern extractants: ketoximes and aldoximes. A general comparison of their properties as well as mixtures of the two is given in Table 2.

*Table 2. Properties for reagents based on ketoximes, modified aldoximes, and ketoxime-aldoxime mixtures.*

Property	Ketoxime	Aldoxime	Mixtures
Extractive Strength	Moderate	Strong	Customized
Stripping	Very Good	Reasonable	Customized
Cu/Fe Selectivity	Excellent	Excellent	Excellent
Copper Kinetics	Very Good	Very Fast	Fast
Phase Separation	Fast	Fast	Fast
Stability	Excellent	Very Good*	Very Good
Crud Generation †	Low	Variable	Low

\* Dependent upon the particular modifier used.

† Dependent upon the leach liquor and modifier.

Ketoximes are moderately strong copper extractants which operate best when the leach liquor is relatively warm and the pH is ~1.8 or above. Modified aldoximes have good metallurgical properties even at low temperatures and low pH. The properties of aldoxime/ketoxime blends reflect the ratio of the components. Today the metallurgist can select the best reagent or reagent blend for his/her leach liquor, plant design and operating conditions. For example, one plant used an aldoxime/ketoxime blend of 55/45 when the pH of the leach liquor was ~1.5, but, today the plant adds a 50/50 blend because the pH of the leach liquor has risen to ~1.7. Metallurgical performance, entrainment, crud generation, mixer stability, price and the performance of the various reagents in plants having a similar design and/or operating with a similar leach liquor should all be considered when making a reagent choice.

### Leaching

Once solvent extraction proved to be a cost-effective way to purify and concentrate copper from leach liquors, copper producers began to regard leaching as a much more important source of copper. Two early advances in leaching include the distribution of large drops of leach solution over the ore at Bagdad in 1970 [19] and the use of drip irrigation by Johnson Camp in 1976 [20]. These improvements resulted in decreased water consumption, increased temperature in the heaps or dumps and higher copper recovery.

The "Thin Layer" (TL) acid cure leaching process reported in 1978 is to date the single greatest advance in copper leaching [21]. The first plant practice of TL leaching for copper was in 1980 at Sociedad Minero Puduhuel (SMP) [22]. SMP obtained high copper recovery from both the oxide and sulfide portions of their ore, low soluble silica in the pregnant leach liquor, and an overall water / acid balance to give a zero discharge plant. The important role of bacteria in leaching metal sulfides had been known [9] and some of the practical aspects of biological leaching had been discussed [23]. However, copper recovery from a high-grade sulfide ore by bacteria assisted heap leaching was not considered economically viable until SMP showed that

the total copper recovery from the chalcocite/bornite portion of their mixed oxide sulfide ore could reach 85% by leaching the tails from their TL operation for another 45 days [22]. Inspiration Copper in Arizona was testing with good results a similar technique called "ferric cure" on heaps of 100% minus four inch mixed oxide/sulfide ore [8].

In 1984 BHAS began agitation leaching copper matte from a lead blast furnace with a sulfuric acid leach solution having about 1 molar chloride ion [24]. This leaching system is reported to be effective for leaching copper sulfide ores and concentrates. Also in 1984 Sunshine Mining company installed a batch plant to pressure leach copper sulfide concentrate with sulfuric acid containing a catalytic amount of sodium nitrite [25].

In the late 1980s low-grade chalcopyrite dumps at Toquepala were wetted with 10 g/l H<sub>2</sub>SO<sub>4</sub>. Naturally occurring bacteria multiplied, oxidized the sulfide minerals and warmed the dumps. When copper SX started in 1995 the initial flush of copper from these dumps was much greater than anticipated and copper recovery over the first five years has been much higher than expected based on the leaching history of other low-grade chalcopyrite dumps.

Forced aeration to increase bacterial activity in heaps and dumps was field tested in the 1970s and successfully commercialized in the mid to late 1990s [26]. Of particular note is the Quebrada Blanca operation in Chile where bacterially assisted heap leaching of chalcocite, aided by forced aeration, is successfully practiced at an elevation of 4,400 meters [27]. The leaching of high-grade chalcocite ore in an autoclave at relatively low temperature and pressure was commercialized at Mt. Gordon in mid-1998 by Western Metals Copper Ltd. [28].

"From an poorly practiced art to a near science" describes the changes in leaching practice since the late 1960s. Heaps and dumps are constructed to retain heat, wet all the ore evenly, and for sulfide ore, to encourage air circulation through the dump or heap. Advances in heap leaching include blasting techniques which size ore to optimize copper recovery, crushing to the optimum size, agglomeration techniques, agglomeration aids, curing methods, heat retention and bacteria augmentation. Copper recoveries of 85% are being reported at several oxide heap operations and many chalcocite heap leaches report 75% to 80% copper recovery.

Sulfuric acid leach solutions treated successfully by copper SX range from < 1 g/l Cu up to about 35 g/l Cu with a pH range of ~0.8 to ~2.5. Leach solutions contain a variety of impurities at various concentrations depending on the ore, available water and evaporation rate. The SX plant must produce an electrolyte from which Grade A copper can be plated and most plants do, some from very difficult leach solutions. For example, the Michilla plant in Chile treats a leach solution having 55 g/l chloride while Lomas Bayas in Chile has treated a leach solution having 35 g/l nitrate and 15 g/l chloride. Both plants consistently produce high quality copper.

### **Electrowinning**

In 1968 Ranchers installed flotation cells to remove entrained organic from the pregnant electrolyte resulting in improved copper quality. In the late 1970s Anamax installed an electrolyte filter to clean the electrolyte of both solids and organic. A major breakthrough in EW came when Bagdad cathode was registered on the Comex in 1975 followed several years later with the registration of Anamax cathode on the London Metal Exchange.

Other important EW developments include: plating hard bright copper consistently onto starter sheets at 320 A/m<sup>2</sup> [29], the addition of cobalt in the electrolyte to reduce lead anode corrosion [30] and the use of water soluble polymers as smoothing agents. Rolled anodes of Pb-Ca and Pb-Sr-Sn are now the anode of choice because of their dimensional stability, lower rate of corrosion and the fact that anode cathode spacing in the cell is slightly less than when a cast anode is used [31]. The use of a cathode press to straighten 2-day cathodes grown on copper starter sheets results in higher current efficiencies and improved copper quality [32].

Capital Wire and Cable plated full size cathodes on stainless steel blanks in the early 1970s while Magma Copper was the first Cu EW tankhouse to use the CRL ISA Process where full size cathodes are grown on stainless steel blanks and then mechanically stripped. Plating copper on stainless steel blanks improves copper quality and increases current efficiency. The use of a manifold to evenly distribute electrolyte to every cathode in a cell was installed at Magma Copper in the late 1980s and was a key factor in their ability to produce LME quality copper at current densities up to  $320 \text{ A/m}^2$  [33].

A modern copper EW tankhouse coupled with copper SX achieves 93 - 95% current efficiency while producing 60% to 80% more copper per unit of tankhouse area than the early EW tankhouses. Full size cathodes are deposited on stainless steel blanks at  $240 - 320 \text{ A/m}^2$  from a solution containing 32 to 37 g/l Cu and 160 to 180 g/l  $\text{H}_2\text{SO}_4$ . Most large tankhouses mechanically strip the copper from the blanks while most small tankhouses combine some automation with hand stripping. The electrolyte stream is cleaned by column flotation followed by filtration through garnet sand and anthracite. Special grades of guar are used as smoothing agents, and acid mist suppressants, either chemical, mechanical or a combination of both, are common. Most EW tankhouses coupled with a copper SX plant consistently produce Grade A copper.

### **Mixer Settler Design**

In 1972 General Mills suggested the addition of one or more properly designed “picket fences” in settlers to distribute the dispersion exiting the mixer evenly across the full width of the settler [34]. This results in improved settler throughput and much lower entrainment.

A major advance in mixer settler design is the low profile concept from P. Paige of Holmes and Narver [35]. The mixer consists of several shallow boxes separated by over/under baffles. A pumping impeller is used in the primary mix box while axial impellers designed to maintain the dispersion are used in the secondary mixers. The settlers have a length to width ratio  $\leq 1$  and are built on the ground, usually at grade. The advantages of this design included lower capital, high mixer efficiency, slower linear flow down the settler resulting in less entrainment, and an overall smoother operation. Most copper SX plants built in the past 25 years are of the low profile design. Typically copper SX plants are designed so that the dispersion exits the mixer directly into the mixer end of the settler with the flow of the phases away from the mixer. Recently several plants have been built where the dispersion is carried to the opposite end of the settler by a side launder as this design offers the potential to reduce capital.

A key improvement in mixer design that reduces entrainment is the swept vane impeller. The Lewis type baffled settler [36] and the Krebs design [37] while commercialized are not considered standard practice in the copper industry. Two recent innovations in mixer design are very promising, the Outokumpu Vertical Smooth Flow mixer [38] and the new Lightnin mixer system at ASARCO Silver Bell. Both have relatively small primary mixers and much larger secondary mixers. It is claimed these mixer systems give lower entrainment and less crud generation because the dispersion spends less time in the highly agitated primary mixer and more time in the more gently agitated secondary mixers. Reagent losses at Silver Bell are among the lowest in the industry suggesting the claims have merit.

Other important design innovations include well designed coalescers on the loaded organic stream, filter presses for crud treatment, clay treatment [39] to keep the organic clean and large flotation settling tanks that recapture organic entrained in the raffinate.

## INSTALLED PRODUCTION CAPACITY FOR SULFURIC ACID COPPER L/SX/EW

The installed capacity for copper production by sulfuric acid L/SX/EW is given in Table 3. Note that from a rather modest beginning in 1968 the installed capacity for copper production by L/SX/EW is today about 2.8 million tonnes annually. This represents about 20% of the primary copper produced. The major reason for the large increase in L/SX/EW capacity is its lower cost, both capital and operating, when compared to the traditional flotation / smelting route. An important feature of the economics is that both large and small plants can achieve low costs. For example, the Dos Amigos operation in Chile (10,000 MT Cu/year) has about the same cash cost to produce copper as the Zaldivar operation in Chile (140,000 MT Cu annually). In addition EW copper from copper SX plants obtains a premium in the market place over most cathode copper produced by the flotation/smelting route. Furthermore, L/SX/EW technology allows plants to obtain copper at a low incremental cost from low-grade overburden that needs to be mined but otherwise would not be processed. Copper SX technology also has great flexibility allowing plants to achieve design production under a variety of conditions. Finally, copper L/SX/EW provides a home for sulfuric acid produced by smelters.

*Table 3. Installed capacity for copper production by sulfuric acid L/SX/EW.*

Year End	Installed Capacity (MT Cu annually)
1970	11,250
1975	108,912
1980	255,122
1985	355,954
1990	800,857
1995	1,563,205
2001	2,844,200

Today there are more than 55 locations (China excluded) with SX plants recovering copper from dilute sulfuric acid leach solutions. The number of SX trains and the complexity of the SX/EW installation range from the simple 2E, 1S single train installation at Mt. Cuthbert in the Australian outback producing 5,500 MT Cu annually, to the Phelps Dodge L/SX/EW complex at Morenci, Arizona, where about 16,500 m<sup>3</sup>/h of heap and dump leach liquors are treated in four separate, multi-train, 1E, 2E, 1W, 1S stage SX plants placed strategically on the property. The SX plants at Morenci feed 3 EW tankhouses that produce a total of about 365,000 MT Cu annually. Copper SX mixer-settlers range in size from the very small treating about 100 m<sup>3</sup>/h of leach solution, to large modules treating about 2,000 m<sup>3</sup>/h of leach solution.

## FUTURE IMPROVEMENTS IN L/SX/EW TECHNOLOGY

There may be incremental advances in today's leaching practice for oxide and chalcocite ores. However, the most abundant copper mineral is chalcopyrite and heap leaching this mineral with dilute sulfuric acid gives recoveries of only 25 to 30%. Obtaining high recoveries by heap leaching chalcopyrite with dilute sulfuric acid would be a truly revolutionary advance that would change the copper industry dramatically. There is ongoing work in this area and, while there has been some progress, much work remains.

In recent years there has been significant progress in leaching copper sulfide concentrates as an alternative to smelting [40]. Both pressure leaching (without nitrite catalysis) and bacteria assisted leaching in stirred tanks have been demonstrated for copper sulfide concentrates in pilot plants and small demonstration plants and both technologies are likely to be commercially installed within 2-4 years.

While revolutionary improvements in the properties of reagents for the extraction of copper from sulfuric acid leach solutions are not likely, small improvements in the blending of reagents and in the processes to produce reagents may come. The reagents of today are very good and the investment required to produce better reagents would not likely pay the needed return.

Increases in the current density at which high quality copper can be plated will be incremental with the current EW cell design. A new cell design that plates high quality copper at high current density from low grade solutions has recently emerged [41] and if certain problems can be solved this design could represent a significant advance in copper EW technology.

## CONCLUSION

By any standard of measurement L/SX/EW technology has made an important contribution to the copper industry. Initially the availability of LIX 64N and the success of Ranchers sparked interest to improve leaching and electrowinning techniques. Since that time a synergistic push-pull mechanism has emerged where an improvement in one aspect of the technology drives improvement in the other aspects. This synergistic push-pull mechanism will continue to advance copper L/SX/EW technology, but not likely at the pace of the past 34 years. The close working relationships between suppliers, engineering companies and copper producers that developed over the years have also contributed significantly to the improvements in the technology and it is important that these relationships continue.

The most fitting way to close this paper is to quote two early believers in copper L/SX/EW technology. Maxie Anderson, president of Ranchers, at the dedication of the Bluebird copper L/SX/EW plant said: "Not often does a small company have the opportunity to change the course of an industry and add to new technology..." In 1970 Ken Power closed his paper describing the operation of the Bluebird copper L/SX/EW plant with the words: "The applicability of liquid ion exchange to the treatment of dilute impure copper solutions has been irrefutably demonstrated, both technically and economically. The field of application in the hydrometallurgical treatment of copper minerals and products appears limitless" [1]. Today, more than 3 decades later, these prophetic words ring with clarity.

## ACKNOWLEDGEMENTS

The author is grateful to Cognis group for the opportunity to write this paper and to the staff of the Mining Chemicals Technology Division of Cognis for their contributions to this paper. The author acknowledges every individual and company that has contributed to the success of copper L/SX/EW technology and apologizes for not being able to cite all of them in this paper.

## SOLVENT EXTRACTION IN THE PRIMARY AND SECONDARY PROCESSING OF ZINC

Peter M. Cole and Kathryn C. Sole\*

Hydrometallurgy Consultant, Johannesburg, South Africa

\*Anglo American Research Laboratories (Pty) Ltd, Johannesburg, South Africa

An unprecedented expansion of the global zinc industry is currently underway. While most new projects and plant upgrades remain committed to traditional processing technologies, recent advances in zinc solvent extraction (SX) have created opportunities for new process routes for both primary and secondary materials. The first commercial plant to use zinc SX for the mainstream processing of a low-grade ore is under construction and promises to become one of the lowest cost zinc producers. Several other oxide and sulphide projects in various stages of feasibility are considering the inclusion of SX in their process flowsheets. Zinc SX has also proved advantageous in the reprocessing of secondary materials, particularly for the treatment of zinc residues and furnace dusts. This review focuses on recent installations and projects under development that feature zinc SX as the key separation step.

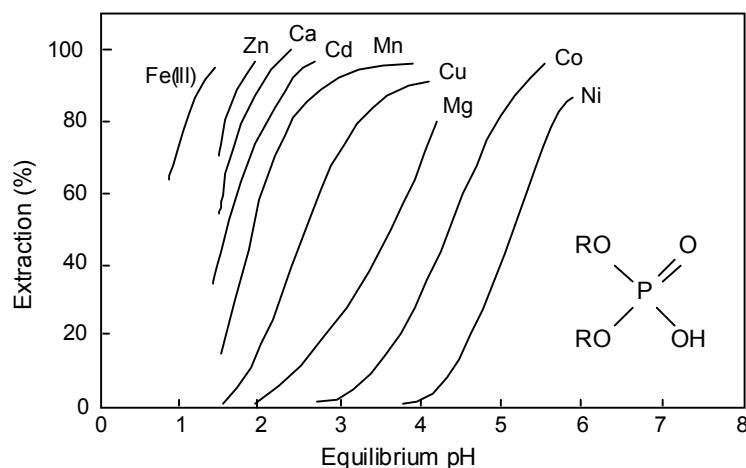

### INTRODUCTION

The traditional roast-leach-electrowin (RLE) zinc production route was developed for the processing of sulphide ores. It can prove inefficient for some complex sulphides and is not readily applicable to the treatment of other ore types. Inherent to this route is the generation of SO<sub>2</sub> gas that has to be fixed for environmental reasons, usually resulting in the production of sulphuric acid. These limitations have encouraged the search for alternative processing routes for both sulphides and other ores.

Approximately 30% of global zinc production arises from recycled zinc. With increasing awareness of secondary zinc materials as a valuable resource and stricter environmental legislation that restricts dumping of these hazardous materials, interest in their recycling has increased [1]. Direct retreatment of such materials *via* the process of origin is not always cost effective and can deleteriously affect the operation of the primary plant due to high levels of impurity species.

The development of process routes for the treatment of both primary and secondary sources of zinc has been hindered by the very stringent requirements for production of high-purity zinc by electrowinning (EW) [2]. Zinc EW from sulphate medium is extremely sensitive to the presence of trace impurities and requires a highly purified electrolyte. The selectivity of modern solvent extractants, an improved understanding of the process chemistry, and engineering innovations, have today enabled SX to provide unique advantages as a purification step ahead of the EW circuit in hydrometallurgical process flowsheets.

In most of the new applications involving SX processing in sulphate media, di(2-ethylhexyl)-phosphoric acid (D2EHPA) is used. This extractant is selective for zinc over most of the species deleterious to EW (Cu, Cd, Co, Ni, and the halides) and is readily stripped by acid concentrations typical of the spent tankhouse electrolyte (~ 180 g/L H<sub>2</sub>SO<sub>4</sub>). Circuit configurations generally include an organic-phase scrub to further ensure electrolyte purity. Iron build up in the organic phase is controlled by a concentrated HCl treatment. The selectivity of D2EHPA for zinc over selected base metal and alkali cations is illustrated in Figure 1.

*Figure 1. pH dependence of the extraction of selected cations by D2EHPA [3].*

In contrast to the zinc industry itself, zinc SX has found wider application in the refining of other base metals, providing an efficient means for the removal of zinc as an impurity species. These applications are surveyed elsewhere [4]. This review focuses on recent installations and developmental projects featuring zinc SX. Some historical perspective is provided by brief descriptions of earlier processes.

## PRIMARY PROCESSING OF ZINC

Flowsheets involving zinc SX for the primary processing of zinc sulphides have been the subject of investigation for some time. Interestingly, however, the first commercial application of zinc SX on the mainstream process liquor will be for the exploitation of an oxide ore body.

### Sulphide Ores and Concentrates

Most zinc ores occur as sulphides and, as such, are amenable to upgrading by flotation. The traditional treatment route includes smelting of the concentrates, followed by hydrometallurgical processing to produce electrolytic zinc metal. Direct ore processing *via* a hydrometallurgical route could enable the economic exploitation of complex ores that yield low upgrading recoveries, while hydrometallurgical processing of concentrates would avoid the generation of SO<sub>2</sub> and would be more flexible with respect to the grade of feed material that can be treated. The inclusion of an SX separation step in potential process flowsheets could also accommodate difficult-to-treat concentrates, such as those with high lead or halide contents.

### Chloride routes

Chloride routes for the treatment of sulphides have been known for over a century, however few have been commercialised because of the associated corrosion problems. Although modern materials of construction have improved this situation considerably, there are currently no known plants that use this technology for zinc. There have, however, been several process developments that have made use of SX for the treatment of zinc sulphides.

The Zinclor Process was developed by Técnicas Reunidas (TR), for the treatment of concentrates [5]. Leaching with ferric chloride was followed by SX with pentylpentylphosphonate and EW in their patented Metclor cell. Another process for the treatment of concentrates proposed leaching in concentrated ammonium chloride, followed by zinc SX using D2EHPA modified with isodecanol [6]. The ammonia fixed in the metal-ammine complex provided neutralisation of the acid released during extraction.

More recently, a detailed engineering design for a plant based on ferric chloride leaching of a complex sulphide New Brunswick ore was reported [7]. The process featured zinc SX using the zinc-selective bisbenzimidazole extractant, ZNX 50, developed by Zeneca (now Aevia). Zinc metal was electrowon in a divided cell in which chlorine gas was also generated for recycle. Interestingly, this process route was reported to be more cost effective for treating the whole ore than for treating the concentrate, generating approximately 10% more revenue.

### **Sulphate routes**

Pressure leaching for the hydrometallurgical processing of zinc sulphides has been applied commercially for many years but purification of these liquors has, to date, relied on a series of precipitation steps to achieve the electrolyte purification required for the production of high-purity zinc. Indications are, however, that SX may be used in future installations, with pilot-plant studies having been carried out by TR on pressure leach liquors using D2EHPA [1].

An alternative approach to the hydrometallurgical treatment of sulphides is the use of bacterial leaching for solubilising the valuable metals. Following a bulk iron-removal step (typically by precipitation), SX has been shown to be successful in producing ultrapure electrolytes suitable for the production of special high-grade (SHG) zinc metal (>99.995% purity) from a variety of bioleach liquors. In pilot-plant studies, MIM Holdings of Australia have proved the feasibility of this route for treating concentrate, demonstrating that the simplified zinc-recovery flowsheet can provide low capital and operating costs with high overall zinc recoveries (96%) [8]. For the development of the Lanping deposit in China, BHP Billiton have proposed bacterial leaching of the sulphide concentrate, an atmospheric leach of the oxide material, and the treatment of the combined leach liquor by SX for the recovery of zinc [9]. A process for the treatment of Mexican polymetallic (Cu/Zn) and chalcopyrite copper concentrates, developed by BacTech and Mintek, includes bioleaching, copper recovery by SX/EW, and zinc recovery by SX/EW [10].

### **Non-Sulphide Zinc Ores**

Extensive feasibility studies have shown that oxide, silicate, and carbonate-based zinc ores, not amenable to conventional processing, can be viably treated using zinc SX technology in a purely hydrometallurgical processing route [9]. A key feature that contributes significant economic advantage to these projects is that SHG zinc cathode is produced at the mine site. This is rarely seen for the processing of sulphide ores. Use of SX enables the entire process stream to be treated for the selective recovery of zinc, with a single SX circuit capable of processing in excess of 150 000 t/a zinc [1]. This means that the impurity-removal operations are small, treating only a bleed stream of the main circuit, rather than the entire process stream as in traditional flowsheets.

### **Skorpion project**

Anglo American's Skorpion project will be the first commercial application of zinc SX for primary zinc processing, involving a capital investment of US\$ 454 million to develop the mine and refinery near Rosh Pinah in southern Namibia [11]. A simplified flowsheet of the proposed process is given in Figure 2 [12].

Following atmospheric leaching in sulphuric acid, iron, aluminium, and silica are removed from solution by precipitation. Zinc is then selectively extracted by SX with D2EHPA, enabling the electrowinning of SHG zinc. The selection of SX as the purification step serves several

purposes. The ore is a low-grade oxidised silicate containing soluble chloride and fluoride minerals. The choice of D2EHPA as the extractant and the inclusion of a scrubbing circuit ensure the rejection of the halides, as well as the base metals that are deleterious to zinc EW. SX also successfully upgrades the rather dilute leach liquor (30 g/L Zn) (produced as a consequence of the leach conditions dictated by the elevated silica content (~26%) of the ore) to an advance electrolyte containing 90 g/L Zn that is suitable for EW. Soluble losses of zinc in the filtration step are minimised by employing a dilute leach liquor, and the problematic formation of silica gel is avoided. Operation with a high extractant concentration ensures minimal calcium co-extraction and allows high zinc transfer in the extraction circuit without the need for neutralisation. The acid generated by the extraction reaction is then available for leaching on recycle of the raffinate.

TR was responsible for providing the SX technology [11] and the plant will be the largest yet built for zinc SX. The circuit comprises three extraction, three scrubbing, and two stripping stages, and an organic regeneration stage. Zinc transfer of 20 g/L across the extraction circuit is achieved, yielding a raffinate of 10 g/L Zn. The first two stages of the scrubbing circuit use demineralised water to wash out physically entrained impurity species; spent electrolyte is employed as the scrub liquor in the third wash stage to ‘crowd off’ co-extracted impurity species from the loaded organic phase. Treating a bleed stream with 6 M HCl controls iron build up in the organic phase. Residual HCl is removed from the regenerant solution by distillation, producing concentrated  $\text{FeCl}_3$  liquor, which is neutralised prior to disposal to tailings.

Construction of the full-scale plant commenced in May 2001, and the first metal is expected in December 2002. The feasibility study conducted for the planned capacity of 150 000 t/a zinc showed that the Skorpion project will be the most profitable zinc facility in the world [9], with an expected production cost of US\$ 0.25/lb.

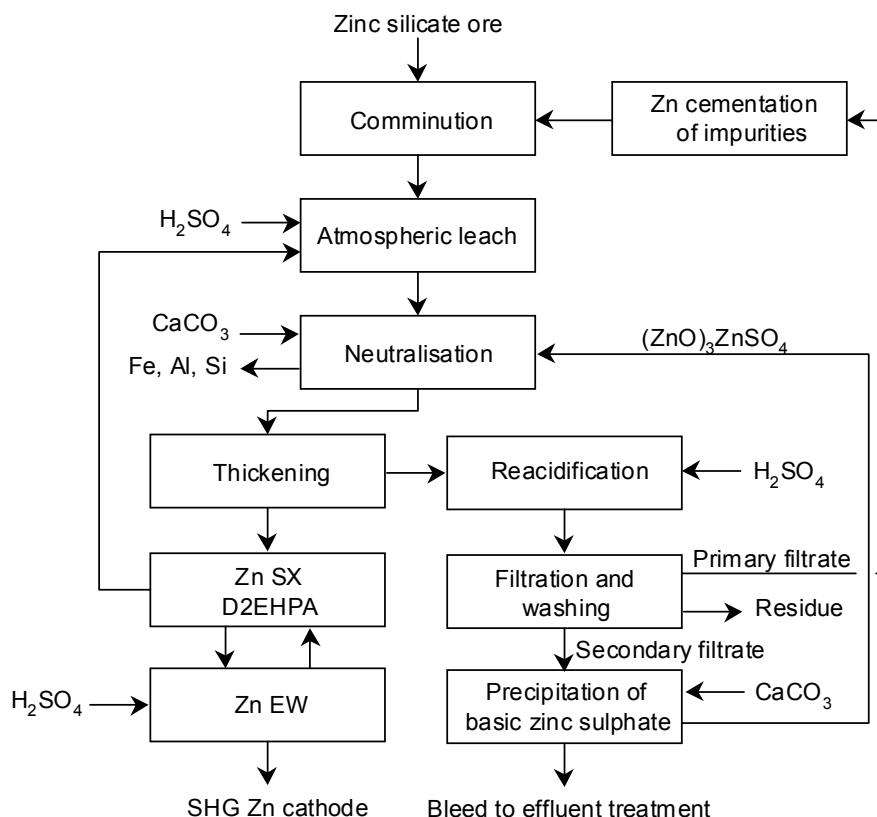

Figure 2. Simplified flowsheet for the Skorpion zinc project [12].

### **Projects under development**

Several non-sulphide ore projects in various stages of development and feasibility studies intend to use zinc SX for primary ore processing (Table 1).

*Table 1. Non-sulphide primary ore processing projects under development that use zinc SX.*

Project	Capacity (t/a Zn)	Ore type	Process route
Shairmerden, Kazakstan [13]	100 000	oxide, silicate, carbonate	Sulphate leach, zinc SX
Angouran, Iran [14]	100 000	carbonate, silicate	Sulphate leach, zinc SX
Sierra Mojada, Mexico [15]	-	oxide	Sulphate leach, zinc SX
Accha, Peru [16]	-	oxide, carbonate	Chloride leach, zinc SX

### **Zinc Recovery from Geothermal Brines**

A process originally developed by BHP for the recovery of zinc from geothermal brine that has been used for power generation is currently being commissioned by Kvaerner Metals for CalEnergy Minerals in the Imperial Valley of California. High-temperature underground brine is brought to the surface and flashed down in pressure vessels to produce steam to drive electricity-generating turbines. Zinc is recovered from the brine before it is pumped back underground. Very hot geothermal brine (19 t/h) is passed through an ion-exchange column to adsorb zinc. A conventional anion-exchange resin (DOWEX 21K XLT) selectively complexes zinc, as it is unique among the species present in forming multivalent anionic complexes in brine solution; other elements remain in solution as cations. The resin is eluted with water. The application of reverse osmosis to the eluate produces a concentrated zinc solution that is purified by SX using D2EHPA, prior to EW to produce zinc cathode. The operation is expected to yield 30 000 t/a zinc [17] in one of the cleanest zinc-recovery operations ever undertaken.

## **SECONDARY PROCESSING OF ZINC**

Several pyrometallurgical processes have been implemented for the treatment of secondary materials, however these are generally only efficient for a constant composition feed and need to have a high production capacity to be economically viable [18]. Some materials are not amenable to treatment by these routes, and environmentally acceptable discharges are not always assured. Hydrometallurgical processes are potentially less sensitive to these constraints; the most successful of these include an SX step to purify and upgrade the zinc.

TR has been at the forefront of developments in the processing of secondary zinc materials. Recycling plants, now closed, were built in Spain and Portugal based on their Zincox process [19,20]. This was superseded by the Modified Zincox Process (MZP), which has found application and is the instrument of numerous new investigations into the treatment of secondaries such as Waelz oxides, galvanizing residues, and electric arc furnace dusts (EAFD) [18,21]. The process uses D2EHPA for the selective extraction of zinc from the acidic sulphate liquor produced on the leaching of these materials. Advantages claimed for the MZP include the high selectivity over species such as halides and magnesium, the production of an electrolyte from which SHG zinc can be produced, high zinc recoveries, and safe and environmentally friendly operation. Gypsum precipitation in the SX circuits remains a problem, with the production of 80 to 150 kg per tonne of material treated. However, by using a source of pure lime for neutralisation in the SX circuit, 'white gypsum' can be produced, which may be sold for certain applications in the plasterboard industry.

### **Reprocessing of Furnace Dusts**

Electric arc furnaces produce 10 to 15 kg of dust per tonne of steel produced, representing one of the more contaminated zinc residues. The steel industry has approved the MZP as "technically, economically and environmentally suitable for the solution of the EAFD problem" [21]. A project for the treatment of 82 000 t/a EAFD in Spain has been proposed, but to date this has not been implemented, despite several successful pilot-plant trials on different EAFD compositions.

Dust generated from blast and reverberatory furnaces at the Met-Mex Peñoles lead smelter in Torreón, Mexico, has since 1998 been treated in a zinc SX plant built at the site [22]. The material was previously recycled, causing saturation of undesirable species such as cadmium, arsenic, and halides in the main circuit. Installation of the SX plant is reported to offer operating, economic, and environmental advantages: greater flexibility now allows the treatment of 'dirty' lead concentrates; increased revenues are realized from the sale of impurity species recovered; and airborne dust generation has decreased. Production is 5000 t/a zinc cathode of 99.99% purity. Table 2 compares the composition of the high-impurity feed material with an assay of the upgraded zinc solution produced by SX.

*Table 2. Composition of furnace dusts and upgraded zinc solution produced by SX at Met-Mex Peñoles [22].*

Element	Blast furnace dust (%)	Reverberatory furnace dust (%)	Upgraded zinc SX solution (mg/L)
Zn	10.6	15.6	95 000
Cd	23.8	1.1	128
As	1.1	8.8	< 1
Pb	39.1	30.2	< 2
Fe	0.1	0.1	< 2
Cl	4.3	0.4	7
F	0.5	0.3	2

Italian trials to recover zinc from EAFD by SX have also been reported [23]. In this process, iron was not removed from the leach liquor prior to SX. Zinc and iron were co-extracted using D2EHPA; zinc was stripped with 1 M H<sub>2</sub>SO<sub>4</sub> and iron was periodically removed from the organic phase by treatment with HCl. It was reported, however, that HCl stripping introduced partial degradation of the extractant, and a reductive stripping process for iron was under development.

Fluor Daniel Wright has also carried out development of an SX process to recover zinc from EAFD. The extraction of zinc chloride by ZNX 50 was evaluated [24].

### **Process Residues and Tailings**

In 1988, Española del Zinc in Cartagena, Spain, integrated SX into a conventional zinc refinery flowsheet for the recovery of water-soluble zinc from stockpiled and fresh leach residues [25,26]. The main refinery treats a mixed sulphide concentrate to produce 40 000 t/a zinc via a RLE circuit. The iron hydroxide precipitate exiting the primary leach circuit contains about 20% zinc. These solids are leached, along with previously dumped material, in a secondary leach using sulphuric acid and the loaded strip liquor generated in the SX plant. Iron is removed as ammonium jarosite. The secondary filtrate from the washing of the jarosite solids (containing 14 g/L Zn, 0.03 g/L Fe, 0.7 g/L Cu, 0.3 g/L Cd, pH 3) is not suitable for EW and is treated by SX to upgrade and purify the zinc into a concentrated (120 g/L Zn) strip liquor for recycle.

### **Zinc Tankhouse Bleeds**

Most operating zinc refineries use precipitation methods for zinc purification, followed by metal recovery by EW. In such processes, there is usually a gradual accumulation of impurities in the electrolyte, especially of species such as magnesium and manganese. Since zinc EW is extremely sensitive to the presence of impurities, it is necessary to bleed the electrolyte to control the composition. Several studies have looked at the use of SX for the recovery of both sulphuric acid and zinc from this bleed. These have involved recovery from both sulphate media with D2EHPA [27] and from chloride media using tri-*n*-butylphosphate [28].

### **Zinc Recovery from Spent Batteries**

The R.F. Procés plant, commissioned in the Spanish province of Cataluña in 1997, is the only plant in the world applying a hydrometallurgical process to the recycling of spent domestic batteries. The MZP is applied as the core separation step, producing a high-purity zinc sulphate solution suitable for electrowinning SHG zinc metal [29]. The loaded strip liquor is transported to Espanola del Zinc for zinc recovery.

A similar process for the recovery of zinc and other hazardous elements from spent batteries has been investigated in Switzerland. The initial flowsheet used D2EHPA for the purification of the leach liquor [30], however it was found that the process was too difficult to operate continuously because of the fine pH control required. CYANEX 301 was also tested for this application [31], and, although the extraction behaviour of this system was appropriate, the difficulties of stripping the irreversibly loaded copper and iron from the organic phase mitigated against it. The process has not been commercialised.

Another hydrometallurgical scheme for recycling of battery waste was developed by PIRA GmbH, Germany [32]. The BATENUS process, which also used D2EHPA SX for the recovery of zinc, was fully piloted and commercialisation was expected in 1995; the reason why this did not go ahead is unknown.

## **CONCLUSIONS**

The advantages afforded by hydrometallurgical processes that feature SX have only recently been realised in the zinc recovery industry. The commissioning of the Skorpion refinery, as the first plant to use SX for the recovery of zinc from a primary source, will add further impetus to this development. An increase in the application of zinc SX technology can be expected during the next decade, particularly in the processing of non-sulphide primary materials and for the treatment of an increasing variety of secondary materials.

## **ACKNOWLEDGEMENTS**

Appreciation is extended to Dr Doug Flett for his thoughtful comments on this manuscript. This review is published by permission of Anglo American Research Laboratories (Pty) Ltd.

## SOME DESIGN AND OPERATING PROBLEMS ENCOUNTERED IN SOLVENT EXTRACTION PLANTS

Gordon M. Ritcey

G.M. Ritcey & Associates Inc., Ottawa, Ontario, Canada

During the past 35 years the author has been involved with many solvent extraction plants. Some were projects of personal involvement in the process design, scale-up, commissioning, training, and trouble-shooting. Others were examined critically for improvements in the overall operation and improvements to the performance, solvent loss reduction, product quality, etc. Additionally, numerous plants were visited during that period to maintain a technical knowledge of new developments in solvent extraction processing—the reagents, contactors, methods of control, and problems in the design and operation. The paper is a summary of typical design and operating problems that were encountered in several types of metal recovery operations, including Cu, Ni, Co, U, Zr, rare earths. The causes and remedy to the problems are stated. No specific extraction systems or specific contactors are cited, and so the presentation is generic.

### INTRODUCTION

Solvent extraction (SX), as one of several unit operations in hydrometallurgy processing and refining, has now been operative for over 50 years. The development started with the nuclear industry, first with the refining of uranium using ether as the extractant in the late 1940s, soon followed by TBP as the safer extractant. Then the extraction process was taken to the uranium mills in the mid 1950s to provide an up-graded uranium product using essentially tertiary amines. Plants and refineries to that date were not large. Then with the copper industry recognizing the potential benefits of the solvent extraction process, the first large copper SX plant went on-stream in 1969. Thus the SX process became generally accepted and larger copper plants were to be placed in operation, using various chelating extractants.

Since that time there have been a considerable number of SX operations, of all sizes in the mining/metallurgical industry from the very small precious metals circuits and the radionuclide and reprocessing circuits, the medium size rare and less common base metals, and to the larger base metal plants. Now there are processes developed for virtually every metal in the periodic table of elements. Some of the processes are in operation; some have reached the pilot plant stage, while others are still in the development and optimization stage.

There are many aspects to be considered in the design and subsequent successful operation of the SX process, and include the following important areas:

- Chemistry--Extractants, Modifiers, Diluents
- Mass transfer--Dispersion and Coalescence
- Equipment-- Selection and Operation
- Economics
- Environmental and Solvent Losses

All impact on the possibility of the successful process, and if some are partially ignored then problems in the plant operation can be anticipated.

In this paper, a summary is presented of typical problems that have been personally encountered in a number of SX plants and refineries over the past 35 years. These include U, Zr, Nb, Cu, Co, Ni and Rare Earths plants. Practical solutions to those problems were often successfully implemented.

## DESIGN AND COMMISSIONING PROBLEMS

The following are some of the problems encountered in the commissioning and early running of some of the plants. It should be noted that other areas than SX, upstream and downstream, often have the greater problems in commissioning.

- excessive mixing in both mixers, with the result that the mixed flow entering the launder from mixer 2 was very turbulent and considerable air was drawn into the mixture to form emulsions. Return eddies travelled back as far as one-half the launder length;
- the launder distributor of the mixed phases (several split flows) appeared to provide for different flow velocities for the 5 flows; short-circuiting could result;
- No. 1 mixer was running slow in all units, as evidenced by the appearance of organic droplets on the surface;
- No. 2 mixer was running with excessive shear and turbulence causing extremely small droplets that were difficult to settle;
- no evidence of improved mass transfer occurred with a second stage mixer;
- the cause of some excessive turbulence encountered was due to the location of the turbine impeller in the mix tank (located about 1/3 down into the tank). A depth of perhaps greater than 2/3 would be better;
- some of the agitator shafts were not running "true";
- there was no provision for capturing any oil leaks that may result from running the agitator motors, which if permitted to enter the system could result in affecting the rate of coalescence;
- on the organic overflow there was considerable drawing in of air as the organic phase overflowed the weir and hit the bottom of the settler;
- stable emulsions-cruds were in all the settlers;
- stable gels formed and plant became inoperative;
- none of the mixers or settlers were covered. Even though there was a roof over the settlers, one or both ends of the "building" were open. The air velocity was therefore high over the settlers. Consequently, the SX circuit was susceptible to dust and bugs that will cause stable emulsions and cruds. Also, air entrainment of the solvent can be very high;
- piping diameters from strip to electrowinning (EW) were not compatible with flows;
- Jameson cell for entrainment removal was installed higher than circuit;
- interface control in the settler was not adequate and had to be improved. Evidence of considerable air entrainment causing stable emulsions and crud;
- inadequate flow control on the recycle streams;
- air locks in mixers had occurred on start-up: overcome by quick stopping of mixing and re-starting at high mixed flow;
- due to either dirty tanks or excessive fines in the PLS, cruds were formed;
- double salts formed in the case of some Ni circuits;
- solvent that was entrained and entered the tank house resulted in cathode pitting;
- darkening and gradual increased viscosity of solvent, and decreased loading;
- crystals in the carbon column (solvent removal prior to EW);
- impurities such as Cu, Co, Mg accumulated in product with solvent recycle.

## OPERATING PLANT PROBLEMS

Common problems that have occurred in many of the operating SX plants can be summarized as follows:

- metallurgical performance was poor (high raffinates, poor discrimination, and/or low loading as compared to the original McCabe-Thiele diagram);
- degradation of certain extractants occurred at high temperatures;
- poor phase separation; high solvent losses;
- excessive agitation (often in both mix stages) and often running under the design flow causing extremely fine droplets, emulsions, poor phase separation, and cruds;
- air entrainment and foam generation – due to over mixing, high shear, weir design, presence of surfactants. The total throughput will be adversely affected as stable emulsions are formed;
- cruds – many types (voluminous, spongy, stringy, gel, crystalline, precipitates) will have adverse effects on throughput and general performance in settlers. Generally an accumulation behind the picket fences in the settler; at the interface, on the bottom of the settler, as well as in the solvent phase;
- gel formation (different from an emulsion) and decreased settling and throughput;
- poor clarification and solids in feed – results in crud and decrease in throughput;
- third-phase formation;
- gypsum scaling and other precipitates – results in poor phase separation, stable emulsions, and crud formation. Settler capacity and total throughput is reduced; Scaling within the total circuit may occur;
- inadequate pH control during extraction / stripping resulted in formation of precipitates;
- formation of double salts, such as Ni ammonium sulphate – creates emulsions-cruds and decreases settler capacity, as well as reduction in total throughput;
- high solvent entrainment losses in the extraction raffinate;
- high solvent entrainment in strip raffinate and reduced EW performance;
- high evaporation/misting losses of solvent;
- solvent degradation and gradual decreased plant performance;
- inadequate control: phase continuity; equilibrium pH; interface; agitation; cross-contamination (solvents + extracted metals) in 2-SX circuits as well as in a single circuit.

## SOME SOLUTIONS TO THE PROBLEMS

### Dealing with Low Mass Transfer Efficiency

- verify extractant concentration, as a low concentration will result in high raffinates and low loading;
- if the solvent concentration analyses appears higher than was added, this would indicate a preferential high evaporation loss of the diluent and possibly the diluent has to be changed;
- poor stripping may be a result of the solvent still partially loaded after the previous stripping cycle;
- inadequate pH control (affects efficiency; promotes precipitation in either phase);
- inadequate control of acidity/alkalinity;
- check for solvent poisoning (by non-strippable organic acids and/or metal contaminants such as Zr, Mn);
- determine whether the PLS metal(s) concentration has changed, and if so, the calculated stages from a McCabe-Thiele plot will then be incorrect;

- determine possible contamination from water used in the circuit by bacteria, and organic acids from recycled pond water;
- continued poor performance may require a change in extractant.

### **Dealing with Excessive Phase Separation Time In the Settler**

The coalescence rate may be increased by:

- decreasing the shear and small droplet formation in mixing; running the process at the design flow to the mixer, based on rate of mass transfer required, so as to prevent excessive mixing under high shear conditions which create extremely fine droplets;
- elimination of a second stage mixer or reduction in agitation in that mixer;
- decrease in the turbulence of the mixed phases exiting mixer, possibly by baffles;
- reduction in entrained air: may be accomplished by better weir control;
- improved entry from the launder to the settle, possibly by increasing the number of split flows to the settler;
- use of wetting properties of dissimilar materials in construction of the picket fences;
- elimination or change/decrease of surfactant chemicals in the liquid-solids separation stage;
- ensuring that the circuit contains no oil leaks from pump motors that may be getting into the SX process;
- ensuring that minimum organic acids are present in the PLS,
- minimize the possible production of bacteria, yeast, mould;
- minimize colloidal silica and be aware of possible adverse effects of amphoteric compounds which may cause gels;
- control phase continuity;
- decrease in the linear velocity down the length of the settler.

### **Dealing with Solvent Losses**

#### **Entrainment**

- improved control in mixing to eliminate small droplets;
- check whether diluent choice is the best;
- check whether a modifier is required;
- contactor design and operation may be improved;
- examine the solvent for possible poisoning, which results in increased surface tension and increased entrainment losses;
- improve coalescing in settler (baffles location and design);
- minimize settler linear velocity;
- use of an external settler;
- eliminate air bubble formation as much as possible;
- phase continuity control may aid in minimizing losses by entrainment;
- examine circuit for the presence of possible surfactants that may have been added upstream of SX;
- examine the circuit for presence of organic acids (e.g., humic acids), bacteria, fungus, mould; and,
- minimize presence of crud, stable emulsions, colloids, and suspended solids.

#### **Evaporation/misting**

- eliminate any high air velocity over mixer-settlers;
- keep the covers over the mixer-settlers closed as much as possible;
- evaporation/misting can be severely enhanced as the temperature is increased, and misting can be higher than evaporation at times;

- creation of aerosols will result in loss of all components of the solvent, whereas evaporation losses will discriminate as regards the temperature. Thus the diluent will probably be lost first;
- recovery may be partially successful by installation of a vacuum scrubber over the mixer-settlers. Activated carbon as well as various coalescers and flotation will have various degrees of success in solvent recovery. If there are inorganic salts or precipitates present in the aqueous solution to be treated, then blocking of the carbon can occur.

#### ***Crud formation and abatement***

- requires the characterization, identification, and analyses of cruds;
- tests to verify mode of formation before crud reduction and possible elimination can be contemplated;
- Any other treatment before considering the above can only be a “band-aid” approach to the solution;
- minimize presence of suspended solids; as well as precipitates in either phase (often due to Ca, colloids of Al, Si and many amphoteric elements. The solids and colloids help to stabilize the crud; Improved clarification is a start and may minimize the amount of crud in the extraction circuit but may not prevent the carry-over of crud to the strip circuit;
- minimize high shear and extended time in mixing;
- minimize formation of air bubbles; weir adjustments can help;
- certain impurities may have to be removed or reduced in concentration;
- flocculants, organic acids in the PLS and solvent degradation products in certain plants can have adverse effects on the solvent and plant performance, such as emulsions and crud formation. Excessive flocculent may cause serious crud problems, particularly in the presence of silica colloids and other amphoteric compounds that may also cause gels;
- reduction/removal of surfactants (chemical and organic acids, e.g., humic, fulvic, degraded reagents, bacteria);
- maximize rate of coalescence;
- a wash stage, perhaps with water, may overcome crud carry-over into the strip circuit.

#### ***Third-phase formation***

- could be caused by several factors, including loading of organics (e.g., organic acids, bacteria), over-loading, stable emulsions;
- may be overcome by the addition of a modifier or the change in the diluent (increase the aromatic content). aromatic content will provide increased solvency of the extracted complex as well as can act as a bactericide;
- addition of a bactericide has a similar effect as an increase in the aromaticity;

#### ***Degradation of solvent***

- the extractant may be degraded, usually under severe oxidation conditions, forming compounds that may be detrimental to the process either in phase separation rates or also in the discrimination over impurities. This is common in some extractants and modifiers. Alcohol modifiers can degrade to carboxylic acids for example, thus forming an extractant that will adversely affect the ultimate purity of the strip product;
- in addition to decreased metallurgical performance due to degradation, the degradation products can have adverse effects on phase separation.

### **Solvent replacement and treatment**

- before reusing entrained solvent determine whether it has had an opportunity for degradation to occur if stored in ponds for subsequent reclamation. Long storage, especially at elevated temperatures, will rapidly degrade the solvent which may produce a number of oxidized products which can adversely affect the performance if not treated before re-use. It may not always be sensible to re-treat, and better to provide fresh solvent make-up to the process.
- periodically the solvent may have to be treated if contaminants are known to be present. These treatment processes to remove the accumulated contaminants include dilute alkali wash ( $\text{NaOH}$  or  $\text{Na}_2\text{CO}_3$  or a mixture); and treatment with clay and may be performed on the entire inventory periodically or on a "bleed" stream continually
- if the extractant is problematic, resulting in overall poor performance in extraction and, stripping, poor phase separation, and increased losses: it may have to be replaced.

### **Dealing with Phase Continuity**

- many plants attempt to control phase continuity at about 1:1 phase ratio. This can be most difficult, particularly as the respective densities change as loading or stripping occurs. There should be a larger difference in the ratio, and determined by conducting some tests and noting where "flipping" of the phases occur.
- flipping of phases can occur due to:
  - surfactants and poisons;
  - extreme phase ratios;
  - extremely fine droplets;
  - solvent concentration;
  - density of phases;
  - stable emulsions/cruds/gels.

### **Dealing with Stable Emulsions and Gels**

- often due to colloids, such as Si and Al and other amphoteric compounds. Often overcome by change in leaching conditions as well as a change of operating conditions, e.g., phase continuity, wetting characteristics, phase ratios in the case of recycles;
- poor contactor choice in original selection in spite of successful pilot plants on other contactor design with less shear; operation protocol changed, 5-day operation and 2-days for cleaning (different contactor was selected but not installed because of increased capital costs that would be incurred);
- because of poor phase separation and emulsions, contactor changed; result was ideal in extraction but insufficient shear mixing for mass transfer in the stripping stage. That is, only the extraction stage contactor should have been changed.

### **Dealing with Reagent and Impurity Carry-Over**

- between stages
  - interstage washing (scrub) required;
- into second circuit
  - solvent wash of the raffinate with diluent.

### **Dealing with Sustained Product Purity**

A gradual decrease in product purity can be caused by:

- entrainment from one stage to next; a wash stage would be required;
- entrainment of extractants from one circuit to a second circuit;
- accumulation of trace metals over time on the solvent;

- accumulation of degraded organics and other organic compounds that become “extractants”;
- steps taken to install scrub stages and/or impurity removal stages (e.g., removal of chloride to prevent entering tank house);
- equipment selection and operation.

### **Oxidation Problems**

One general comment relevant to the leaching and subsequent solvent extraction is that of the oxidation potential of the feed solution to solvent extraction. An overdose of the oxidant that might be necessary during leaching, or the production of an highly oxidized species during leaching or electrowinning, and the high operating temperature of the circuit have caused serious degradation of some extractants. Typical of the metals that can be expected to cause oxidation-degradation of the organic are  $\text{Co}^{3+}$ ,  $\text{V}^{5+}$ ,  $\text{Cr}^{6+}$ , and  $\text{Mn}^{7+}$ . The higher the valency state, together with high operating temperatures, and longer contact time than required for mass transfer, all lead to degradation problems.

### **Some Problems Due to Silica**

It was evident in many examples that Si, in its various forms, could provide a problem, and enhance the possibility for the formation of cruds. Following are some conclusions [1-4]:

- 1) The presence of Si can cause or enhance the formation of cruds and emulsions.
- 2) Most cruds are composed of Si as the major constituent, together with Fe, Mg, Ca, Al and the metal being extracted.
- 3) Unless there is a scrub stage between extraction and stripping, Si and other impurities may carry-over and appear in the strip product.
- 4) Organic continuous operation appears to minimize emulsion formation in the presence of Si.
- 5) The presence of humic acids together with Si enhances emulsions and cruds, as does high shear.
- 6) Solutions containing colloidal silica, in the aqueous continuous system, are severely retarded in phase separation rates and tend to form stable emulsions. Noticed in amines, alkylphosphates and oxime systems.
- 7) Colloidal silica and low molecular weight amines result in slower phase disengagement than higher molecular weight amines.
- 8) Most emulsions are produced by a third phase emulsifier consisting of a colloidal substance (such as silica-alumina, hydrosols or clays, ferric or aluminium hydroxide or colloidal phosphate).
- 9) Each emulsion or crud has its own characteristics and require laboratory identification. Methods of identification include microscopic, X-ray diffraction, infrared and emission spectrographic techniques.
- 10) TBP emulsions are stabilized by silicic acid.
- 11) Temperature, acidity and nature of the aqueous phase influence the stability of the TBP emulsion in the presence of silicic acid.
- 12) Possible methods of prevention include:
  - changes in pH;
  - addition of flocculating agents to remove the emulsifier;
  - addition of dispersion agents to disperse the emulsifying phase;
  - change plant practice to avoid formation of the surface-active materials;
  - addition of fluoride or other complex to solubilize the silica colloid.

## SUMMARY

In most cases the problems could be attributed to a few or all of the following operating parameters, some of which were not being performed correctly, or others that were not considered as an important factor:

- loading to saturation,
- scrubbing to remove entrainment of feed PLS,
- selective scrubbing/stripping,
- extractant choice and concentration,
- modifier choice (or none at all),
- diluent selection,
- co-extraction vs. selective extraction,
- pH control,
- kinetics,
- contactor selection and operation protocol.

The plant assessments have indicated that there are numerous causes of plant inefficiency. However one of the common causes that has been demonstrated is that of the solvent being fouled resulting in decreasing rates of coalescence, decreased loading, and ultimately reduced throughput. The high shear of most of the contactors (high shear mixer settlers), together with colloids of Si, Al, and ore slimes and fines enhances the problems. More attention has to be paid during the process design, piloting and ultimate plant scale-up to ensure that such possible costly problems will not occur. Each plant will be site-specific, and therefore a good interface between the metallurgists involved in the process design and the engineers involved in the plant design is necessary.

## THE EXTRACTION OF COPPER, ZINC, CADMIUM AND LEAD FROM WASTE STREAMS IN THE ZINC-LEAD INDUSTRY

M. Cox, D. S. Flett and L. Gotfryd\*

University of Hertfordshire, Hatfield, UK

\*Institute of Non-Ferrous Metals, Gliwice, Poland

Extractants have been assessed for the extraction and recovery of zinc, cadmium, copper and lead from wastewaters generated in the zinc-lead industry with specific reference to Poland. Initial assessment of potential extractants for recovery of these metals either in bulk or individually resulted in the selection of di(2-ethylhexyl)phosphoric acid, the dialkylphosphinic acid CYANEX 272® and a mixture of a carboxylic acid (di-isopropylsalicylic acid) and tri-*iso*-butylphosphine sulphide (CYANEX 471X®) for in-depth assessment in experimental studies. The testwork was carried out using synthetic solutions containing appropriate concentrations of zinc, cadmium, copper and lead. The results from all these studies are presented, collated and assessed and conclusions drawn with regard to viable options for commercial treatment, using solvent extraction, of such waste liquors.

### INTRODUCTION

At the Miasteczko Slaskie zinc plant in Poland zinc and lead metal are produced by the Imperial Smelting Process. Resulting from this process there are two liquors that appear to be amenable to the application of solvent extraction for the recovery of metals. The first is an acidic effluent arising from the off-gas washing system of the sulphuric acid plant with the following composition 0.25 g/l Zn; 0.34 g/l Cd; 0.0023 g/l Pb; 1.92 g/l SO<sub>4</sub><sup>2-</sup> and 0.17 g/l SO<sub>3</sub><sup>2-</sup> at a pH of 1.86. The second solution will arise after a cadmium cementation process to be introduced by management and has been forecast to have the following approximate composition: 40 g/l Zn; < 1 g/l Cd; 0.005 g/l Pb; 0.01 g/l Cu; 0.03 g/l Fe; 0.006 g/l Sb; < 0.01 g/l Sn and < 0.003 g/l Bi.

Options for treatment of these two liquors differ. For the first acidic effluent bulk removal of Zn, Cd and Pb would provide an effluent requiring minimal treatment prior to discharge or recycle except perhaps for neutralisation. For the second liquor however it would appear to be more appropriate, if possible, to remove all the impurities from zinc with the subsequent recycle of the purified zinc liquor to an appropriate part of the flow-sheet at the Miasteczko Slaskie plant.

Initial assessment of potential extractants for recovery of these metals either in bulk or individually resulted in the selection of di(2-ethylhexyl)phosphoric acid (DEHPA), the dialkylphosphinic acid CYANEX 272® and a mixture of a carboxylic acid (di-isopropylsalicylic acid (DIPSA)) and tri-*iso*-butylphosphine sulphide (CYANEX 471X®) for in-depth assessment in experimental studies. The choice of DEHPA and CYANEX 272 is based on these extractants known properties in extracting zinc, lead and cadmium. The mixture of DIPSA and CYANEX 471X was selected based on the work of Preston *et al.* [1-4] where it was shown that this combination of reagents had a remarkable synergistic effect on the extraction of cadmium in the presence of zinc. This is of obvious interest in the treatment of the second liquor only.

## EXPERIMENTAL

DEHPA was purchased from SIGMA/Aldrich. This was ~95% pure and was used without further purification. CYANEX 272 and CYANEX 471X were kindly provided by Cytec Industries France and were used as received. DIPSA was prepared according to Desseigne [5]. Diluents used in this work were either Escaid 120<sup>®</sup> (Exxon) or Solvesso 150<sup>®</sup> (Exxon). All synthetic aqueous solutions were prepared from analytical grade chemicals. The determination of metal ion concentrations were made using ICP emission or atomic absorption spectrophotometry or by EDTA titration for single metal solutions. Adjustment to solution pH was made by additions of NaOH or H<sub>2</sub>SO<sub>4</sub> as appropriate. Solution 1 was used as received from the smelter. Solution 2 was a synthetic solution made up to the composition as forecast by smelter personnel.

## RESULTS AND DISCUSSION

### Solution 1

The variation in the extraction of Zn, Cd and Pb with 0.2 M DEHPA and 0.2 M CYANEX 272 with pH are shown in Figures 1 and 2.

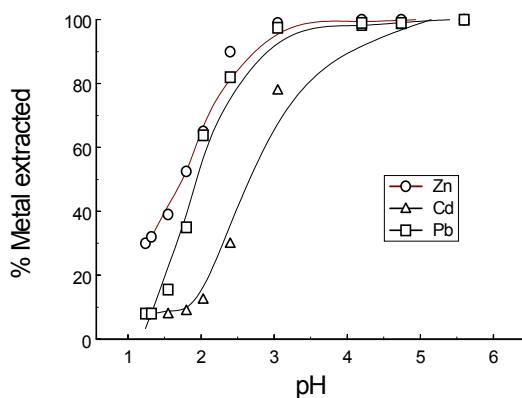

Figure 1. Extraction of Zn, Cd and Pb from solution 1 with 0.2 M DEHPA.

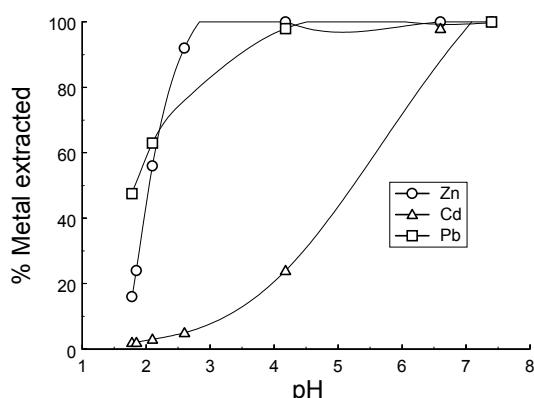

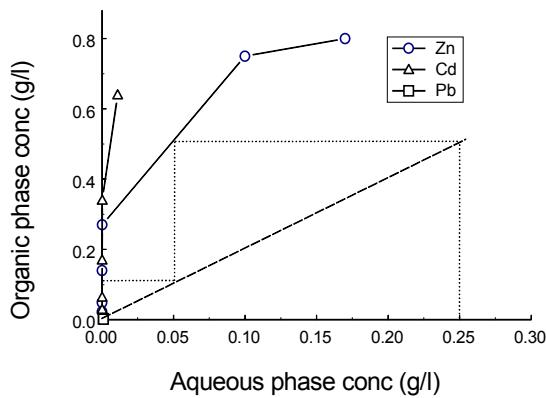

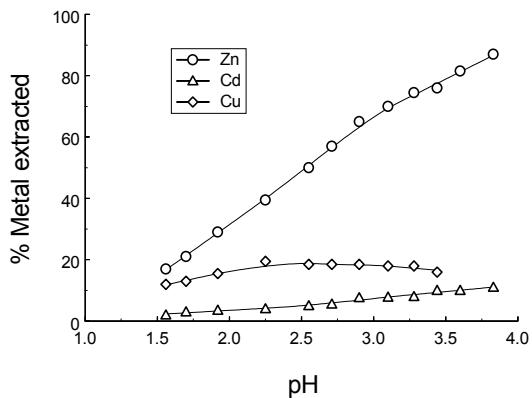

Figure 2. Extraction of Zn, Cd and Pb from solution 1 with 0.2 M CYANEX 272.

The figures show that removal of all three metals is essentially achieved at a pH value of >4.5 for DEHPA and ~7.0 for CYANEX 272. Both Zn and Pb are extracted strongly while Cd is less strongly extracted. These results show that there is no possibility of complete extraction of all metals at the natural pH of this effluent stream (pH 1.86) and that neutralisation is necessary to achieve full extraction of all the metal ions. Because of the significantly higher pH required for complete metal removal with CYANEX 272 all further work was based on DEHPA.

An extraction isotherm was developed for DEHPA partially converted to the sodium salt by contacting the DEHPA solution with Na<sub>2</sub>SO<sub>4</sub> at pH 5.0. This is shown in Figure 3 together with the appropriate McCabe-Thiele construction. This shows that complete removal of Zn, Cd, and Pb below 0.001 g/l is achievable in two counter-current stages at an O/A phase ratio of 2:1. The apparent anomalous selective extraction of Cd shown in Figure 3 is probably an artefact of the computer package and the actual zinc isotherm should be extended higher than depicted, which would then reflect the total extraction of Zn and Cd. The single point for Pb reflects its low concentration and thus the inability to include other points because of the scale required to plot the Cd and Zn results. Stripping of the metals from DEHPA is easy and tests have shown that a single stage using 2 M H<sub>2</sub>SO<sub>4</sub> can be used for this purpose.

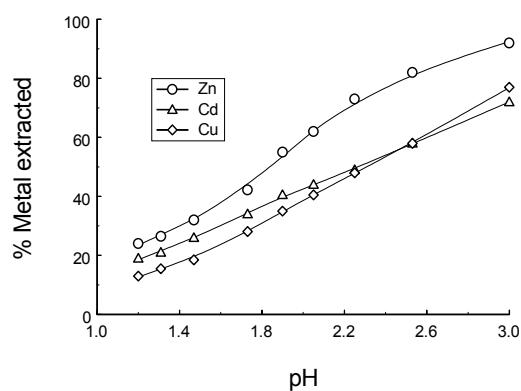

*Figure 3. Extraction isotherm for Zn, Cd and Pb with 0.2 M NaDEHPA at pH ~ 5.0.*

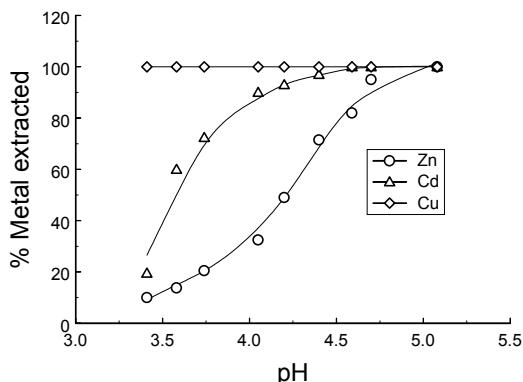

*Figure 4. Extraction of Cd, Cu and Zn from solution 2 with 0.5 M DEHPA.*

### Solution 2

The variation in extraction with pH for DEHPA, CYANEX 272 and DIPSA/CYANEX 471X is shown in Figures 4 to 6. Examination of the figures shows that it is not possible to extract all the metals, including zinc, without a significant degree of neutralisation. Furthermore, neither DEHPA nor CYANEX 272 can extract Cu and Cd selectively from Zn, a result that confirmed by the widely published behaviour of these extractants. Examination of Figure 6 however shows that both copper and cadmium can be extracted selectively from zinc with the DIPSA/CYANEX 471X mixed extractant system. This system was therefore selected for further study.

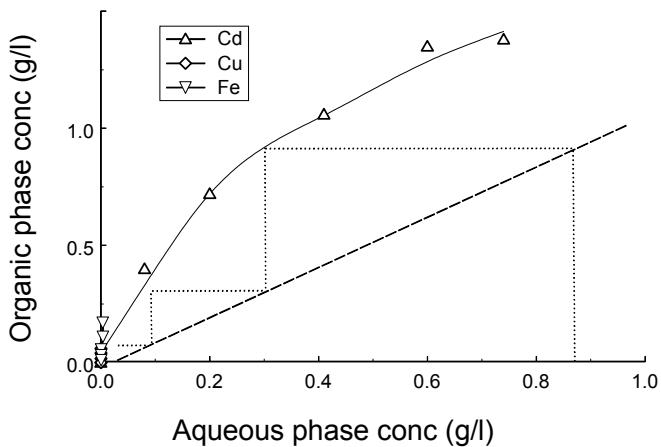

*Figure 5. Extraction of Cd, Cu and Zn from solution 2 with 0.5 M CYANEX 272.*

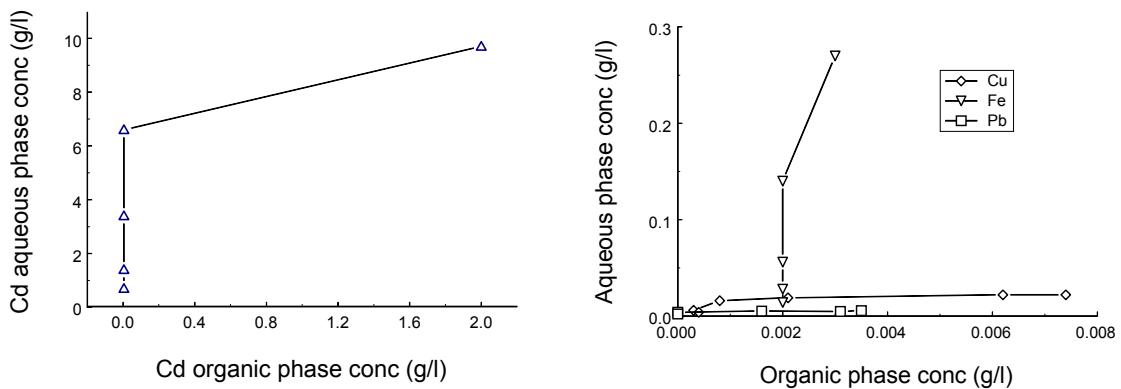

*Figure 6. Extraction of Cd, Cu and Zn from solution 2 with 0.5 M CYANEX 471X/0.5 M DIPSA.*

Extraction isotherms for Cu, Fe and Cd with a 0.1 M DIPSA/0.1 M CYANEX 471X reagent mixture at pH 5.5 are shown in Figure 7. These show that these metals and also Pb can be reduced to < 0.001g/l in 3 to 4 counter-current stages at an A/O ratio of 1.0 with only co-extraction of 5.5% of the zinc feed. Because of this co-extraction it will be necessary to scrub the loaded organic phase. Preliminary tests suggest that scrubbing with dilute H<sub>2</sub>SO<sub>4</sub> will readily remove the co-extracted Zn but detailed results are as yet incomplete.

*Figure 7. Extraction isotherms for Cd, Cu and Fe with 0.1 M DIPSA/ 0.1 M Cyanex 471X at pH ~5.5.*

Stripping isotherms are shown in Figures 8a and b. These show that Cd and Fe can be readily removed in essentially one stage by 1 M H<sub>2</sub>SO<sub>4</sub> but neither Cu nor Pb are stripped with this concentration of acid. Further work is necessary to determine the appropriate stripping regime for these metals.

*Figure 8. Stripping isotherms of Cd, Fe, Cu and Pb from loaded 0.1 M DIPSA/ 0.1 M CYANEX 471X with 1 M H<sub>2</sub>SO<sub>4</sub>.*

## CONCLUSIONS

For solution 1, the contained metal ions can be successfully removed in two stages using 0.5 M DEHPA, with the possibility of either discharging the treated liquor or recycling within the plant. Stripping of the metals from DEHPA is easy, with only a single stage using 2 M H<sub>2</sub>SO<sub>4</sub> being required.

For solution 2, Cd, Fe, Pb and Cu can be selectively removed with the mixed extractant system DIPSA/CYANEX 471X from Zn in three to four stages, with possibly one to two stages of scrubbing with dilute H<sub>2</sub>SO<sub>4</sub> to minimise loss of zinc, although the stripping regime has not yet been finalised. The organic phase can be stripped of Cd and Fe with 1 M H<sub>2</sub>SO<sub>4</sub>. Neither Cu nor Pb are satisfactorily stripped with this acid concentration and a satisfactory stripping regime is yet to be determined. The purified zinc-containing raffinate can be recycled within the plant.

## **ACKNOWLEDGEMENTS**

Thanks are due to Cytec Inc for the supply of reagents and to the management of the Miasteczko Śląskie zinc plant for the supply of solutions and valuable discussions. This work formed part of a project under the EU INCO-Copernicus programme contract number ERB IC15 CT 98 0146.

# THE EXTRACTION OF ARSENIC (V) AND SULPHURIC ACID FROM ACIDIC SULPHATE MEDIA BY TRI-N-BUTYL PHOSPHATE (TBP) IN SHELLSOL A OR T: I - AN EQUILIBRIUM STUDY

Afif Demirkiran, Nevill M. Rice and A. Ruth Wright

Department of Mining and Mineral Engineering, School of Process, Environmental and Materials Engineering, University of Leeds, Leeds, U.K.

The composition of the sulphuric acid and arsenic(V) species extracted by tri-*n*-butyl-phosphate (TBP), in either Shellsol A (aromatic) or Shellsol T (non-aromatic) diluent, from aqueous media, containing either H<sub>2</sub>SO<sub>4</sub> alone or both H<sub>2</sub>SO<sub>4</sub> and As(V) was studied by slope analysis. Other extractants, including amines, did not extract much As(V). The average compositions of the H<sub>2</sub>SO<sub>4</sub> species for 1.8-3.66 mol/L TBP from pure 1-5 mol/L H<sub>2</sub>SO<sub>4</sub> were (TBP)<sub>3</sub>(H<sub>2</sub>O)<sub>5</sub>H<sub>2</sub>SO<sub>4</sub> and (TBP)<sub>4</sub>(H<sub>2</sub>O)<sub>6</sub>H<sub>2</sub>SO<sub>4</sub> in Shellsol T or A, respectively. With As(V) present the extracted species were similar but less H<sub>2</sub>SO<sub>4</sub> was extracted. The As(V) species extracted from 0.25-4 mol/L H<sub>2</sub>SO<sub>4</sub> were (TBP)<sub>3</sub>H<sub>3</sub>AsO<sub>4</sub> in Shellsol T or (TBP)<sub>5</sub>H<sub>3</sub>AsO<sub>4</sub> in Shellsol A. The enthalpy of extraction was estimated to be -26.6 kJ/mol from the variation with temperature (12-33.5°C). As(V) extraction decreased slightly as the pH increased from 0.3 to 1.6.

## INTRODUCTION

Solvent extraction with tri-*n*-butyl phosphate (TBP) for the removal of arsenic from copper electrorefinery bleed streams has been applied in a number of refineries around the world including that operated by Mount Isa Mines Ltd. in Townsville, Queensland [1], who used results from the present study [2,3] in the development of their process. This paper reports a study of the composition of the organic phase species extracted from aqueous media with TBP dissolved in either Shellsol A (aromatic) or Shellsol T (non-aromatic) diluents[2].

## LITERATURE REVIEW

The TBP-H<sub>2</sub>SO<sub>4</sub>-water system has been studied extensively [4-11]. Much has been reported on methods for the removal and recovery of arsenic in process development, including solvent extraction and ion exchange (see part II) [12], but very little has been published on the nature of the arsenate species extracted by TBP [13-15]. Sealy and Freeman [11] reported a developmental study of a process for the extraction of As(V) from copper refinery electrolytes, including TBP-H<sub>2</sub>SO<sub>4</sub>-H<sub>2</sub>O ternary equilibria, based upon this earlier Soviet work [13-15]. The extraction of arsenic by other reagents, including carboxylic acids, Cyanex 301 and Cyanex 923, TOPO and Adogen 464 has been reported in the literature [16-19] but only neutral alkyl-phosphates showed any promise.

## THEORY

The overall composition of the extracted species was deduced by slope analysis of logarithmic plots of the distribution ratio as a function of varying reagent concentrations.

### Sulphuric Acid

The extraction reaction may be written as:

$$\text{for which the extraction equilibrium constant, } K_{\text{ex}} = \frac{[(\text{TBP})_n(\text{H}_2\text{O})_m\text{H}_2\text{SO}_4]_{\text{(org)}}}{[\text{H}_2\text{SO}_4]_{\text{(aq)}} [\text{TBP}]^n_{\text{(org)}} [\text{H}_2\text{O}]^m} \quad (2)$$

$$\text{whence } \log D_{\text{H}_2\text{SO}_4} = n \log [\text{TBP}]_{\text{(org)}} + \text{constant} \quad (3)$$

where  $D_{\text{H}_2\text{SO}_4}$  is the distribution ratio of  $\text{H}_2\text{SO}_4$ , assuming constant water activity and activity of TBP = mole fraction [20]. The value of m may be found [4, 6] using the equation:

$$(dN_w/dN_A) = m - n \quad (4)$$

where  $N_w$  and  $N_A$  are the respective number of moles of water and acid in the organic.

### Arsenic

Tserekova *et al.* [14] proposed  $(\text{TBP})_n(\text{H}_2\text{O})_m\text{H}_2\text{SO}_4 \text{ H}_3\text{AsO}_4$  as the organic phase species. composition. The extraction equilibrium may be generalised to:

$$\text{whence: } \log D_{\text{As}} = n \log [\text{TBP}]_{\text{(org)}} + p \log [\text{H}_2\text{SO}_4]_{\text{(aq)}} + \text{constant} \quad (6)$$

where  $D_{\text{As}}$  is the distribution ratio of As(V) assuming constant water activity and ideal TBP behaviour [20].

## EXPERIMENTAL

All reagents were A.R. grade (BDH) except Shellsol A and T diluents (Shell Chemicals Ltd.). Extraction equilibrium of As was achieved within 60 s. Normally 20 cm<sup>3</sup> of each phase were contacted for 10 minutes using a flask-shaker at ambient temperature (~ 20°C) followed by centrifuging at 2000 rpm, except when an AKUFVE mixer-centrifuge [21] was used to study the effect of varying temperature or pH.  $\text{H}_2\text{SO}_4$  concentrations were measured either by titration or (in the presence of both solutes) β-liquid scintillation counting of <sup>35</sup>S tracer with quenching corrected by the channels ratio method using an external <sup>226</sup>Ra standard. Distribution of As in both phases was determined by γ-scintillation counting of <sup>74</sup>As with a NaI well crystal. Organic water content was measured by Karl Fischer titration.

## RESULTS AND DISCUSSION

### Sulphuric Acid Extraction

Figures 1 to 4 show the results obtained for the extraction of sulphuric acid with TBP. From equations (3) and (4) and the results in Table 2 it was concluded that the average composition of the species extracted from sulphuric acid media were  $(\text{TBP})_3(\text{H}_2\text{O})_6\text{H}_2\text{SO}_4$  or  $(\text{TBP})_4(\text{H}_2\text{O})_6\text{H}_2\text{SO}_4$  in Shellsol T or A respectively in the absence of As(V) for concentrations of TBP from 1.8-3.66 mol/L (100% TBP) and  $\text{H}_2\text{SO}_4$  from 1-5 mol/L. Results were similar in the presence of 0.2 mol/L As (Figures 2 and 4) but slightly less sulphuric acid was extracted. However the slopes of 1.5 and 2 obtained for the variation with  $[\text{H}_2\text{SO}_4]$  indicate that reaction (1) may not fully represent the extraction equilibrium and that the composition of the extracted species depends on the concentrations of both acid and TBP in agreement with previous work [9]. From equation (4) the number of water molecules in the complex, m, was estimated between 5 and 6 in Shellsol T and 6 to 7 in Shellsol A, respectively.

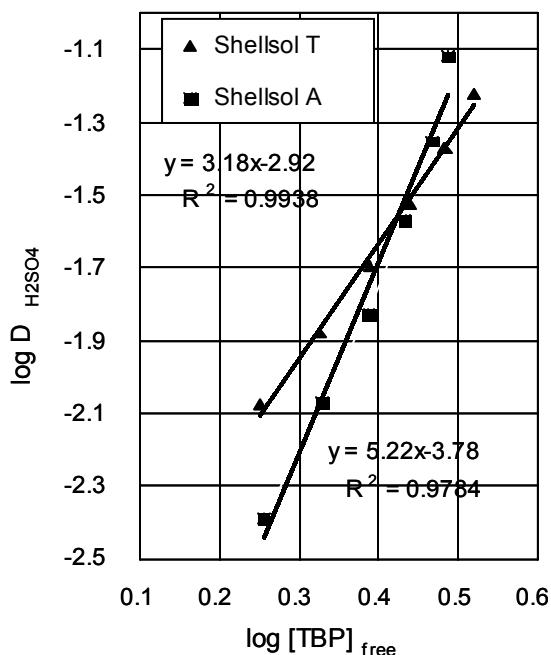

Figure 1. Variation of sulphuric acid extraction with free TBP concentration.

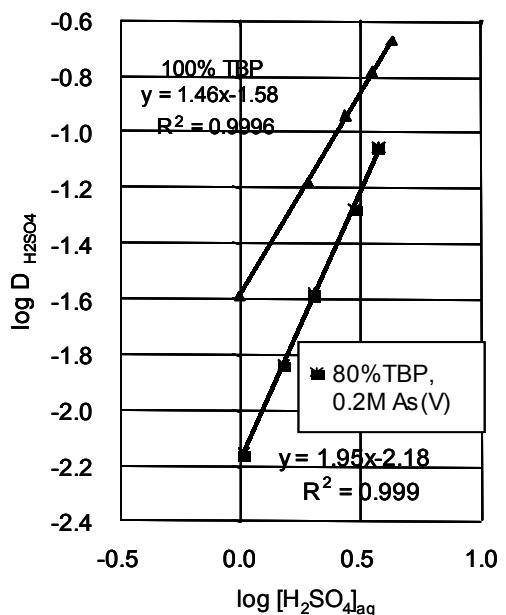

Figure 2. Variation of sulphuric acid extraction with aqueous sulphuric acid concentration.

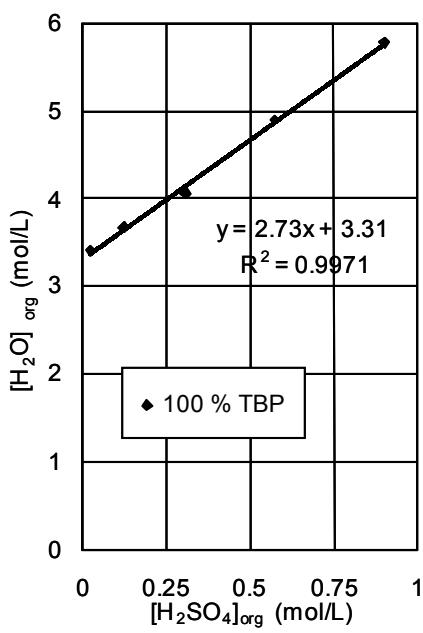

Figure 3. Water content of TBP phase as a function of organic  $H_2SO_4$  concentration.

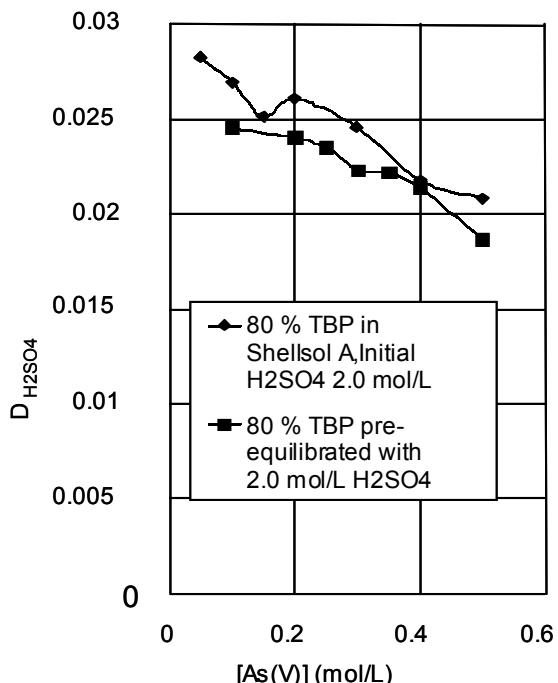

Figure 4. Effect of arsenic(V) concentration on sulphuric acid extraction.

### Arsenic(V) Extraction

Figures 5 to 8 shows the results obtained for the extraction of As (V). Table 1 shows results for the extraction of As(V) with a selection of other extractants. For 80% TBP in Shellsol T, variation of the As(V) concentration from 0.05 to 0.40 mol/L in 2.0 mol/L  $H_2SO_4$  increased the distribution ratio of As(V),  $D_{As}$ , from 0.347 to 0.418. With the same solvent pre-equilibrated with 2.0 mol/L  $H_2SO_4$ ,  $D_{As}$  varied from 0.404 to 0.442 for 0.10 - 0.40 mol/L As(V). Extraction of

As(V) from a copper refinery liberator bleed sample, that contained 2 mol/L H<sub>2</sub>SO<sub>4</sub>, gave comparable results to synthetic solutions with and without copper with D<sub>As</sub> = 0.405 and 0.412 respectively for 80 % TBP in Shellsol A.

Table 2 summarizes data for the slopes obtained from various plots of log D<sub>H<sub>2</sub>SO<sub>4</sub></sub> and log D<sub>As</sub> as a function of free and initial TBP concentrations and other variables. Values for the correlation coefficient, r<sup>2</sup>, are shown on the figures except where the plots were clearly non-linear and were mostly about 0.99. Free TBP concentrations were calculated using values of n estimated from the slopes of the plots with initial TBP concentration as a first approximation.

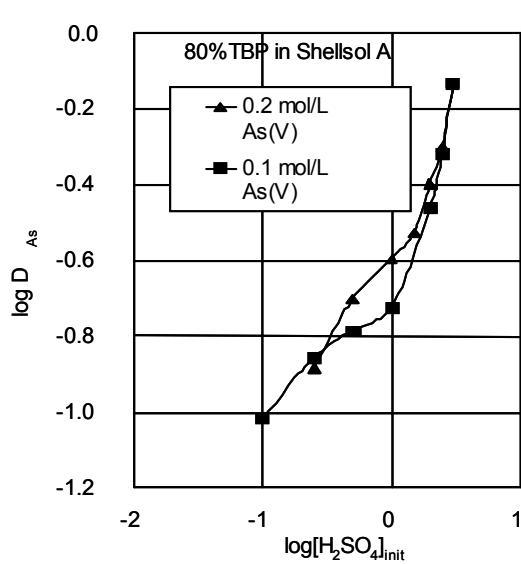

Figure 5. Variation of As(V) distribution with sulphuric acid concentration.

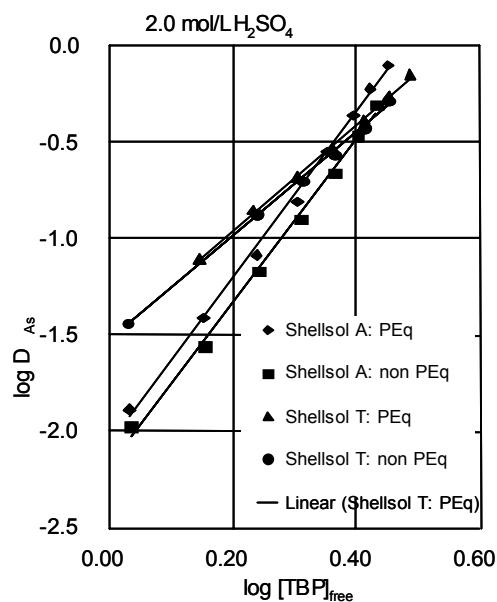

Figure 6. Variation of As(V) distribution with free TBP concentration.

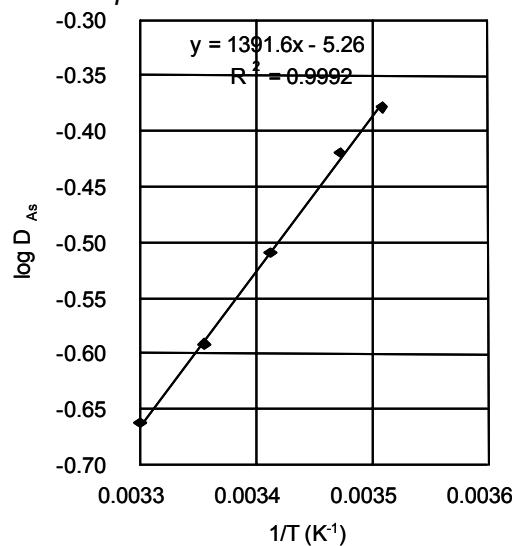

Figure 7. Variation of As(V) distribution with temperature (Arrhenius plot).

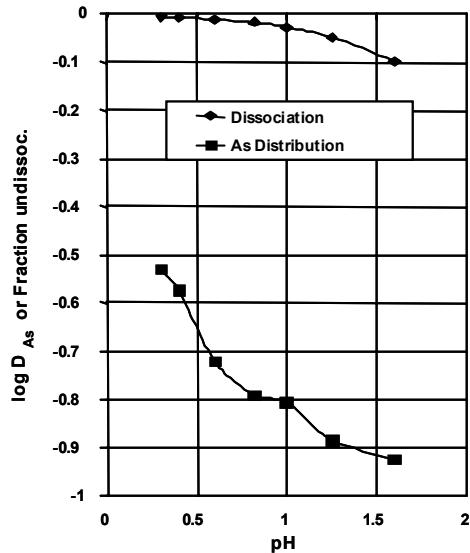

Figure 8. Variation of As(V) distribution and H<sub>3</sub>AsO<sub>4</sub> dissociation with pH.

From Table 1 it appears that TBP is the only reagent capable of extracting reasonable quantities of As(V) from acidic sulphate media though LIX X1-8A showed some extraction of As(V). Higher pH values were necessary for amine extractants to extract As(V). From Figure 5 and equation (6) the As(V) species extracted were found to be  $(TBP)_3H_3AsO_4$  in Shellsol T and  $(TBP)_5H_3AsO_4$  in Shellsol A but Figure 6 shows that the  $H_2SO_4$  composition varied over the concentration range 0.25-4 mol/L for both 0.1 and 0.2 mol/L As. Extraction increased rapidly above 2 mol/L  $H_2SO_4$  and increased slightly with pre-equilibrated TBP. From the slope of the Arrhenius plot (Figure 7) the enthalpy of extraction was estimated to be -26.6 kJ/mol in the temperature range 12 - 33.5°C. Extraction decreased with increasing pH from 0.3 to 1.6 (Figure 8) probably due to the increasing aqueous dissociation of the  $H_3AsO_4$  to  $H_2AsO_4^-$ . Figure 8 also shows the fraction of  $H_3AsO_4$  calculated taking  $pK_1 = 2.19$  [22]. This decreases with pH but less rapidly than  $\log D_{As}$  does.

## CONCLUSIONS

TBP is the best extractant for arsenic(V) from acid sulphate media. The extracted species contains both H<sub>2</sub>SO<sub>4</sub> and H<sub>2</sub>O to varying extents depending on concentration.

## ACKNOWLEDGEMENTS

Financial support from the SRC (now EPSRC) and RTZ (now Rio Tinto plc) is acknowledged with thanks. AD wishes to thank ETIBANK (Turkey) for a scholarship.

## THE EXTRACTION OF ARSENIC (V) FROM COPPER REFINERY ELECTROLYTES WITH TRI-N-BUTYL PHOSPHATE: II - FLOWSHEET DEVELOPMENT

Afif Demirkiran and Nevill Matson Rice

Department of Mining and Mineral Engineering, School of Process, Environmental and Materials Engineering, University of Leeds, Leeds, U.K.

A preliminary laboratory study to define the parameters of a solvent extraction circuit for extracting arsenic from a bleed stream from the liberator cells of a copper electrorefinery is described. Equilibrium isotherms for arsenic(V) extraction with 80% tri-*n*-butyl phosphate (TBP) in Shellsol A diluent at various H<sub>2</sub>SO<sub>4</sub> concentrations were obtained by batch shake-out tests. Scrubbing isotherms with water or 0.2 mol/L Na<sub>2</sub>HAsO<sub>4</sub> were also obtained. The extraction of H<sub>2</sub>SO<sub>4</sub>, scrubbing of the acid from the loaded solvent and stripping of As(V) with water or 0.5% w/v Na<sub>2</sub>CO<sub>3</sub> solution were investigated. Batch counter-current simulation of the proposed circuit was carried out. A relatively high As concentration was necessary to recover As from the strip liquor by reduction to As<sub>2</sub>O<sub>3</sub> with SO<sub>2</sub>. Another possibility was the precipitation of a metal arsenate, e.g., bicupric arsenate (BCA), depending on local circumstances.

### INTRODUCTION

Solvent extraction with tri-*n*-butyl phosphate (TBP) for the removal of arsenic from copper electrorefinery bleed streams has been applied in a number of refineries around the world including that operated by Mount Isa Mines Ltd. in Townsville, Queensland [1-5], who used results of a preliminary laboratory study carried out at the University of Leeds [6,7] in the development of their process. This paper describes the results of that study.

### LITERATURE REVIEW

Biswas and Davenport [8] have described the electrolytic refining of copper. The nature of the sulphate and arsenate species extracted by TBP and the possible use of other extractants was reported in Part I [9] from which it appeared that TBP was the only reagent of those tested that was capable of extracting reasonable quantities of As(V) from acidic sulphate media and also that a relatively high pH was necessary for amine extractants to extract As(V). Much has been reported on methods for the removal and recovery of arsenic and on process development, including solvent extraction. Sealy and Freeman [10,11] were the first to report the development of a process for the extraction of As(V) from copper refinery electrolytes, based upon earlier basic Soviet work [12-14] but their company did not proceed further. However several other companies have also exploited this method [1-5,15-23] and

several patents were granted, e.g. [15,16,18]. Most of these processes exploited the extraction of As(V) by TBP but the  $\text{H}_2\text{SO}_4$  tenor varied. Figure 1 shows a flowsheet for a Cu electrolyte purification circuit. The main motivation for As removal is the danger of arsine gas evolution from the liberator cells when the copper tenor falls below about 15 g/L – generally during the 3<sup>rd</sup> stage. There are three points where solvent extraction of As can be applied, viz. (i) the feed to the liberator cells; (ii) the spent electrolyte from liberator stages 1 or 2; or (iii) the more concentrated liquor after evaporation for recovery and concentration of  $\text{H}_2\text{SO}_4$ . Because As(V) extraction is highly dependent on  $\text{H}_2\text{SO}_4$  tenor (figure 2) [9] the type of circuit depends on the acidity. Both points (ii) and (iii) but not (i) have been used before. Point (iii) leads to a smaller plant but requires more acid resistant construction materials. The MHO plant at Olen, Belgium is based on point (iii) [17] but that at Townsville uses (ii) [1-5].

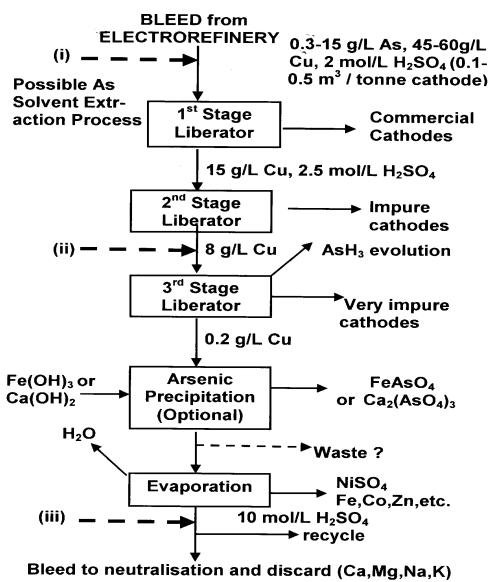

Figure 1. Purification of copper refining electrolytes

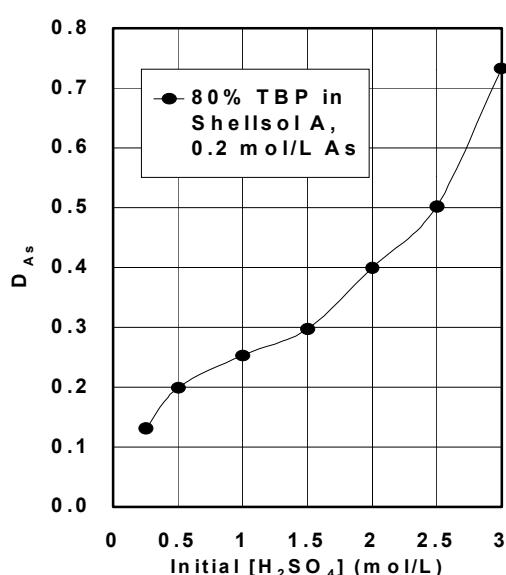

Figure 2. Variation of arsenic distribution with sulphuric acid concentration.

Studies of process chemistry have also been undertaken [6,9,20,24]. Other methods of As control or disposal used include periodic current reversal in the liberator cells [25,26] or precipitation of either sulphides or Fe(III) arsenates [27,28]. Improved As extraction with TBP plus various additives [29] or various alkyl-phosphonates [30] were reported recently.

## EXPERIMENTAL

For simplicity most of the test work was carried out using synthetic solutions containing only As and  $\text{H}_2\text{SO}_4$ , but a bleed stream of the following approximate composition:  $\text{H}_2\text{SO}_4$  2 mol/L, Cu 8.7 g/L; As 15 g/L; Sb 0.15 g/L; Fe 1 g/L; Ni 0.4 g/L; Zn 20 mg/L from the liberator cells of a copper electrorefinery (BICC, Prescott, Lancs, U.K) was also tested for comparison. Reagents were A.R. grade (BDH) except the Shellsol diluents (Shell Chemicals Ltd.). Shellsol A was the preferred diluent for the process development because of better phase disengagement and solubility of TBP. Extraction equilibrium of As was achieved within 60 s. 20 cm<sup>3</sup> of each phase were contacted for 10 minutes using a flask-shaker at ambient temperature ( $\sim 20^{\circ}\text{C}$ ) followed by centrifuging at 2000 rpm.  $\text{H}_2\text{SO}_4$  concentrations were measured by  $\beta$ -liquid scintillation counting of  $^{35}\text{S}$  tracer with quenching corrected by the channels ratio method using an external  $^{226}\text{Ra}$  standard. Distribution of As in both phases was determined by  $\gamma$ -scintillation counting of  $^{74}\text{As}$  with a NaI well crystal. Equilibrium isotherms were obtained by varying initial aqueous concentrations of reagents, volumetric phase ratios or crosscurrent loading of either the organic or aqueous phase with successive

contacts of the other phase. Similar procedures were followed for scrubbing using water or 0.2 mol/L Na<sub>2</sub>HAsO<sub>4</sub> and for stripping using water or Na<sub>2</sub>CO<sub>3</sub> solution. The McCabe-Thiele diagrams, that were plotted from shakeout test data were compared with batch counter-current simulation data for each step (separately) obtained after using 7 cycles of contacts to try to achieve steady state conditions.

## RESULTS AND DISCUSSION

Extraction of As(V) from the copper refinery liberator bleed sample gave comparable results to synthetic solutions with and without copper. D<sub>As</sub> = 0.405 and 0.412 respectively for 80 % TBP in Shellsol A. All subsequent work was undertaken using synthetic media.

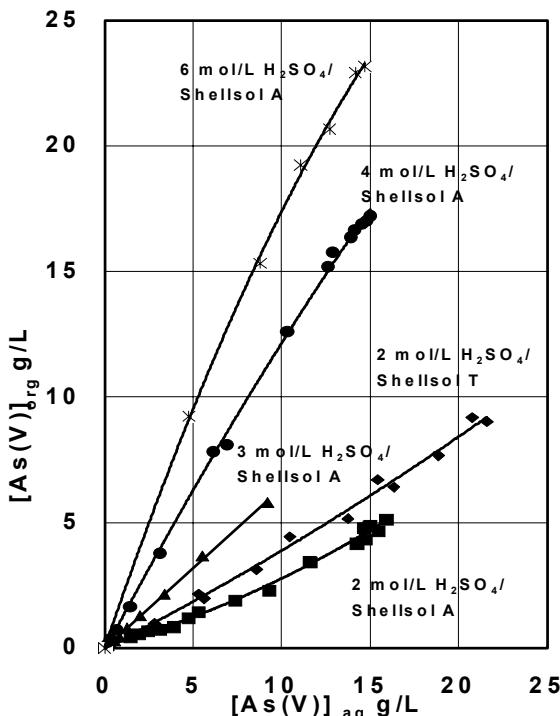

Figure 3. Extraction isotherms for As(V) at various sulphuric acid concentrations with Shellsol A or T, initial [As(V)] 15 g/L.

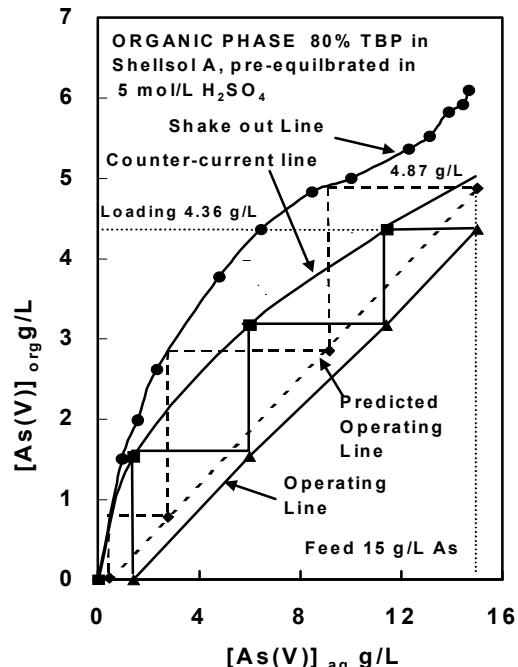

Figure 4. McCabe-Thiele diagram for loading of As(V) for 80%TBP 80% in TBP in Shellsol A from shake out and counter-current tests.

### Loading

Figure 3 shows the improvement in the extraction isotherms for As(V) with TBP (pre-equilibrated with 5 mol/L H<sub>2</sub>SO<sub>4</sub>) due to increased H<sub>2</sub>SO<sub>4</sub> concentration. Aliphatic Shellsol T is slightly better than aromatic Shellsol A at 2 mol/L H<sub>2</sub>SO<sub>4</sub>. Figure 4 shows the McCabe-Thiele plot, as predicted from shake out tests, for the loading of As from a feed containing 0.2 mol/L Na<sub>2</sub>HAsO<sub>4</sub> (15 g/L As) at an initial concentration of 2 mol/L H<sub>2</sub>SO<sub>4</sub> using 80% TBP in Shellsol A, pre-equilibrated in 1 stage 5 mol/L H<sub>2</sub>SO<sub>4</sub> at O/A = 0.5 as solvent. The recycled solvent was predicted to contain 0.17 g/L As. Data from a simulated batch counter-current run are also plotted. The difference in the plots was due to different H<sub>2</sub>SO<sub>4</sub> concentrations in each stage, which led to a slightly lower loading in the counter-current test. The simulation resulted in >90% reduction in As to 1.4 g/L with 3.4 mol/L H<sub>2</sub>SO<sub>4</sub> in the raffinate in 3 stages at O:A = 3.1. A further stage could be included if necessary. Figure 5 shows a McCabe-Thiele plot for H<sub>2</sub>SO<sub>4</sub> showing that back extraction of H<sub>2</sub>SO<sub>4</sub> occurs during loading. The operating line was not straight possibly due to varying phase ratio or the non-achievement of steady state or equilibrium for the sulphuric acid transfer.

## Scrubbing

Scrubbing of the extract to decrease the remaining  $\text{H}_2\text{SO}_4$  content was necessary for efficient stripping. A decrease from 0.07 to < 0.004 mol/L was achieved in 1 stage with either water or 0.2 mol/L As (which could be a strip liquor bleed) at O:A = 10 (Figure 6). The latter agent was preferred so as to decrease the loss of As from the extract, which fell from 4.3 to 4 g/L As. Scrub raffinate containing 16.75 g/L As would join the aqueous feed to the loading step after some dilution.

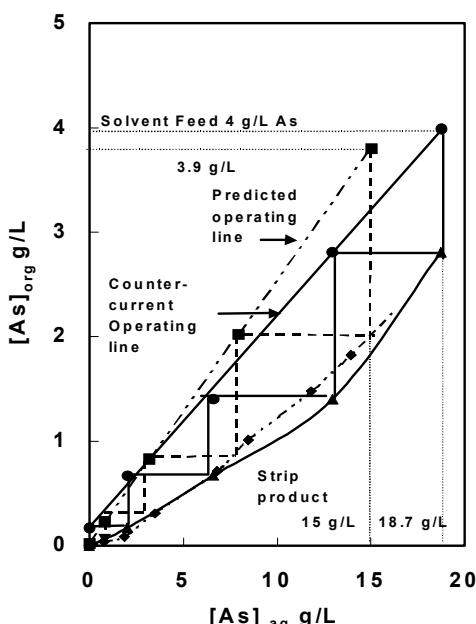

Figure 7. Stripping of scrubbed organic phase with water.

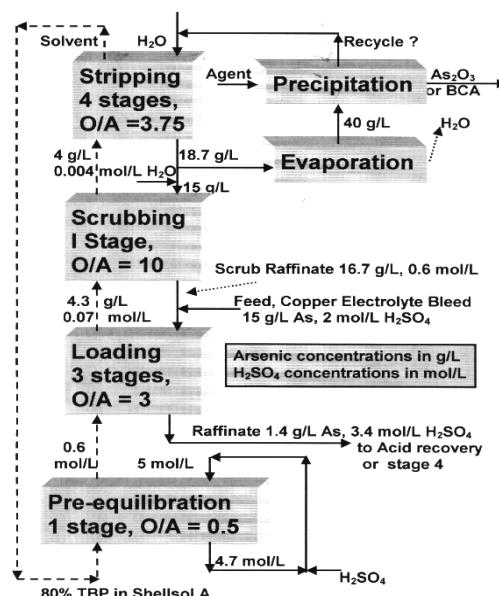

Figure 8. Proposed flowsheet for As recovery from Cu electrolytes.

### Stripping

Table 1 shows that As can be stripped by either water or dilute  $\text{Na}_2\text{CO}_3$  solution. If the residual acid is scrubbed from the organic phase water is the cheaper stripping agent. Figure 7 shows the McCabe-Thiele plots for stripping, both as predicted and from a batch counter-current simulation test. The results were in reasonably good agreement. Stripping with water in 4 stages at O:A = 3.75 gave an aqueous product that contained 18.7 g/L As with little  $\text{H}_2\text{SO}_4$  and a recycled solvent containing 0.17 g/L As.

Table 2 shows that the recycled solvent after stripping extracts As efficiently but that pre-equilibration in 1 stage with 5 mol/L  $\text{H}_2\text{SO}_4$  at O:A = 0.5 is required to maintain the  $D_{\text{As}}$  value.

Table 1. Stripping of As from 80% TBP in Shellsol A containing 4 g/L As(V) at O:A =1.

% $\text{Na}_2\text{CO}_3$ (w/v)	0 ( $\text{H}_2\text{O}$ )	0.25	0.5	1.0	2.0

2	0.292	0.355	0.41

### Arsenic Recovery and Overall Flowsheet

Figure 8 shows the proposed overall flowsheet for an arsenic recovery process based on the above results and gives data for the expected concentrations of As and  $\text{H}_2\text{SO}_4$  for each process step. A brief study of reduction to  $\text{As}_2\text{O}_3$  with  $\text{SO}_2$  indicated that concentration of As to about 40 g/L, perhaps by evaporation, might be needed at pH < 2. Arsenic can be recovered from the strip product either by reduction to  $\text{As}_2\text{O}_3$  with  $\text{SO}_2$ , or by precipitation of  $\text{As}_2\text{S}_3$  or as a metal arsenate, e.g., bicupric arsenate, BCA (Townsville), depending on local requirements and markets. Recycling of the strip liquor might also be necessary.

## CONCLUSIONS

A feasible solvent extraction circuit for the recovery of arsenic from copper refining electrolytes has been developed as illustrated in Figure 8.

## ACKNOWLEDGEMENTS

Financial support from the SRC (now the EPSRC) and RTZ (now Rio Tinto plc) and also from ETIBANK (Turkey) for a scholarship is acknowledged with gratitude.

# THE SOLVENT EXTRACTION PROPERTIES OF DI-*n*-HEXYL SULPHOXIDE IN RELATION TO THE REFINING OF PLATINUM-GROUP METALS

Anna C. du Preez and John S. Preston

Mintek, Randburg, South Africa

In this paper we describe some aspects of the solvent-extraction chemistry of di-*n*-hexyl sulphoxide (DnHSO) that are of relevance to the refining of platinum-group metals (PGMs). Although DnHSO is not used as such in the processing of PGMs, it can nevertheless be formed *in situ* by the oxidation of the parent di-*n*-hexyl sulphide (DnHS), which is used commercially as an extractant for palladium. The impact of the presence of DnHSO in PGM refining circuits may be favourable or unfavourable. Thus, the strong extraction of ferric iron from hydrochloric acid solutions by DnHSO results in this metal being co-extracted with palladium when DnHS is used in the recovery of the latter metal. Fortunately, however, the iron can be selectively washed out of the loaded organic phase by water, thereby providing a convenient exit from the process for this impurity. On the other hand, dialkyl sulphoxides are also able to extract rhodium from concentrated hydrochloric acid media, apparently by the formation of complexes such as  $(L_2 \cdot H_3O^+)RhCl_4L_2^-$ , where L = dialkyl sulphoxide. This complex is difficult to strip, and contributes to a gradual build-up of PGM values in the organic phase. Finally, the presence of small quantities of DnHSO in recycled organic solutions of DnHS causes a fortuitous increase in the extraction rate of palladium(II).

## INTRODUCTION

Recently, we carried out a study that entailed the dissolution of PGM scrap in hydrochloric acid sparged with chlorine, and the recovery of the individual metals by solvent-extraction techniques. During this work, we observed certain features that suggested the possibility that one of the extractants used (di-*n*-hexyl sulphide, R<sub>2</sub>S, where R = *n*-hexyl) might be undergoing gradual oxidation to the corresponding sulphoxide, R<sub>2</sub>SO. These features were:

- the co-extraction of considerable quantities of iron in the palladium extraction circuit;
- the build-up of rhodium in the stripped organic phase;
- a gradual increase in the extraction rate of palladium as the organic phase was recycled.

In this work, some aspects of the solvent extraction of iron(III), rhodium(III) and palladium(II) by dialkyl sulphoxides are examined in order to rationalize the above behaviour.

## EXPERIMENTAL METHODS

All the experimental procedures were as described previously [1,2]. Di-*n*-hexyl sulphide was prepared [1] and purified by distillation under reduced pressure (b.p. 69°C at 0.1 mm Hg,  $n_D^{20}$  1.4587,  $d_4^{20}$  0.8412). The sulphoxide was prepared and purified by recrystallization from petroleum ether as white needles (m.p. 59°C) [1]. Rhodium solutions were aged for several months before use. All extraction experiments were carried out using xylene as the diluent.

## RESULTS AND DISCUSSION

### Extraction of Iron(III) from Hydrochloric Acid Solutions

In its role as an extractant for palladium, di-*n*-hexyl sulphide (DnHS) is commonly used at high concentrations (e.g., 50 vol.%, equivalent to 2.08 M). At this concentration, even 5% oxidation of DnHS would produce 0.1 M di-*n*-hexyl sulphoxide (DnHSO). The presence of such quantities of DnHSO in recycled DnHS has been confirmed by infrared spectrophotometry [3]. Whilst DnHS (2.0 M in xylene) itself does not extract appreciable amounts of iron(III) from, for example, 0.02 M FeCl<sub>3</sub> in 4.0 M hydrochloric acid, increasing additions of DnHSO cause the extraction to increase markedly (Table 1).

*Table 1. Extraction of iron(III) from 4.0 M hydrochloric acid solutions by 2.0 M DnHS containing various concentrations of DnHSO in xylene at 20°C.*

Concentration of DnHSO (M)	Extraction of iron (%)
0.00	1
0.01	16
0.02	42
0.05	86
0.10	99

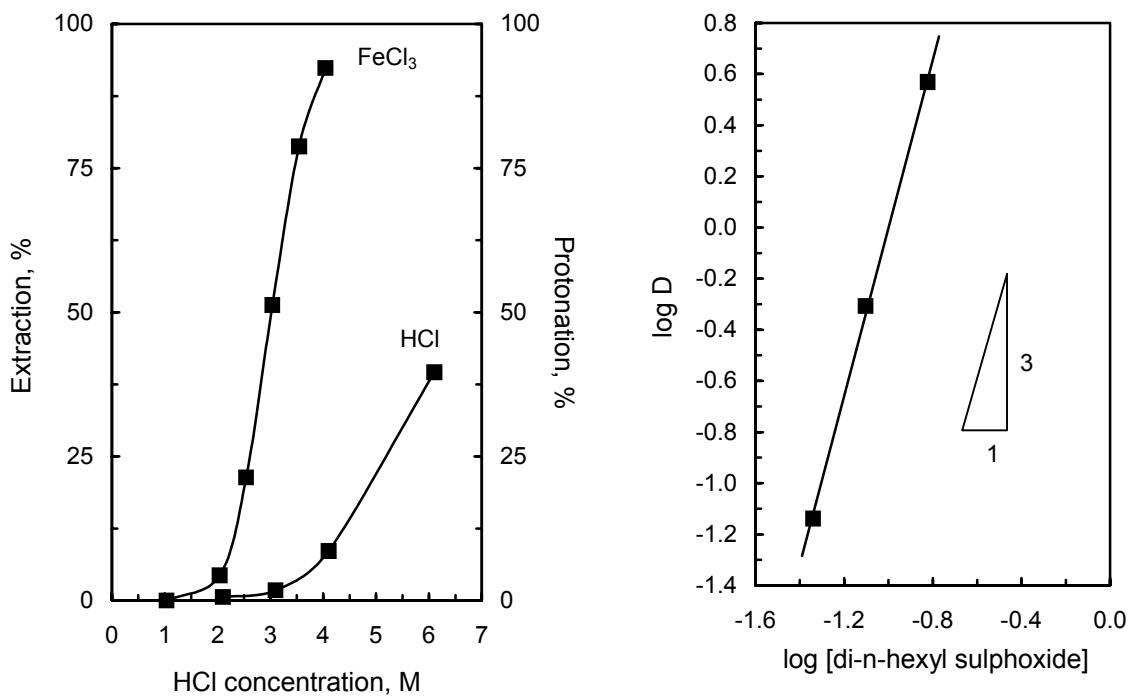

The effect of hydrochloric acid concentration on the extraction of iron(III) by DnHSO (0.20 M in xylene) is shown in Figure 1. It can be seen that extraction increases strongly over the region 2-4 M acid, and that extraction-stripping cycles could be carried out over this range.

With respect to the mechanism of extraction of iron(III) from hydrochloric acid solutions, Figure 2 shows the distribution coefficient of iron as a function of the concentration of DnHSO in the organic phase at a constant concentration of HCl (3.6 M) in the aqueous phase. The slope of this plot (3.2) is consistent with an extraction mechanism of the type in which an ion-pair is formed between a trisolvated hydronium ion and the iron(III) chloro-anion:

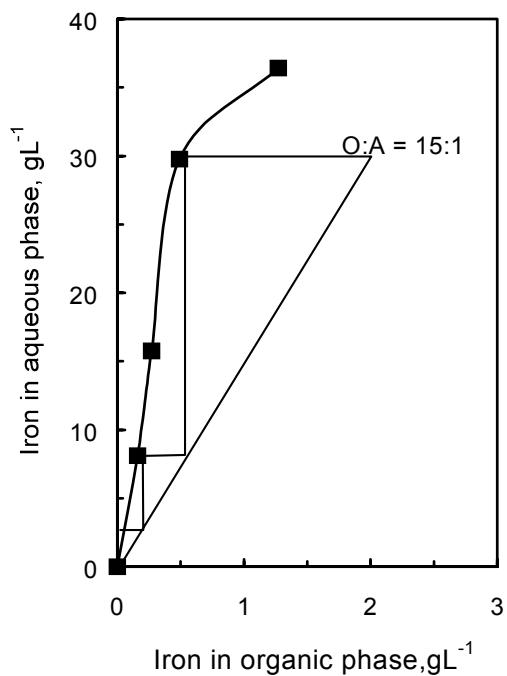

in which charged species are present in the aqueous phase, and neutral species (including ion-pairs) are in the organic phase.

This type of mechanism lends itself to a simple reversal by contacting the loaded organic phase with water, whereby both deprotonation of the solvated hydronium cation and aquation of the chloro-anion are favoured. The distribution isotherm for the stripping of iron(III) from 0.20 M DnHSO in xylene by water is shown in Figure 3. The McCabe-Thiele construction shows that, for example, iron can be effectively stripped (97%) from an organic phase containing 2 gL<sup>-1</sup> in 3 countercurrent stages at an organic-to-aqueous phase ratio of 15:1 to give an iron(III) chloride solution containing 30 gL<sup>-1</sup> Fe.

*Figure 1.* Dependence of extraction of iron(III) ( $0.02\text{ M}$ ) and protonation of  $\text{DnHSO}$  ( $0.20\text{ M}$ ) on aqueous concentration of  $\text{HCl}$  at  $20^\circ\text{C}$ .

*Figure 2.* Dependence of distribution ratio ( $D$ ) on  $\text{DnHSO}$  concentration for the extraction of iron(III) from  $\text{HCl}$  ( $3.6\text{ M}$ ) at  $20^\circ\text{C}$ .

*Figure 3.* Distribution isotherm for the stripping of iron(III) from  $\text{DnHSO}$  ( $0.20\text{ M}$ ) in xylene by water at  $20^\circ\text{C}$ .

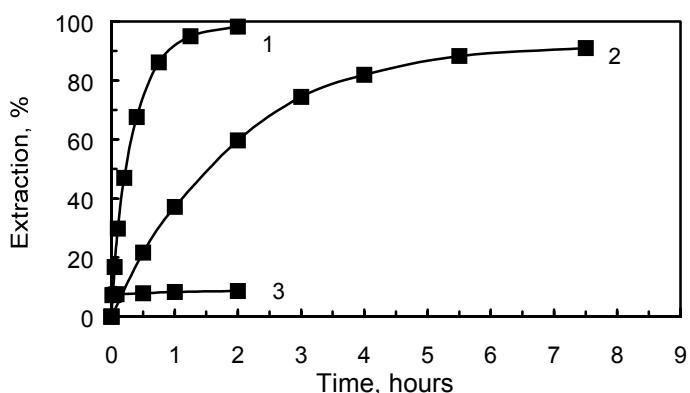

### Extraction of Rhodium from Hydrochloric Acid Solutions

Rhodium(III) is not extracted by dialkyl sulphides, yet appears to build up in organic phases that use these reagents for the recovery of palladium [3]. In contrast, dialkyl sulphoxides are reported to extract rhodium(III), albeit slowly [2,4]. The effect of hydrochloric acid concentration on the extraction of rhodium(III) by DnHSO (0.50 M in xylene) at 40°C is shown in Table 2. It can be seen that the extraction of rhodium(III) is low from dilute hydrochloric acid (under which conditions aquated cationic complexes such as  $\text{Rh}(\text{H}_2\text{O})_6^{3+}$  and  $\text{Rh}(\text{H}_2\text{O})_5\text{Cl}^{2+}$  are present), but is markedly enhanced in high concentrations of hydrochloric acid (where anionic complexes such as  $\text{RhCl}_6^{3-}$  and  $\text{Rh}(\text{H}_2\text{O})\text{Cl}_5^{2-}$  predominate). Nevertheless, the organic extracts (which are orange-yellow in colour, and show a molar absorptivity  $\varepsilon = 320$  at 424 nm) do not contain the  $\text{RhCl}_6^{3-}$  species (which is red in colour, and shows  $\varepsilon = 109$  at 529 nm and  $\varepsilon = 134$  at 417 nm when extracted into xylene solutions of trioctylammonium chloride (TOA.HCl), for example [2]).

*Table 2. Effect of hydrochloric acid concentration on extraction of rhodium(III) by 0.50 M DnHSO in xylene at 40°C.*

Concentration of HCl (M)	Extraction of rhodium(%)
0.0	0.4
1.0	7.2
2.0	13.6
4.0	51.7
6.0	95.9

A logarithmic plot of the distribution coefficient for rhodium against the concentration of DnHSO shows a linear slope of 3.9 [2], which is consistent with the formation of a species such as  $(\text{L}_2\text{H}_3\text{O}^+)(\text{RhCl}_4\text{L}_2^-)$ , as proposed earlier by Grant [5]. The dimethyl sulphoxide analogue of this compound has been characterized in the solid state [6]. The slow rate of extraction of rhodium(III) by DnHSO alone (curve 2 in Figure 4) is to be expected in view of the ligand substitution reaction required to form the  $\text{RhCl}_4\text{L}_2^-$  anion.

*Figure 4. Rate of extraction of Rh(III) (0.01 M) from HCl (6.0 M) by: (1) 0.25 M TOA + 0.25 M DnHSO, (2) 0.50 M DnHSO, and (3) 0.50 M TOA in xylene at 20°C.*

Interestingly, the rate of extraction of rhodium(III) is considerably enhanced in the presence of an amine salt, such as tri-*n*-octylammonium chloride ( $\text{R}_3\text{NHCl}$ , where  $\text{R} = n\text{-octyl}$ ). This effect (curve 1 in Figure 4) may result from a stepwise process starting with the weak, but rapid extraction of rhodium(III) by the amine salt (curve 3 in Figure 4):

which allows the ligand-substitution reaction to take place homogeneously in the organic phase:

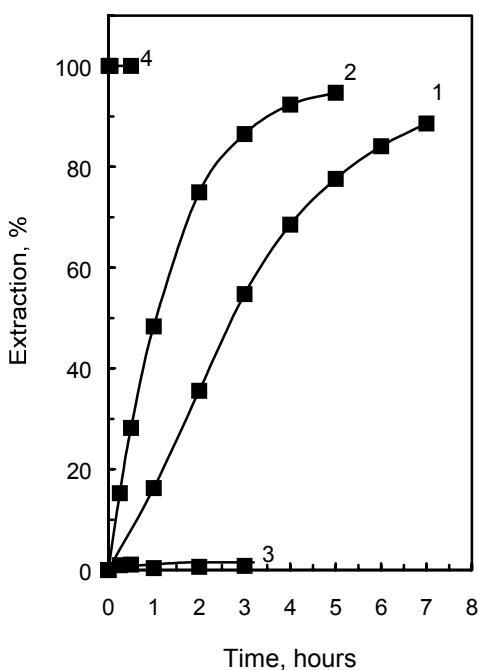

It is pertinent that tri-*n*-octylammonium chloride (TOA.HCl) is commonly added to commercial DnHS in order to increase the rate of extraction of palladium [7].

At this stage, however, it has not been possible to confirm the suggested composition of the extracted rhodium complex by slope analysis, owing to the very slow reaction rates at concentrations low enough to result in less-than-quantitative metal extraction at equilibrium. With regard to stripping the extracted rhodium complex from the organic phase, various solutions such as hydrochloric acid (0.1 and 10 M), ammonia (2 M) and dimethyl sulphoxide (1.4 M) were ineffectual. However, nearly quantitative stripping (99%) was achieved using sodium nitrite solution (1 M) in 30 min. contacting at 45°C. The  $Rh(NO_2)_6^{3-}$  complex so formed can be re-converted to  $RhCl_6^{3-}$  by heating the strip liquor with an equal volume of concentrated hydrochloric acid to drive off nitrogen oxides.

### Extraction of Palladium(II) from Hydrochloric Acid Solutions

The extraction of palladium(II) from 4 M hydrochloric acid by pure DnHS (0.13 M) is shown in Figure 5 (curve 1). The rate of extraction is increased considerably by the addition of a relatively small concentration (0.01 M) of DnHSO (curve 2), although this concentration of the sulfoxide alone extracts palladium very weakly (curve 3).

*Figure 5. Rate of extraction of Pd(II) (0.01 M) from HCl (4.0 M) by (1) 0.13 M DnHS, (2) 0.13 M DnHS + 0.01 M DnHSO, (3) 0.01 M DnHSO, and (4) 0.13 M DnHS + 0.01 M TOA.HCl.*

It was shown previously [2] that the distribution data for the extraction of palladium(II) by dialkyl sulfoxides are consistent with the extraction of the neutral complex  $PdCl_2L_2$  at low hydrochloric acid concentrations (1-2 M), and the ion-pair complex  $(L_2H_3O^+)(PdCl_3L^-)$  at higher concentrations (4-6 M). This change in the mechanism of extraction can be ascribed to the increasing extent of protonation of the weakly basic sulfoxide in the region above

about 3.5 M hydrochloric acid (shown in Figure 1). The presence of this ion pair in the organic phase evidently allows the normally slow interfacial reaction for the extraction of palladium(II) by DnHS [7],

to be replaced by the faster homogeneous process,

Since the formation of the  $(\text{L}_2\text{H}_3\text{O}^+)$  cation increases with increasing acidity, the enhancement in the rate of extraction of palladium would be expected to increase accordingly. This was found to be the case in the extraction of palladium by mixtures of DnHS (0.13 M) and DnHSO (0.01 M), the rate of which increased more than twofold over the range 4 to 6 M hydrochloric acid (times of 26 min and 61min to 50% extraction, respectively).

The catalytic effect is understandably less than that caused by the addition of the corresponding amount (0.01 M) of TOA.HCl (Figure 5, curve 4), since the TOA cation ( $\text{R}_3\text{NH}^+$ ) remains in the protonated form even at very low acidities.

## CONCLUSIONS

Some specific features that were observed when di-*n*-hexyl sulphide was used for the recovery of palladium from PGM chloride solutions (co-extraction of iron, build-up of rhodium on the organic phase, and increasing rate of palladium extraction) can be rationalized with reference to the presence of di-*n*-hexyl sulphoxide in the organic phase.

In order to replace  $\text{CN}^-$  ions in the leaching of gold and silver, systems which employ thiourea have been investigated. In this paper, the results of silver and gold ion recovery, by liquid-liquid extraction, from aqueous thiourea solutions which originate from ore dissolution processes are discussed. The influence of thiourea on the extraction efficiency of the metal ions is studied. The highest extractions in the presence of thiourea were obtained when the alkylthiophosphinic acids Cyanex 302 and Cyanex 301 were used. To elucidate the nature of the species extracted into the organic phase, a simple thermodynamic model of extraction is proposed for the case of the extraction of gold(I) from  $\text{H}_2\text{SO}_4$ /thiourea media. In this model, the complexation of the metal ion with thiourea in the aqueous phase is taken into account through a side reaction coefficient.

### INTRODUCTION

Due to its toxicity, there has been a movement in the gold and silver industry to limit the use of cyanide in leaching systems. Leaching studies performed with thiourea solutions have shown satisfactory results [1, 2], and utilization on an industrial level may be possible if Ag(I) and Au(I) are recovered from the thiourea solution and passed on for electrowinning of both metals. Aqueous thiourea leaching solutions contain appreciable quantities of thiourea and Fe(III), which is used as an oxidant. The system is complex and requires the development of a process which permits gold and silver extraction, as well as the recycling of the thiourea solution back to the leaching step. Liquid-liquid extraction may be useful for this purpose since it is a versatile separation technique which may be easily adapted to industrial scale.

Diverse extraction systems in different acid media have been reported in the literature for Au(III). Extractants such as Cyanex 923, Cyanex 921 and Cyanex 471X have been used in HCl and cyanide media with favorable extraction results [3-6]. In the case of Ag(I), Cyanex 301 has been used in HCl and  $\text{H}_2\text{SO}_4$  media [7] and in nitrate media [8]. However, stripping of the silver was very difficult. Neutral ligands, such as acidic alkylthiophosphinic and alkylthiophosphinic esters, have been employed for silver extraction [9]. Cyanex 471 (triisobutyl phosphine) has also been studied as an extractant for Ag(I) in nitrate [10, 11] or concentrated HCl [12-14] media. The results obtained from these studies indicate that Cyanex 471 shows high affinity and selectivity for the Ag(I) ion in the different media. However, the extraction efficiency is limited in the presence of thiourea [14].

In the present work, results of gold and silver recovery from aqueous thiourea solutions by liquid-liquid extraction are presented. Different extractants were studied and the influence of the thiourea on the extraction efficiency was analyzed. In order to determine the nature of the extracted species in the organic phase, a simple thermodynamic model of extraction is proposed. In this model, the aqueous-phase metal ion (gold or silver)-thiourea complexes are considered using a side reaction coefficient.

## EXPERIMENTAL

All reagents used were analytical grade. The extractants studied in this paper were bis(2,4,4-trimethylpentyl)phosphinic acid (Cyanex 272), bis(2,4,4-trimethylpentyl)dithiophosphinic acid (Cyanex 301) and bis(2,4,4-trimethylpentyl)thiophosphinic acid (Cyanex 302), all of which were supplied by Cytec (Canada). The trioctylamine (Alamine 300) and the 7-(4-ethyl-1-methyloctyl)-8-hydroxyquinoline (LIX 26) were supplied by Cognis. The bis(2-ethylhexyl)-phosphoric acid (DEHPA), the 2-ethylhexyl phosphoric acid (EHPA) and the Ionquest 801 (2-ethylhexyl phosphoric acid, mono-2-ethylhexyl ester), were supplied by Rhodia. The organic phase consisted of the extractant diluted to different concentrations in kerosene containing 10% (V/V) of *n*-decanol. The aqueous phase consisted of the metal ion (Ag(I), Au(I), Fe(II) or Fe(III)) in HNO<sub>3</sub>, HCl or H<sub>2</sub>SO<sub>4</sub>. The volume ratio of the organic phase (*V*<sub>org</sub>) to the aqueous phase (*V*<sub>aq</sub>) was in each case equal to one (*V*<sub>aq</sub> = *V*<sub>org</sub> = 10 mL). The solutions (aqueous phase /organic phase) were shaken with a Cole Palmer 51502 ping-pong shaker at 150 rpm for 90 minutes (25°C), which was sufficient time to reach equilibrium. Once equilibrium was attained, the phases were separated and the concentration of metal ion in the aqueous phase was determined by atomic absorption spectrometry (AAS). The concentrations of metal ion in the organic phase were calculated by mass balance. The pH of the solutions were measured with a Titrino 716 (Metrohm) using a glass electrode.

## RESULTS AND DISCUSSION

### Selection of Extraction System

The affinity of the above mentioned 8 extractants were studied with respect to Au(I), Ag(I), Fe(II) and Fe(III), at pH 2, in the presence and absence of thiourea (0.06 mol/L). These conditions were similar to those originating from gold and silver leaching. Table 1 shows the results obtained.

*Table 1. Comparative extractions of Ag(I), Au(I), Fe(III) and Fe(II) with 0.1 mol/L of different extractants.*

Extractant	%E Ag(I)		%E Au(I)		Fe(III)		Fe(II)	
	NT	T	NT	T	NT	T	NT	T
Cyanex 301	99.0	99.0	91.2	98.2	99.6	95.8	99.7	98.5
Cyanex 302	99.9	99.1	92.6	99.5	98.7	51.7	17.6	11.26
Cyanex 272	41.0	2.9	92.6	6.5	99.6	99.51	99.7	97.3
Ionquest 801	43.8	5.5	89.7	12.9	98.7	73.8	19.4	70.7
LIX 26	54.8	3.33	86.8	2.5	70.3	56.6	97.9	60.8
EHPA	64.8	6.5	89.7	37.5	97.7	97.1	98.5	98.5
DEHPA	94.5	6.9	76.5	11.6	99.6	87.3	47.8	78.1
Alamine 300	50.1	12.9	89.7	11.6	3.0	< 1	14.6	13.11

NT = without thiourea; T = with thiourea

As may be observed, in the absence of aqueous phase thiourea, the extraction efficiencies obtained were all above 40%, except in the case of Fe(III) and Fe(II) extraction with Alamine 300, which were very low. In the presence of thiourea, the Au(I) and Ag(I) extraction efficiencies drastically decrease, except for Cyanex 301 and Cyanex 302, which maintained extractions of about 99%. The reduction in the extraction efficiency in the presence of thiourea may be explained considering the formation of strong Au(I) and Ag(I) complexes with the thiourea in aqueous solution, which impede the transport of the metal ions into the organic phase. Table 1 shows that the sulfur extractants, as electron donors, present a greater affinity for Au(I) and Ag(I) than the other extractants studied. This behavior may be explained by Pearson's hard and soft acids and bases empirical rule. Gold as well as silver show a strong covalent character in their complexes and they are also easily polarizable. Elements of this type are referred to as soft acids. On the other hand, sulfur is considered to be a soft base. Since soft acids form stable compounds with soft bases, stable compounds of Ag(I)/thiourea and Au(I)/thiourea result which reduces metallic ion transfer into the organic phase.

In the cases of Fe(III) and Fe(II) extraction in the presence of thiourea, a lesser influence on extraction efficiency is observed. These species behave as hard acids and the stability of their complexes with thiourea are less stable.

The results contained in Table 1 indicate that Cyanex 301 and Cyanex 302 may be employed for the recovery of Au(I) and Ag(I) from aqueous thiourea solutions. Additionally, for both extractants, selective extraction of gold and silver over iron has been shown in the presence of thiourea [15]. However, Cyanex 301 forms a complex so stable with the Ag(I) ion that stripping and extractant recovery are difficult.

With these results, a possible separation scheme could contemplate a first stage for the selective extraction of excess Fe with Cyanex 272, followed by the selective recovery of Ag(I) and Au(I) from aqueous thiourea with Cyanex 302. Finally, a stripping step would permit recovery of Au(I) and Ag(I).

### **Thermodynamic Extraction Modelling of Au(I) from H<sub>2</sub>SO<sub>4</sub> / Thiourea Media by Cyanex 302**

The extraction model of Au(I) from H<sub>2</sub>SO<sub>4</sub>/thiourea media considers the existence of the thiourea in the complex extracted into the organic phase. In this manner, the overall extraction reaction may be written as follows:

where  $HL$  = bis(2,4,4-trimethylpentyl)thiophosphinic acid (Cyanex 302)

$T$  = thiourea

The overlined species are present in the organic phase.

The above reaction may be represented by an apparent extraction constant,  $K_{ext}^{app}$ :

$$K_{ext}^{app} = \frac{[\overline{AuL_n.T_t.(HL)_p}][H^+]^n}{[Au^+][T]^t [\overline{HL}]^{(n+p)}} \quad (2)$$

Experimentally, one determines the distribution coefficient ( $D$ ), which is defined by the following expression:

$$D_{Au(I)} = \frac{[\overline{Au(I)}]}{[Au(I)]} \quad (3)$$

where  $[Au(I)]$  and  $\overline{[Au(I)]}$  denote the total concentration of metal ion in the aqueous and organic phases, respectively.

The thiourea forms a complex with Au(I) in the aqueous phase ( $\log \beta_2 = 21.5$ ). To consider its influence on the extraction process, the complex coefficient,  $\alpha_{Au(T)}$ , will be defined as follows:

$$\alpha_{Au(T)} = \frac{[Au(I)]}{[Au^+]} = 1 + \beta_2 [T]^2 \quad (4)$$

Introducing  $\alpha_{Au(T)}$  into equation (2) and considering that Au(I) is extracted into the organic phase principally as the complex  $\overline{AuL_n.T_t.(HL)_p}$ , equation (2) takes on the following form:

$$K_{ext}^{app} = \frac{D_{Au(I)} [H^+]^n \alpha_{Au(T)}}{[T]^t [\overline{HL}]^{(n+p)}} \quad (5)$$

Solving for  $D_{Au(I)}$  and  $\alpha_{M(T)}$ , and representing the equation in its logarithmic form:

$$\log D_{Au(I)} + \log \alpha_{Au(T)} = \log K_{ext}^{app} + t \log [T] + (n+p) \log [\overline{HL}] + npH \quad (6)$$

With equation (6) it is possible to determine, using slope analysis, the number of  $H^+$  ions ( $n$ ) involved in the extraction process, as well as the number of thiourea ( $t$ ) and extractant ( $n+p$ ) molecules in the extracted complex. Figure 1 shows the variation of  $\log D_{Au(I)} + \log \alpha_{Au(T)}$  as a function of pH (Figure 1a) and of  $\log [\overline{HL}]$  (Figure 1b).

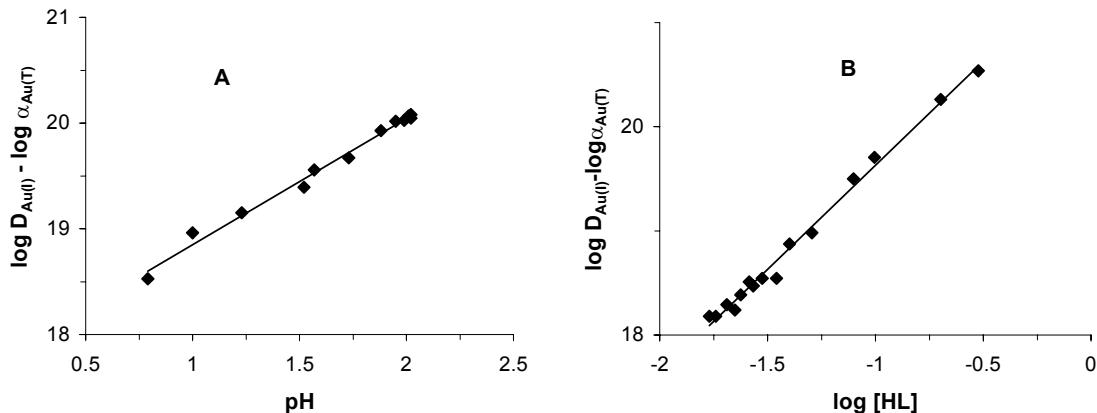

Figure 1. Variation of  $\log D_{Au(I)} + \log \alpha_{Au(T)}$  as a function of (A) pH ( $[Cyanex\ 302] = 0.1\ M$ );  $y = 1.19x + 20.45$ ; (B)  $\log [\overline{HL}]$  ( $pH = 1.7$ ),  $y = 1.99x + 16.48$ .

The analysis of this figure demonstrates that, in the case of the variation of  $\log D_{Au(I)} + \log \alpha_{Au(T)}$  with respect to pH, the experimental points denote a linear function whose slope is close to 1 ( $y = 1.19x + 20.45$ ). From this result, it may be concluded that the number of  $H^+$  ions involved in the extraction process is equal to one.

The variation of  $\log D_{Au(I)} + \log \alpha_{Au(T)}$  with respect to  $\log [\overline{HL}]$  indicates that the slope of the linear function which represents the experimental data is nearly two ( $y = 1.99x + 16.48$ ). For this reason, the number of extractant molecules ( $n+p$ ) in the complex is equal to two.

For the number of thiourea molecules ( $t$ ), the results of the slope analysis of the extraction of Au(I) with ethylhexylphosphoric acid (EHPA) were considered. In this study, the variation of  $\log D_{Au(I)}$  with respect to  $\log [T]$  was analyzed. The results indicate that there is one thiourea molecule in the complex extracted at the same conditions studied. Therefore, the proposed stoichiometry for the Au(I) complex in the organic phase is AuL.T.HL. If Cyanex 302 is considered to be dimerized in the organic phase, the formation of the extracted complex is in accordance with Au(I) complex geometries.

The value of the apparent extraction constant was determined by minimizing the function  $U = \sum (D_{exp} - D_{calc})^2$ . Different stoichiometries for the Au(I)/Cyanex 302/thiourea complex were tested, however the minimum of  $U$  was obtained considering the proposed complex. Therefore, the extraction reaction is proposed to be the following:

The value of the apparent extraction reaction constant is  $K_{ext}^{app} = 10^{21.13}$ .

The variations of  $D_{exp}$  and  $D_{calc}$  as a function of the extractant concentration are shown in Figure 2 in two different media,  $H_2SO_4$  ( $K_{ext}^{app} = 10^{21.13}$ ) and  $HNO_3$  ( $K_{ext}^{app} = 10^{21.31}$ ).

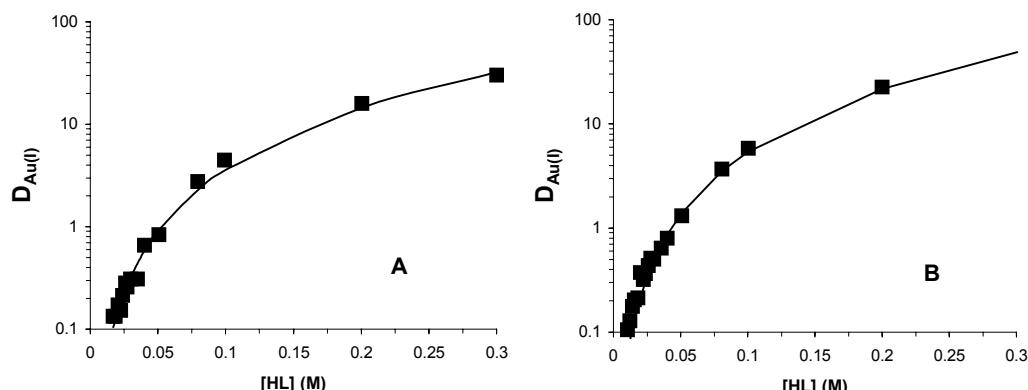

Figure 2. Distribution curves of Au(I). (A)  $H_2SO_4$ /thiourea and (B)  $HNO_3$ /thiourea.  $pH = 1.7$ . Experimental data (■), continuous lines represent those obtained from the model.

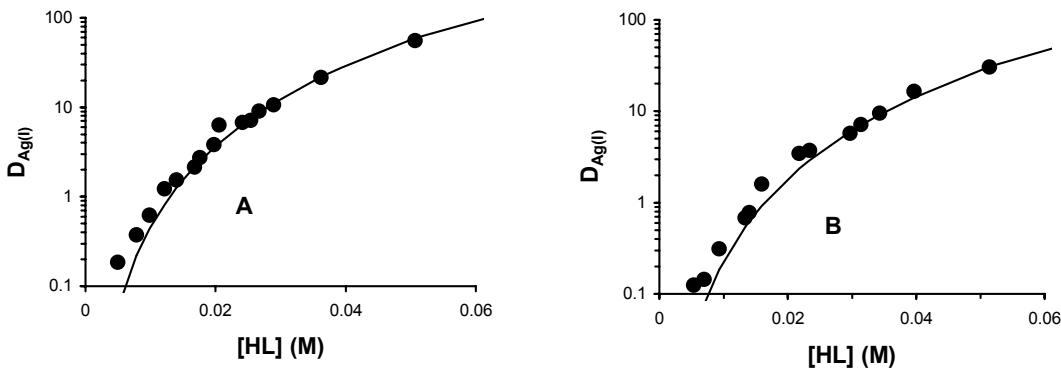

A satisfactory correlation may be observed between the experimental data and the distribution coefficient values obtained from the model developed in this work.

A similar study was performed for Ag(I) extraction in  $H_2SO_4$ /thiourea media. The variation of  $\log D_{Ag(I)} + \log \alpha_{Ag(T)}$  was analyzed as a function of the solution pH and  $\log [HL]$ . The value of the slope with respect to the pH was found to be close to 1 ( $y = 1.08x + 8.86$ ), showing behavior similar to that of Au(I). However, the function relative to the variation of  $\log [HL]$  showed a line whose slope was approximately 3 ( $y = 2.78x + 14.82$ ). As in the case of Au(I), the estimation of the thiourea participation in the Ag(I) organic phase complex was performed by slope analysis by EHPA.

The proposed stoichiometry for the Ag(I) complex in the organic phase is AuL.T.(HL)<sub>2</sub>. The values of the extraction constants of Ag(I) in the systems  $H_2SO_4$  / thiourea / Cyanex 302 and  $HNO_3$  / thiourea / Cyanex 302 obtained were respectively  $K_{extAg(I)}^{app} = 10^{13.01}$  and

$K_{extAg(I)}^{app} = 10^{13.16}$ . Figure 3 shows the correlation between the experimental data ( $D_{exp}$ ) and those obtained with the extraction model ( $D_{calc}$ ), for the two different media studied:  $H_2SO_4$ /thiourea and  $HNO_3$ /thiourea. As in the case of gold(I), a satisfactory correlation

between the experimental data and the theoretical distribution coefficient values was obtained.

*Figure 3. Distribution curves of Ag(I). (A)  $H_2SO_4$ /thiourea pH = 3.3 and (B)  $HNO_3$ /thiourea. pH = 2.8. Experimental data (■), continuous lines represent those obtained from the model.*

## CONCLUSIONS

Au(I) and Ag(I) recovery from aqueous thiourea solutions is possible with liquid-liquid extraction using Cyanex 302. The extraction model developed, which considers the influence of the aqueous phase Au(I) and Ag(I) thiourea complexes, allows the determination of the nature of the extracted species. The stoichiometries of the complexes extracted into the organic phase were  $AuL.T.HL$  and  $AgL.T(HL)_2$ , in both  $H_2SO_4$  and  $HNO_3$  media.

## OPPORTUNITIES AND CHALLENGES IN DEVELOPING A SOLVENT EXTRACTION PROCESS FOR RHODIUM BASED ON THE USE OF STANNOUS CHLORIDE

George P. Demopoulos, Yuxing Shang, Elyse Benguerel and Mark Riddle

McGill University, Montreal, Canada

Stannous chloride at a Sn(II)/Rh(III) ratio of (at least) 3 may be used to render rhodium 100% extractable via the formation of Rh(III)-Sn(II)-Cl complexes. A host of extractants may be used to effect the extraction. In this work Kelex 100 is used. The paper reports on the role of stannous chloride in effecting Rh extraction, its interaction with a great variety of impurities, such as Se, Te, Bi, As, Sb, Pb, Cu, Zn, Ni, Co, Fe, and ultimately its role in recovery-stripping of rhodium from the organic phase.

### INTRODUCTION

Rhodium has defied all past efforts to render itself amenable to recovery from refinery chloride solutions by conventional solvent extraction. Its complex coordination chemistry, and in particular its propensity to readily form mixed aquo-chloro complexes of the general formula  $[RhCl_{6-n}(H_2O)_n]^{(3-n)-}$ , has been held responsible for the poor response of rhodium to separation - particular by direct solvent extraction [1]. Hence, research efforts at McGill University have focused on converting these non-extractable mixed aquo-chloro complexes of Rh(III) to extractable ones via the use of "activating" agents. One such agent is stannous chloride [2,3]. In the McGill work the extractant used is Kelex 100 - an alkylated 8-hydroxyquinoline - however, other extractants may be used as well, such as dialkyl sulphides [5], TBP [6], amines [7] or other analogous anionic or solvating extractants. Depending on the amount of stannous chloride used two different Rh-Sn complexes are formed, either  $[RhCl_3(SnCl_3)_3]^{3-}$  at  $Sn/Rh < 6$  or  $[Rh(SnCl_3)_5]^{4-}$  for  $Sn/Rh > 6$  [4]. In an earlier communication [2] it was reported that despite the fact that rhodium may be quantitatively extracted with  $Sn/Rh > 2$  nevertheless it was only at molar ratio  $> 12$  that stripping was possible using a concentrated sulphuric acid medium ( $1.7\text{ M H}_2SO_4 + 1\text{ M Na}_2SO_4$ ) and this via cross-current contacts only. This stripping procedure was not satisfactory since it resulted in a large circulating load of stannous chloride (minimum  $Sn/Rh$  ratio = 12), lack of selectivity against tin and production of very dilute strip liquors. Since then further work was done focusing on the low  $Sn/Rh$  system ( $Sn/Rh = 3-4$ ) and in particular in the area of impurity behaviour and control and identification of alternate stripping methods. It is the object of this paper to outline the progress made in this regard and highlight the opportunities and challenges opened by the use of stannous chloride in the solvent extraction of rhodium.

## ACTIVATION AND EXTRACTION

### Rhodium and Tin

Prior to extraction the rhodium-containing feed liquor is activated by adding  $\text{SnCl}_2$  at a molar ratio  $\text{Sn(II)}/\text{Rh(III)} = 3\text{-}4$ . The selection of this ratio is justified on the basis of the data plotted in Figure 1. The respective activation reaction is:

Typical activation conditions (not optimized) are 15 min reaction at  $70^\circ\text{C}$  or 3 hours at  $25^\circ\text{C}$ . Activation works equally well for fresh or aged rhodium feed solution of a wide HCl/total chloride composition range. Since Sn(II) can be easily oxidized by air care should be exercised to prevent prolonged exposure of activated solutions to air. The rate of oxidation of Sn(II) by air at  $70^\circ\text{C}$  was determined to be  $6 \times 10^{-3}$  M/h while the rate at lower temperature is significantly lower. Finally, as discussed later, a number of impurities may react with stannous chloride hence the Sn(II)/Rh(III) ratio has to be appropriately adjusted.

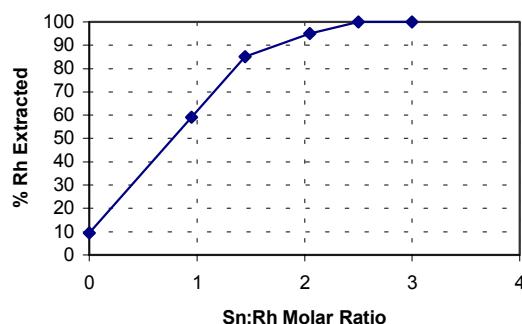

Figure 1. Effect of Sn(II)/Rh ratio on rhodium extraction  
(400 mg/L Rh, 1.5 M HCl - 4 M  $[\text{Cl}^-]_{\text{total}}$ , 2 vol. % Kelex 100).

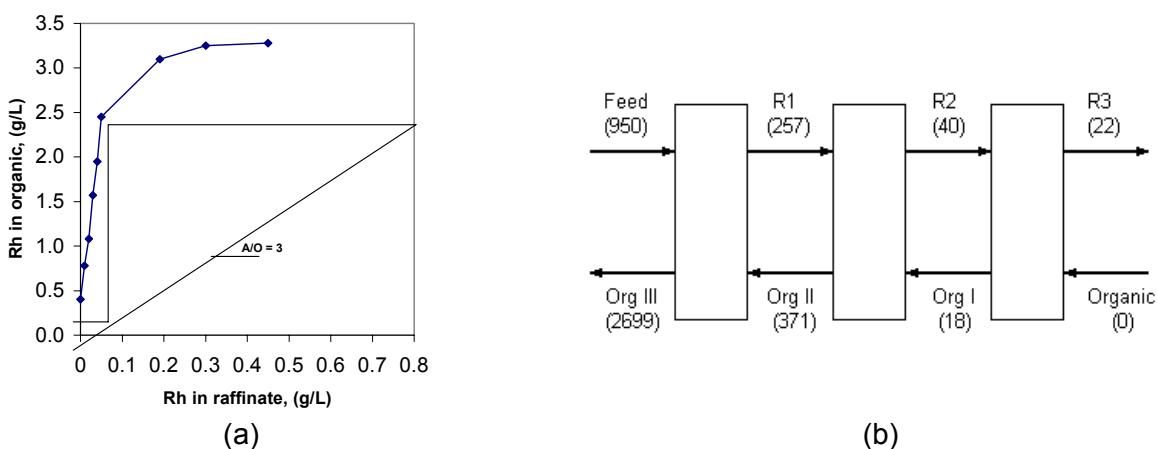

The extractant used throughout this study was Kelex 100 along with tridecanol as modifier diluted in an aromatic diluent: Solvesso 150. Most of the tests were done with the following organic formulation (unless otherwise stated): 5 vol. % Kelex 100, 15 vol. % tridecanol, 80 vol. % Solvesso 150.

The extraction of the activated rhodium-tin species was found to be very fast and quantitative: 99% extraction in less than 5 minutes. Phase separation was also very fast with no incidence of third phase formation even after a 15 vol. % Kelex 100 solvent was fully loaded with 10 g/L Rh and 50 g/L Sn ( $\text{Sn/Rh} = 3.5$ ). Analysis of the extraction data by slope analysis and complex characterization [3] revealed the following extraction mechanism:

where HQ represents Kelex 100.

Extraction isotherms were obtained and McCabe-Thiele diagrams were constructed for 2 vol. % [3], 5 vol. % and 15 vol. % Kelex 100 solvents. The 5 vol. % extraction isotherm is shown in Figure 2(a). Batch-wise simulation [8] of a 3-stage counter-current extraction circuit (Figure 2(b)) yielded the following "steady-state" results: Rhodium in loaded organic = 2.7 g/L and rhodium in raffinate = 20 mg/L. The respective tin values were: 12.98 g/L and 4 mg/L. The residual rhodium in the raffinate was above the typical < 5 mg/l level due to the (accidentally) lower Sn/Rh ratio used (2.88 vs. the typical 3.5).

*Figure 2. (a) Rhodium extraction isotherm and McCabe-Thiele diagram for Sn/Rh = 3.57 and 5 vol. % Kelex 100.*

*(b) Batch-wise simulation of 3-stage continuous extraction circuit (AF = 0.95 g/L Rh, 3.17 g/L Sn, A/O = 3, CT = 3 min; numbers in brackets indicate rhodium concentration in mg/L).*

### Impurity Behaviour and Control

The behaviour of a large host of impurity elements that may potentially be present in refinery feedstocks was studied during both activation and extraction stages. The impurities investigated were: Se(IV), Te(IV), Sb(V), As(V), As(III), Bi(III), Cu(II), Fe(III), Zn(II), Pb(II), Ni(II) and Co(II). Since Sn(II) is a relatively strong reductant (the  $E_h$  for the couple Sn(IV)/Sn(II) 1 M HCl/4M total Cl<sup>-</sup> solution is estimated to be 0.0 V), some of the impurity elements were found to react with SnCl<sub>2</sub>. As a result, the concentration of Sn(II) available for the activation of Rh(III) is reduced. In order to understand the reaction between each impurity element and stannous chloride and consequently control impurity co-extraction, a number of titration-type tests were carried out at 70°C (under a nitrogen atmosphere to exclude air) by monitoring the solution potential. Some typical data are shown in Figure 3. Thus according to this work stannous chloride was found to react preferentially with a number of impurity elements such as Se(IV), Te(IV), Sb(V), Fe(III) and Cu(II) prior to formation of the stannous-rhodium complexes. The first two elements were found to precipitate in easily-filterable elemental forms with no rhodium losses by co-precipitation, while Sb, Fe and Cu remained in solution but in their lower oxidation states, i.e., Sb(III), Fe(II) and Cu(I). No reaction was observed between Sn(II) and the other impurity elements.

From a process point of view, the progress of these redox reactions can be controlled by the solution potential. The cut-point potential is 80 mV (vs. Ag/AgCl reference electrode). As soon as this potential is reached, the addition of SnCl<sub>2</sub> is stopped and the solution is filtered to remove the selenium and tellurium precipitates. Subsequent to this SnCl<sub>2</sub> is added to establish a Sn(II)/Rh(III) ratio of 3 hence to effect rhodium activation.

The potential for co-extraction of the various impurity elements after activation was tested by performing single contacts at A/O = 1. The obtained results are shown in Table 1. Scrubbing (single contact) with 1-2 M HCl proved effective in removing the small amounts of impurities extracted with the exception of antimony. It is noteworthy that no rhodium is lost from the loaded organic phase during scrubbing.

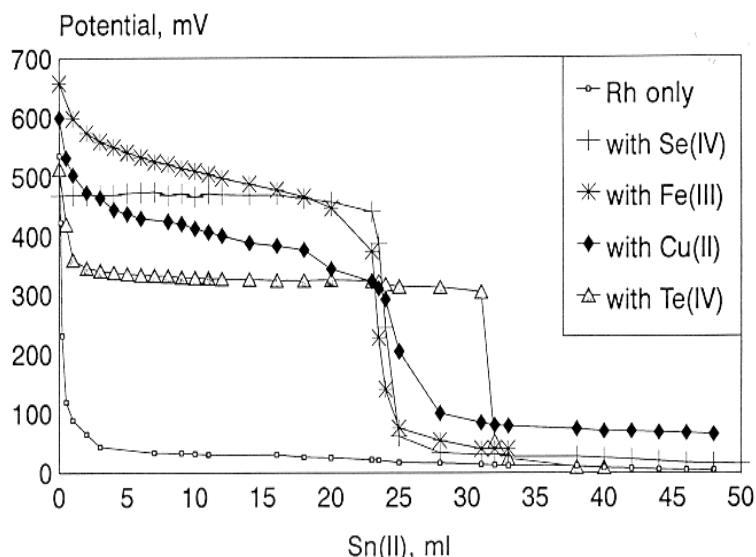

Figure 3. Potential variation during activation in the presence of reacting impurities (70°C, N<sub>2</sub> bubbling; the potential values are wrt Ag/AgCl electrode).

Table 1. Distribution of impurities during activation, rhodium extraction and scrubbing.  
 (Conditions: AF = 1.5 M HCl, 1.5 M MgCl<sub>2</sub>, activated at 70°C; Sn(II)/Rh(III) = 3.5 after the solution potential was reached to < 80 mV, 2 vol. % Kelex 100; A/O = 1 (in both extraction and scrubbing); scrub solution = 2 M HCl.)

Impurity Species		Concentration (mg/L)		
Feed	After Activation	Activated Feed	Loaded Organic	Scrubbed Organic
Se(IV)	Se(0)	< 5	trace	nil

Ni(II)	Ni(II)	209	4	nil
Co(II)	Co(II)	123	2	nil

## STRIPPING AND RECOVERY

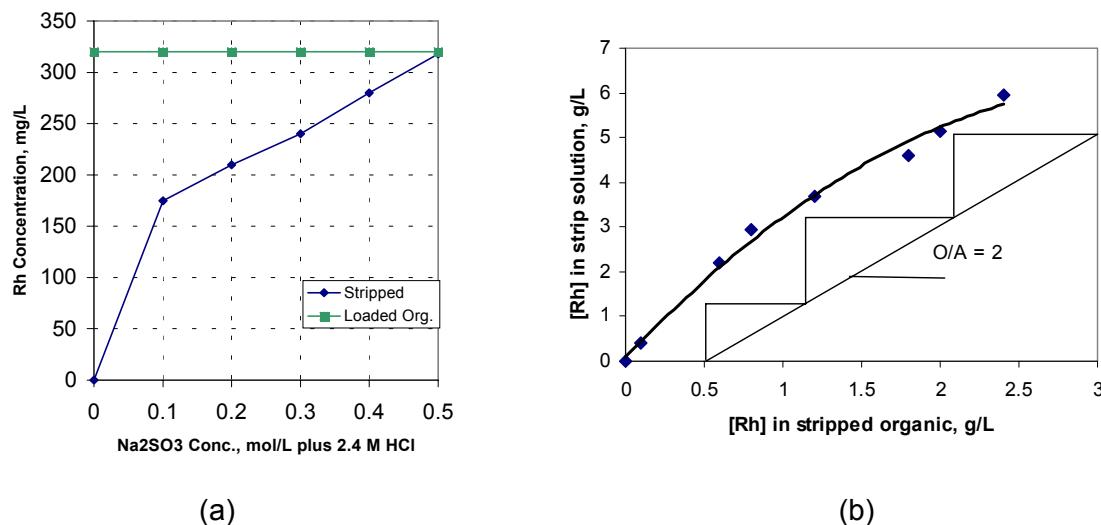

Various stripping approaches and media were tried. One approach was to use an oxidant (such as FeCl<sub>3</sub> in HCl) to cause stripping via destabilization of the extracted Rh(III)-Sn(II) complex by oxidation of Sn(II). Despite elevated temperatures (60°C) applied this approach proved ineffective. Use of stronger oxidants (such as Cl<sub>2</sub> as suggested by Zou *et al.* [6]) was not pursued due to fear of extractant decomposition - use of K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub> did indeed lead to such decomposition. The other approach tried was the use of sulphite (Na<sub>2</sub>SO<sub>3</sub>) in HCl due to the well-known reducing and complexing properties (including rhodium [9]) of sulphite ligands. This approach proved indeed effective initially when dilute solutions were used. However, as described below, when concentrated solutions were tried precipitation was observed to occur. Finally direct precipitation stripping was attempted with very encouraging results.

### Stripping with $\text{Na}_2\text{SO}_3$ - HCl

The effectiveness of sodium sulphite as rhodium stripping agent in HCl (2-2.5 M HCl is the optimum concentration range) is illustrated in Figure 4(a). Stripping times in the order of 20 to 30 min per contact had to be employed. Slope analysis and complex characterization led to the determination of the following stripping reaction stoichiometry:

The above reaction suggests 100% separation between Rh and Sn. In reality, however, a certain amount of Sn was found to co-strip with rhodium. The Sn/Rh ratio in the strip liquor was found to depend on the O/A ratio (see data in Table 2) and the type of modifier used. Unfortunately D2EHPA was found to form a stable emulsion in the downstream caustic tin scrub stage and could not be used further.

*Figure 4. (a) Effect of sodium sulphite concentration on rhodium stripping (2 vol. % Kelex 100, Sn/Rh = 3.4, CT = 20 min, A/O = 1, 2.4 M HCl).  
(b) Rhodium stripping isotherm and McCabe-Thiele diagram  
for 5 vol. % Kelex 100 (loaded organic = 3.02 g/L Rh, Sn/Rh = 3.2,  
Strip = 0.5 M  $\text{Na}_2\text{SO}_3$  and 2.4 M HCl, CT = 30 min.)*

In addition to  $\text{Na}_2\text{SO}_3$  other forms of sulphite salts such as  $\text{Na}_2\text{S}_2\text{O}_5$  gave comparable results but gaseous  $\text{SO}_2$  was not as effective. The stripping isotherm for 5 vol. % Kelex 100 is shown in Figure 4(b). Batchwise simulation [8] of a 4-stage counter-current stripping circuit (based on the isotherm of Figure 4(b) with O/A = 2) yielded the following “steady-state” results: Rhodium in strip liquor = 3.3 g/L and rhodium in stripped organic = 0.65 g/L; rhodium in the loaded organic feed was 3.24 g/L. The respective tin values were 1.9 g/L and 10.12 g/L. This is clearly not a very satisfactory performance. Moreover upon standing for a few hours, rhodium started to precipitate out of the strip liquors. An extensive investigation of the precipitation problem revealed the  $\text{Rh(III)} - \text{SO}_3^{(II)} - \text{Cl}$  strip solutions to be metastable in nature with induction times varying from a few hours to a few days depending on the rhodium concentration and the Sn/Rh ratio in the strip liquor. The precipitate was determined to be a complex  $\text{Rh(III)} - \text{SO}_3 - \text{Cl} - \text{H}_2\text{O}$  salt.

*Table 2. Variation of Sn/Rh ratio in the strip liquor with O/A. (Conditions: 3 g/L Rh loaded in 5 vol. % Kelex 100 - 15 vol. % Modifier-Solvesso 150; 0.5 M Na<sub>2</sub>SO<sub>3</sub> in 2.4 M HCl Strip; Sn/Rh in loaded organic = 3.3).*

	Tridecanol	D2EHPA
1/5	1.6	0.25
1/2	1.2	0.15
1/1	1.0	0.10
2/1	0.7	0.06
5/1	0.3	0.04

### Thermal Redox Stripping

From a thermodynamic point of view, SnCl<sub>2</sub> is capable of reducing RhCl<sub>6</sub><sup>3-</sup> to metal:

$$E^\circ = e_{\text{Rh(III)/Rh(0)}} - e_{\text{Sn/Cl2/SnCl2}} = 0.44 \text{ V}$$

Such reaction, however, was not observed under the conditions of activation applied due to apparently unfavorable kinetics - although partial reduction of Rh(III) to Rh(I) was indeed observed when a high Sn/Rh ratio (= 12) was used [3]. It was, therefore, decided to exploit this redox reaction for the purpose of recovering rhodium directly from the organic phase by thermal treatment in an autoclave. Through a few tests it was determined that this type of redox precipitation stripping is indeed feasible. Thus treating the loaded organic (containing ~1 g/L Rh and Sn/Rh = 3.5) in mixture with 0.2 M HCl (A/O = 1) at 150° for two hours resulted in quantitative precipitation of rhodium (> 95%) as a fine metallic black powder. No tin precipitation took place. No apparent signs of organic decomposition were noticed. To assess the potential for impurity co-precipitation with rhodium, an activated aqueous feed spiked with impurities was thermally treated at 150°C for 2 hours. The results obtained are shown in Table 3. Metal impurities such as Cu, Zn or Pb do not co-precipitate but metalloid impurities (Bi, Sb, As) do, hence they need to be recovered by scrubbing prior to stripping. Of interest are the results of platinum and iridium. No precipitation of iridium apparently occurs, opening the opportunity for Rh/Ir separation - more on this in a following section - but platinum does precipitate and needs to be absent from the feed.

*Table 3. Impurity behaviour during thermal redox precipitation of rhodium from activated aqueous solution (conditions: 150°C, Sn/Rh = 4.2, 2 hours).*

Element	Feed (mg/L)	After Treatment (mg/L)
Rh	908	47
Sn	4375	4413

Pb	213	226
Bi	180	120
Sb	111	35
As(III)	35	10
Pt	93	21
Ir	100	95

## TIN SCRUBBING AND ORGANIC RECYCLING

Following rhodium stripping/recovery the organic phase is subjected to caustic scrubbing with 1 N NaOH to remove tin. Attempts to recycle the tin-loaded organic directly into the activation stage failed hence the need for tin removal prior to recycling. Caustic scrubbing is effective for both tin species, i.e., Sn(II) and Sn(IV). Typically >80% of tin (and >30% of Sb if present) is recovered in a single contact of 60 minutes with 1 N NaOH at 20°C. Any rhodium left in the stripped organic follows tin, hence the importance of maximizing rhodium recovery during stripping.

Following tin scrubbing, the organic solvent is re-conditioned with 3 M HCl to remove any caustic prior to its recycling to activation. Recycling the same organic (2 vol. % Kelex 100 - 10% tridecanol - Solvesso 150) up to 4 cycles of activation-extraction-stripping with Na<sub>2</sub>SO<sub>3</sub> - tin scrubbing - reconditioning with HCl showed no sign of loss of rhodium extraction-stripping performance. The organic solvent was also subjected to long-term degradation tests in contact with simulated HCl feed and NaOH scrub solutions for up to 60 days with no signs of degradation.

## THE BEHAVIOUR OF IRIDIUM

Rhodium recovery is envisaged to be practiced following platinum/palladium extraction. Iridium may be present in the platinum raffinate liquor, hence its behaviour during extraction of rhodium following activation with SnCl<sub>2</sub> was briefly examined. Iridium in the form of Ir(III) - Sn(II) - Cl complexes was found to be co-extracted along with rhodium but to a lower extent (99% Rh vs. 65% Ir after one contact at A/O = 1 of an aqueous feed containing 988 mg/L Rh and 282 mg/L Ir with Sn/Rh = 4.2). The behaviour of iridium during stripping and scrubbing operations is exemplified with the data of Table 4. In general iridium stayed in the organic except in the case of the caustic scrub. A general deterioration of the phase separation characteristics was observed when iridium was present. Phase separation was facilitated at elevated temperature (50°C).

*Table 4. Iridium behaviour under various scrubbing and stripping operations.

## CONCLUDING REMARKS

Stannous chloride at a molar Sn(II)/Rh(III) ratio of 3 renders rhodium(III) completely extractable from chloride feed liquors at very high loadings (10-12 g/L Rh(org)) and kinetics (3 min) via the formation of Rh(III)Sn(II)<sub>3</sub>Cl<sub>12</sub><sup>3-</sup> complexes. The extraction of rhodium(III) is selective against common impurities such as Se, Te, Bi, As, Pb, Cu, Zn and Fe but not against PGM (in particular iridium and platinum). Stripping of rhodium using a 0.5 M Na<sub>2</sub>SO<sub>3</sub> - 2.4 M HCl ratio was found to be only partly successful as the resultant Rh-rich strip liquor is metastable in nature causing rhodium to precipitate. An alternate promising stripping approach is the direct precipitation of rhodium in the organic phase via redox coupling of

Rh(III)/Sn(II) at elevated temperatures ( $> 150^{\circ}\text{C}$ ). This thermal redox treatment appears to be selective against tin and iridium. Tin is recovered from the stripped organic by caustic scrubbing. Any rhodium or iridium remaining in the organic phase following stripping reports in the tin caustic scrub solution.

Despite the significant progress made there remains a significant amount of work before the stannous chloride-assisted SX approach to rhodium refining proves successful. Further work is required to consider in detail (i) the behaviour and control of other PGMs and in particular that of iridium; (ii) the testing of new extractants; (iii) the further development of the thermal redox stripping and the determination-control of the rhodium metal purity, and finally (iv) the recovery for re-use of the stannous chloride from the caustic scrub liquor.

## EXTRACTION OF CHLOROCOMPLEXES OF Pt AND Pd BY DIAMINES AND THEIR SALTS WITH ORGANIC ACIDS

V.V. Belova, T.I. Jidkova\*, A.I. Kholkin, Yu.Yu. Brenno\* and L.L. Jidkov\*

\*Institute of Chemistry and Chemical Technology of SB RAS, Krasnoyarsk, Russia

The extraction of Pt and Pd from chloride solutions by binary extractants, salts of tetraoctylhexylenediamine with organic acids (di(2-ethylhexyl)phosphoric and di(2-ethylhexyl)dithiophosphoric acids), has been studied. Recovery of Pt from aqueous solutions decreases with increasing pH values in both extractant systems. The extraction of  $\text{PdCl}_4^{2-}$  by diamine dialkylphosphate proceeds through the formation of monomeric and dimeric extracted species in the organic phase depending on the Pd concentration. Palladium distribution in the diamine dialkyldithiophosphate system does not depend on the aqueous acidity. Under conditions of the loaded organic phase, the extracted species involving the diamine cation ( $\text{AmH}_2^{2+}$ ) and Pd complex anion with coordinated dialkyldithiophosphate is formed. With excess of the binary extractant, the dialkyldithiophosphate of palladium,  $\text{PdA}_2$ , is extracted into the organic phase. After separating, Pt and Pd can be stripped from the organic phase by  $\text{NH}_3$  solution in the diamine dialkylphosphate system.

### INTRODUCTION

Earlier we have studied the extraction of Pd chlorocomplexes by chlorides of diamines [1]. Tetraoctylalkylenediamines (Am) were found to be more effective extractants compared to diethylamine and triethylamine. In the extraction of Pd by tetraoctylalkylenediamine chlorides, monomeric  $(\text{AmH}_2)\text{PdCl}_4$  and dimeric  $(\text{AmH}_2)\text{Pd}_2\text{Cl}_6$  extracted species are extracted into the organic phase. Palladium extraction from solutions with high HCl concentration (extractant excess) occurs through an anion-exchange mechanism, forming monomeric extracted species.

Systems involving binary extractants based on monofunctional amines and quaternary ammonium bases are characterized by reversibility of the distribution process. As a result, platinum metals can be stripped from the organic phase more easily than for single extractant systems [2, 3]. We describe here the extraction characteristics of several systems involving diamines and their salts with organic acids.

## EXPERIMENTAL

The complex acids,  $H_2PtCl_6$  and  $H_2PdCl_4$ , were used as the initial compounds. Solutions of diamine chlorides ( $Am\cdot2HCl$ ), di(2-ethylhexyl)phosphate and di(2-ethylhexyl)dithiophosphate of tetraoctylhexylenediamine in toluene were used as extractants. The binary extractants,  $Am\cdot2HA$ , were prepared by mixing equimolar amounts of diamine and organic acid (HA) in toluene. Di-*n*-octylamine ( $R_2NH$ ), tri-*n*-octylamine ( $R_3N$ ), disubstituted ( $R_2N_2H_2(CH_2)_6$ ,  $R = C_8H_{17}$ ) and tetrasubstituted ( $R_4N_2(CH_2)_n$ ,  $R = C_8H_{17}$ ;  $n = 2; 4; 6$ ) diamines were employed. The compounds,  $R_3N$  and  $R_4N_2(CH_2)_n$ , were used as chlorides salts,  $R_3NHCl$  and  $R_4N_2(CH_2)_n\cdot2HCl$ , which were obtained by mixing organic solutions of amine and diamines with 3 M HCl solution for 10 min.

## EXTRACTION OF PLATINUM BY CHLORIDES OF DIAMINES

Disubstituted and tetrasubstituted diamines were used for the platinum extraction. Figure 1 shows that the extraction of Pt chlorocomplexes from 0.1 to 3 M HCl solutions by tetraoctylalkylenediamine chlorides gives percentage recoveries of platinum that are higher than those measured with  $R_2NH$  and  $R_3NHCl$  under comparable conditions. The extraction power of tetraoctylalkylenediamine chlorides was found to be well above that of dioctylhexylenediamine, as well as the extraction power of tertiary amines is higher than that of secondary amines.

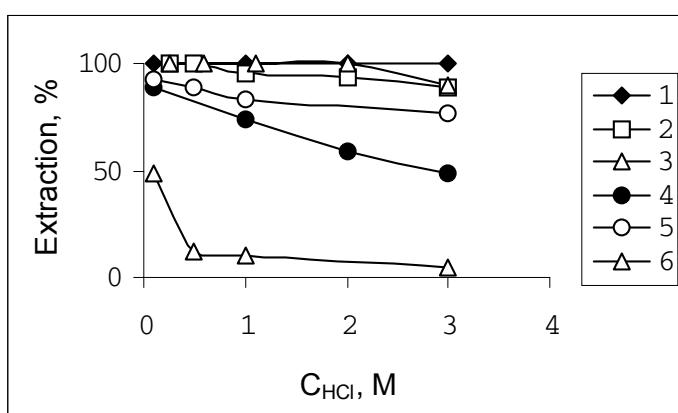

Figure 1. Extraction of Pt by 0.005 M solutions of  $R_4N_2(CH_2)_n\cdot2HCl$  (1-3);  $R_2NH$  (4);  $R_3NHCl$  (5) and  $R_2N_2H_2(CH_2)_6$  (6).  
 $C_{Pt\ init.} = 7 \times 10^{-4} M$ ;  $n = 2$  (1); 4 (2); 6 (3).

Thus, the experimental data showed that tetraoctylalkylenediamines are more effective extractants for platinum metals compared to monofunctional amines.

## EXTRACTION OF Pt AND Pd BY SALTS OF DIAMINE WITH ORGANIC ACIDS

In binary extractant systems, distribution of the chlorocomplex acids of platinum metals occurs through a binary or anion-exchange mechanism depending on the state of the binary extractant in the organic phase that is determined by the aqueous acidity and the nature of the extractant [2, 4]. Distribution of the chloride ion between  $Am\cdot2HA$  solutions in toluene and aqueous solutions with different concentrations of  $H^+$  at a constant chloride concentration ( $C_{Cl\ (aq)} = 3 M$ ) was studied. Experimental data showed that the dialkylphosphate of the diamine is mainly in the binary form at an equilibrium pH above 2, and that the

dialkyldithiophosphate is stable at equilibrium pH values above 1 because di(2-ethylhexyl)dithiophosphoric acid is stronger. With mixing of the binary extractant solution and acidic aqueous solutions, binary extraction of HCl occurs:

The extraction of platinum chlorocomplexes by binary extractants based on diamine was studied (Figure 2). The recovery of platinum was found to decrease with an increase in the pH values of the aqueous phase accordingly to the binary extraction regularities of mineral acids [5]. The data on spectrophotometrical studies showed that in the absorption spectra of the organic phases forming in the Pt extraction by binary extractants from aqueous solutions of different acidity, one absorption band at  $\lambda_{\max} = 475$  nm is observed in the visible range, which is characteristic for the spectrum of  $\text{PtCl}_6^{2-}$  complex anion [6]. Taking into account the state of binary extractants, the distribution of platinum in the systems involving salts of diamines with organic acids is described as binary extraction of  $\text{H}_2\text{PtCl}_6$ :

The platinum extraction by the diamine dialkyldithiophosphate proceeds with lower distribution coefficients (Figure 2, curve 2) in comparison with the dialkylphosphate system, due to higher stability of the first extractant.

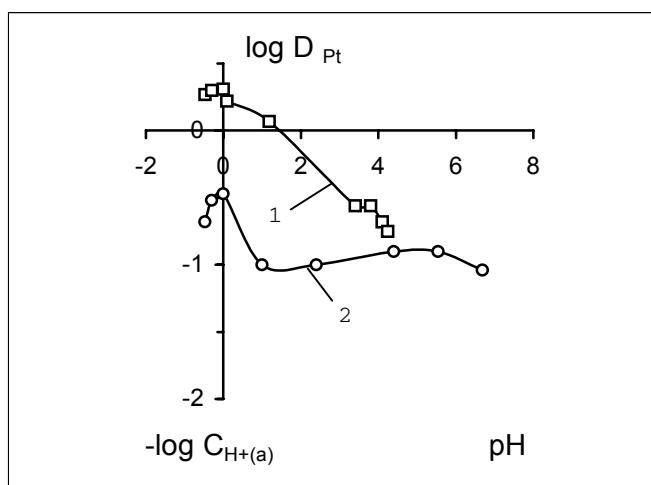

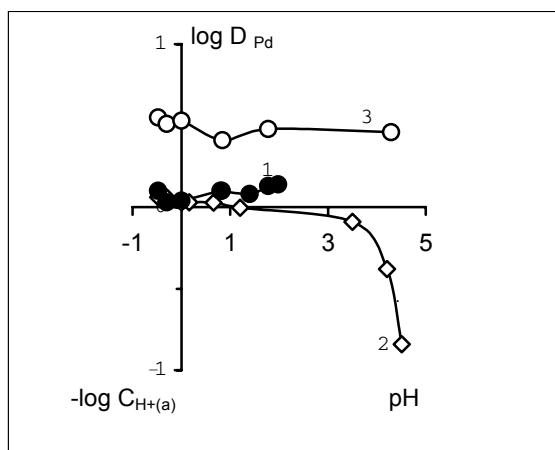

Figure 2. Extraction of Pt from chloride solutions by 0.005 M solutions of dialkylphosphate (1) and dialkyldithiophosphate (2) of tetraoctylhexylenediamine in toluene.  
 $C_{\text{Pt}} = 5.6 \times 10^{-3} \text{M}$ ;  $C_{\text{Cl}^-(\text{a})} = 3 \text{M}$ .

The reversibility of extraction and stripping is characteristic for binary extractant systems. The Pt stripping from the extracts forming in the dialkylphosphate diamine system by a 1 M ammonia solution was found to vary from 40 to 90%, depending on platinum concentration in the organic phase (Table 1).

*Table 1. Stripping of Pt and Pd from the organic phase by 1 M solution of NH<sub>3</sub> in the diamine dialkylphosphate system.*

$C_{M(o)} \times 10^3, M$		Recovery of metal into strip solution, %	
Pt	Pd	Pt	Pd
3.44	3.10	46.8	52.1
3.63	3.30	36.0	47.8
3.24	1.64	40.0	62.2
2.92	1.80	62.5	55.9
1.17		96.5	
1.23		86.7	

The data for the extraction of  $\text{PdCl}_4^{2-}$  by different salts of tetraoctylhexylenediamine are given in Figure 3. In the Pd extraction from acidic solutions ( $3\text{ M HCl}$  – pH ~ 1.5) the extraction power of diamine salts increases in the series: dialkylphosphate ~ chloride < dialkyldithiophosphate. With increasing pH values of the aqueous phase ( $\text{pH}_{\text{eq}} > 3$ ), the extraction of Pd by diamine dialkylphosphate decreases similar to in the binary extraction of mineral acids, while in the diamine dialkyldithiophosphate system,  $D_{\text{Pd}}$  does not change. Thus, in contrast to platinum extraction, palladium is more effectively recovered into the organic phase with diamine dialkyldithiophosphate.

*Figure 3. Extraction of Pd from chloride solutions by 0.005 M solutions of chloride (1), dialkylphosphate (2) and dialkyldithiophosphate (3) of tetraoctylhexylenediamine in toluene.  $C_{\text{Pd}} = 5.6 \times 10^{-3} M$ ;  $C_{\text{Cl}(o)} = 3 M$ .*

The composition of the palladium extracted species was studied by a spectrophotometrical method. Spectrophotometrical data indicate that in the Pd extraction by dialkylphosphate from 3 M HCl solution, the  $\text{PdCl}_4^{2-}$  complex anion is distributed into the organic phase ( $\lambda_{\text{max}} = 476\text{ nm}$  [7]). With decreasing acidity of the aqueous phase, in the spectra of the corresponding extracts, the maximum of absorption is shifted to the low frequency spectra region. At pH > 3, an extracted species with  $\lambda_{\text{max}} = 440\text{ nm}$ , characterized as the spectrum of the dimeric anion,  $\text{Pd}_2\text{Cl}_6^{2-}$ , is extracted into the organic phase. Thus, the distribution of palladium from aqueous solutions of different acidity in the diamine dialkylphosphate system, taking into account the extractant state in the organic phase, can be described as follows:

(extraction from acidic solutions)

(extraction from weak acidic solutions).

In the region of pH ~1 to 2, two extracted species of palladium are recovered into the organic phase because the spectra of the corresponding extracts have an intermediate character ( $\lambda_{\max} = 460$  to  $450$  nm). The influence of the concentrations of the binary extractant and palladium on the distribution of  $\text{PdCl}_4^{2-}$  in the diamine dialkylphosphate system was studied. Results obtained showed that with increasing Pd concentration in the organic phase ( $C_{\text{Pd(o)}} : C_{\text{ex.}} \geq 0.5$ ), both monomeric and dimeric species are also extracted ( $\lambda_{\max} \sim 460$  nm).

Unlike the Pd extraction by diamine dialkylphosphate, in the extraction of  $\text{PdCl}_4^{2-}$  by dialkyldithiophosphate, the distribution coefficients do not change with varying aqueous acidity from 3 M HCl to pH ~ 5 (Figure 3, curve 3). The spectra of the corresponding organic phases ( $C_{\text{Pd(o)}} : C_{\text{ex.}} \geq 1$ ) exhibit an absorption band at  $\lambda_{\max} = 415$  nm. In the extraction of Pd by diamine dialkyldithiophosphate under conditions of extractant excess, the extracted species has an absorption band at  $\lambda_{\max} = 466$  nm, which is characteristic for the  $\text{PdA}_2$  spectrum [8]. Thus, when the binary extractant is used in excess, the distribution of Pd from solutions with pH > 1 is described as follows:

Earlier we found that in the extraction of palladium from chloride solutions by dialkyldithiophosphates of tetraoctylammonium and amines under conditions of the loaded organic phase, extracted species involving the alkylammonium cation and the dialkyldithiophosphate anion, such as  $(\text{R}_4\text{N})[\text{PdCl}_2\text{A}]$  and  $(\text{AmH})[\text{PdCl}_2\text{A}]$ , are formed in the organic phase [8]. In the *d-d* spectra of such palladium complexes, the absorption band of the  $\text{PdCl}_4^{2-}$  complex anion ( $\lambda_{\max} = 476$  nm) shifts to lower frequencies. On the basis of these data, we supposed that the extracted species with  $\lambda_{\max} = 415$  nm also involves a complex anion with mixed ligands. Chemical analysis of the saturation product obtained in the Pd extraction by diamine dialkyldithiophosphate indicated the ratio of  $C_{\text{Pd (o)}} : C_{\text{e (init.)}}$  is close to 2. Thus, the composition of the extracted species can be presented as  $(\text{AmH}_2)[\text{PdCl}_2\text{A}]_2$ . The distribution of palladium chlorocomplexes from acidic and weak acidic solutions, taking into account the state of the binary extractant in the organic phase, can be represented respectively:

Table 2 shows compositions of the extracted species of Pt and Pd forming in the systems involving salts of diamines.

*Table 2. Pd(II) and Pt(IV) species extracted by salts of diamines from 1 M HCl.*

## COMMISSIONING OF THE NEW HARMONY GOLD REFINERY

**Angus Feather, Wendy Bouwer, Ronel O'Connell and Johan le Roux \***

Mintek, Randburg, South Africa

\*Harmony Gold Mining Company Ltd., South Africa

In 1997, a 24-tonne per annum gold refinery was commissioned at Harmony Gold Mine in South Africa making use of solvent-extraction technology to produce gold of 99.99% purity. Feed material for the refinery was cathode sludge arising from carbon-in-pulp/electrowinning circuits, zinc precipitate or atomised doré bullion.

Following Harmony's purchase of a further five gold mines, a larger refinery capable of producing 70 tonnes per year of high-purity gold, has been installed. Implementation of this process results in significant cost benefits compared with conventional smelting/toll-refining. Any premiums on the sale of high-purity gold products are realised. Harmony has established its own brand name.

### INTRODUCTION

The Minataur™ Process (Mintek Alternative Technology for Au Refining) is a solvent-extraction (SX) route for the purification of gold from chloride media. The process is capable of treating a range of gold-containing feed materials to produce refined gold of 99.99% purity. The process is selective for gold over silver, base metals, and minor quantities of platinum-group metals (PGMs). Following evaluation in two pilot-plant campaigns [1-3], a refinery with a production capacity of 24 tonnes of gold of 99.99% purity per annum was constructed at Harmony Gold Mine [4]. With the subsequent acquisition of other gold mines in South Africa by the Harmony group, a larger refinery was required to cope with the additional throughput of gold. A refinery to produce approximately 70 tonnes per annum has recently been constructed and commissioned.

### PROCESS DESCRIPTION

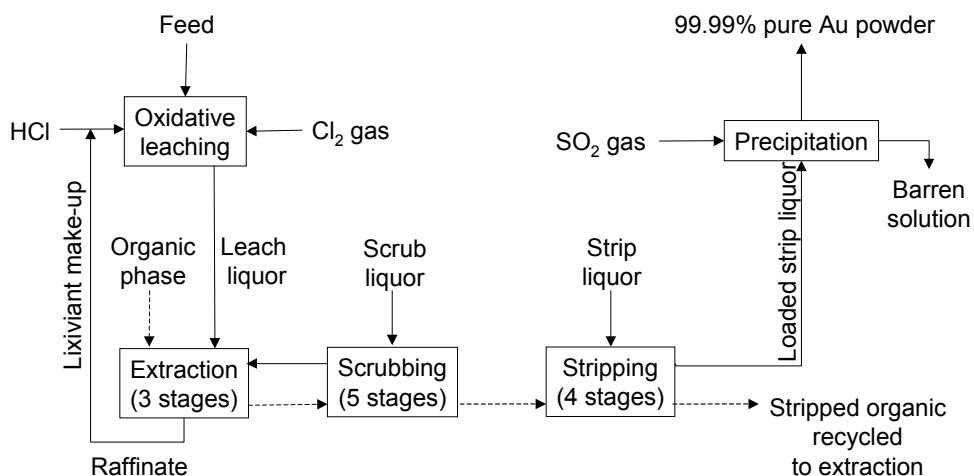

The gold plants that supply feed material to the Harmony Refinery operate conventional gold-processing plants, typical of most South African gold mining operations [5]. The ore is treated by run-of-mine milling followed by cyanidation in a carbon-in-pulp (CIP) circuit. Gold in the pregnant solution from elution of the loaded carbon is electrowon onto stainless-steel mesh cathodes, producing finely divided cathode sludge containing between 50 and 85% gold, or cemented from solution using zinc dust to produce a gold sludge containing approximately 40% gold.

The Minataur™ process as applied at the Harmony Refinery, uses dried cathode sludge or zinc precipitate as feed material, eliminating the traditional smelting and toll refining. The flowsheet of the Harmony Refinery is shown in Figure 1.

The gold content of the feed (~ 75%) is dissolved by leaching in HCl under oxidising conditions, using conventional technology [6]. The bulk of the base metals and PGMs are also solubilised under these conditions. Most of the silver precipitates as silver chloride and, along with any silica or fine carbon dust, is filtered off as a solid residue. This material is treated in a separate plant to recover residual gold and purify the silver using conventional anode casting followed by standard electro-refining technology.

Gold is selectively extracted from the leach solution by SX, while other soluble metal ions report to the raffinate. Small quantities of co-extracted impurities are scrubbed from the loaded organic phase before it is stripped to produce a purified, concentrated gold chloride solution. The stripped organic phase is recycled to the extraction circuit. Approximately 75% of the HCl-rich raffinate from the extraction section is returned to the leach, with a 25% bleed to control the build up of impurities in the leach/SX circuit and to preserve the solution balance in the plant.

Gold is recovered as a metal powder after reduction with sulphur dioxide from the loaded strip liquor. This step is relatively selective for gold over base metal impurities, and gold of 99.99% purity is produced.

*Figure 1. Process flowsheet for the Harmony Refinery.*

## PLANT CONSTRUCTION

The Engineering Services Division of Mintek carried out the engineering, design and construction of the Harmony Refinery. The manufacture of some specialist items of equipment was contracted to local suppliers. Harmony Refinery is designed to treat approximately 70 tonnes of gold per year, operating a single 8-hour shift per day, with expansion capacity to accommodate 150 tonnes of gold per year.

The plant was constructed over a 7-month period. As the refinery staff at Harmony are highly skilled in the refining process, process and plant commissioning as well as the acceptance run was completed in three weeks. A new laboratory constructed to ISO 9001 standards is currently under consideration for the analysis of all samples for process control, and also to ensure the control of final product quality. Gold meeting the design specification for purity (99.99%) was produced from the second batch.

## OPERATING RESULTS

### Leaching

It is planned that Harmony Refinery will treat material from a variety of gold plants in South Africa. All feed materials are dried, passed through a sampling tower into a hopper for transfer into the leach reactor, using an overhead crane. There are currently two batch leach reactors, each capable of treating 100 kg of fine gold at a time.

The leach reactor is charged with approximately 100 kg of fine gold, irrespective of the impurities in the feed material. Based on the mass of gold in the feed material and the HCl concentration of the SX raffinate, appropriate volumes of fresh HCl and raffinate are added to the leach reactor. The liquid:solid ratio is calculated to produce leach liquor with a gold concentration of approximately 65 g/L. The reactor is pressurised at 0.4 bar with chlorine gas to provide the oxidising conditions necessary for gold dissolution. An inducing impeller is used to maintain the required gas dispersion in the leach reactor. The reactor is sealed using a standard double mechanical seal on the impeller shaft. The leach is done at ambient temperature with no provision for heating. The temperature increases to approximately 45 °C during the leach.

Any solids left at the end of the leach are mainly silver chloride, with minimal unleached gold, silica and carbon fines from the CIP process forming the remainder of the leach residue. The solids are removed from the leach liquor by filtration using a plate and frame filter press. Entrained leach liquor is washed from the filter cake with SX raffinate. The filter cake is refined using conventional electrolytic technology to recover the silver as high-purity crystals and any residual gold in the form of a finely divided powder. This can then be returned to the gold-refining leach circuit. A summary of the leaching conditions and typical results is shown in Table 1.

*Table 1. Batch leaching performance.*

Typical leaching time	2.5 – 5 h
HCl concentration	5.5 M
Average feed gold concentration	75%
Leaching efficiency	> 99%
Cl <sub>2</sub> consumption	0.7 kg per kg of gold

### Solvent Extraction

The SX plant both concentrates and purifies the gold. The SX plant comprises three extraction, five scrub and four strip stages. The stages are conventional box-type mixer settlers equipped with facility for the internal recycle of aqueous solutions. Solutions are fed to the SX plant by positive displacement peristaltic pumps. Table 2 shows the typical steady-state compositions of the leach liquor fed to the SX plant, with the corresponding loaded strip liquor and raffinate produced.

*Table 2. Typical compositions of leach liquor and loaded strip liquor.*

Sample analysis	Au	Ag	Cu	Fe	Pb	Se
Leach liquor (g/L)	65	0.5	8.3	0.2	1.3	0.02
Loaded strip liquor (g/L)	82	< 0.001	< 0.001	< 0.001	< 0.002	0.002
Raffinate (g/L)	0.1	0.5	8.2	0.2	1.2	0.02

Typical operating efficiencies for the SX circuit at steady-state conditions are given in Table 3. There is little incentive to reduce the gold concentration of the raffinate below 0.1 g/L, as 75% of this solution is recycled to the leach. Gold in the raffinate bleed (25%) is recovered from this stream in the CIP adsorption circuit.

Since treating a feed material with a high gold content minimises the proportion of the raffinate, which must be bled to control impurities, efforts are underway at Harmony to improve the operation of the upstream circuits and thereby increase the grade of the refinery feed material.

*Table 3. Operating efficiency of SX circuit.*

<i>Extraction</i>	
Extraction efficiency for gold (%)	> 99
Organic loading of gold (g/L)	64
Gold concentration of raffinate (g/L)	0.1
<i>Stripping</i>	
Stripping efficiency (%)	> 99.7
Au : impurities in loaded strip liquor (%)	> 99.97

### Precipitation

The precipitation of gold from the loaded strip liquor is carried out once per shift in a batch operation by sparging SO<sub>2</sub> gas through the solution. The reaction goes readily to completion and introduces a further degree of selectivity. Typical operating conditions and results are indicated in Table 4.

*Table 4. Operating efficiency of precipitation.*

Gold concentration in loaded strip liquor (g/L)	82
Gold concentration in precipitation barren (g/L)	0.002
Reduction efficiency (%)	> 99.9
Reaction time (h)	1.5 – 2

The gold powder is thoroughly washed with water to remove entrained waste solution from the reduction, then dried in a rotary drier at approximately 450 °C. The gold recovered has a powder morphology, and average particle size of < 100 µm, although some agglomeration does occur due to the nature of the material.

Analysis of the gold is carried out on site in the refinery using a spark spectrometer in SAFT mode (spark analysis for traces). Table 5 shows typical analyses of the major impurities of the gold produced at Harmony. The ASTM specification for 99.99% gold is shown for comparison (ASTM, 1986). All gold is produced to 99.99% purity. Some of the gold is then diluted for specialised products, such as the ten-tola bars, which are generally sold at a gold specification of 99.9%.

*Table 5. Typical analysis of Harmony PureGold.*

Element (ppm)	Ag	Bi	Cr	Cu	Fe	Mn	Ni	Pb	Pd	Sn	Au <sup>†</sup>
ASTM, 99.99%	90	20	3	50	20	3	3	20	50	10	99.99
Harmony	14	0.1	3	6	6	0.4	1.5	1.2	2	2.6	> 99.99

<sup>†</sup> Au calculated by difference

### Gold Products

The dried powder is weighed into batches of predetermined mass and melted in an induction furnace before being cast into products. All Harmony's gold products are marketed internationally by Pechiney, who have successfully established the Harmony brand in certain areas of the world. A variety of bars, including ten-tola, kilo, good-delivery bars and granules for the jewellery industry are produced. Market conditions determine the product range.

## PROCESS ECONOMICS

### **Capital and Operating Costs**

The capital and operating costs for the new Harmony Refinery are shown in Table 6. The battery limits for the refinery commence with the reception of impure gold material to the plant, and end with dry high-purity gold powder for bar casting or granule manufacture. The capital cost includes commissioning fees. In estimating the fixed costs, only labour costs directly attributable to the operation of the refinery are included. Infrastructure development, maintenance and insurance have been excluded. Effluent is discharged at the refinery battery limits. The operating costs do not include amortisation of the capital costs. All costs relate to South African conditions as at April 2001 and are quoted in South African Rands (R).

*Table 6. Capital and operating costs for Harmony Refinery.*

Item	Cost
Capital Cost	R 8 000 000
Operating Costs (per kg gold)	R 56
Fixed (per kg gold)	R 38
Variable (per kg gold)	R 18
Total Cost (per oz gold)*	US\$ 0.22

\*An exchange rate of R 8.00 = US\$ 1.00 is currently applicable.

The operating cost of the in-house refinery is approximately half the cost of the conventional smelting and toll-refining route. A payback period of the capital investment of less than 2.5 years has been calculated. If a premium can be obtained for gold of 99.99% purity (rather than 99.9%), the payback period is decreased further. These numbers are dependent on the tonnage of gold refined annually.

### **Variable Operating Costs**

The average reagent consumptions using the SX refining route are presented in Table 7. Reagent use in the two batch operations is close to the stoichiometric requirement. The major requirement is hydrochloric acid make-up from that lost to the circuit through the raffinate bleed stream.

*Table 7. Reagent consumption.*

Reagent	Consumption (kg / kg Au)
Chlorine	0.76
Hydrochloric acid	3.05
Solvent	0.001
Sulphur dioxide	0.65
Sodium hydroxide (off-gas neutralisation)	0.2

### **Gold Lock up**

As part of the refinery is operated on a batch basis, the lock-up time of the gold in the circuit depends largely on how the plant is operated. A small permanent inventory of gold is maintained in the SX circuit due to the continuous nature of its operation. This is typically between 40 to 50 kg gold. Pulsed columns to replace the mixer-settler plant will be tested in the near future. This will further reduce gold lock up if implemented.

### **FUTURE REFINERY EXPANSION**

As most of the unit operations are batch processes, expansion of the refining capacity is merely a case of adding extra modules to the plant. A further two leach reactors and two additional precipitation vessels are planned for the refinery. The SX plant from the old refinery may be refurbished to operate in parallel with the existing SX circuit. Once complete, the refinery will be capable of producing up to 1200 kg of gold powder per day if continuous operation is employed.

In addition to the ten-tola bars (116.64 g), kilogram bars, good delivery bars (12.5 kg), gold granules, and gold powder, The Minataur™ Process is also capable of producing gold of 'five nines' purity (99.999%) by introducing a greater degree of selectivity to the reduction process (1-3). As demand for this higher purity gold is appears to be on the increase, Harmony is considering the possibility of introducing this product line in addition to the 'four nines' product.

### **CONCLUSIONS**

The SX-based Minataur™ Process has been established as a commercially viable alternative to conventional gold-refining technologies. This process has made substantial savings for Harmony Gold Mine and allowed the company to establish its own branding on many of its products.

### **ACKNOWLEDGEMENTS**

The new Harmony Refinery was designed, constructed, and installed by Mintek under the site management of Allan Menton. This paper is published with the permission of Mintek and Harmony Gold Mining Company.

## BEHAVIOUR OF Os(IV) AQUACHLORO AND AQUACHLOROHYDROXO COMPLEXES IN SOLVENT EXTRACTION FROM SULPHURIC ACID MEDIA

A. Mayboroda, H. Lang\*, I. D. Troshkina, and A. M. Chekmarev

D. Mendeleyev University of Chemical Technology, Moscow, Russia

\*Technische Universität Chemnitz, Chemnitz, Germany

The effect of chloride concentration on the composition of products resulting from osmium tetroxide reduction in sulphuric acid medium is described. The separation of the mixture of Os(IV) aquachloro and aquachlorohydroxo complexes was carried out by ion exchange chromatography. Three cationic complexes (cis- and trans-isomer of  $\{[\text{OsCl}_2(\text{OH})(\text{H}_2\text{O})_2]_2(\mu-\text{OH})\}^+$  as well as fac- $\{[\text{OsCl}_3(\text{OH})(\text{H}_2\text{O})_2](\mu-\text{OH})\}^-$ ) and one anionic species ( $[\text{OsCl}_5(\text{H}_2\text{O})]^-$ ) are shown to be present in solution at low chloride concentration. The increase of chloride concentration leads to an increase of the number of different osmium-containing species in solution. The behaviour of seven isolated Os(IV) complexes in solvent extraction with tri-n-octylamine (TOA) and tri-n-butyl phosphate (TBP) is also studied.

### INTRODUCTION

The promising sources for osmium recovery at nickel- and copper-producing plants are sulphuric acid solutions, which are used for wet cleaning (scrubbing) of gases from pyrometallurgical processes. During the smelting of the Ni or Cu concentrate and the blowing the matte, osmium is oxidised to its tetroxide and sublimes into gaseous phase [1]. The gases formed in the corresponding pyrometallurgicac processes pass dry and wet cleaning. In the wet cleaning step, the gases are generally scrubbed with dilute sulphuric acid. During the scrubbing,  $\text{OsO}_4$  is absorbed and reduced to a number of coordination species. The general osmium content in the scrub solutions of some plants is comparable with the osmium content in anode slims. The sulphuric acid solutions from scrubbers contain dissolved sulphur dioxide, chloride and fluoride ions, arsenic(III) oxide, ions of iron and non-ferrous metals. The presence of chloride in such solutions results in the formation of Os(IV) aquachloro and aquachlorohydroxo complexes, whose extraction chemistry is up to now only a less studied [2]. So far, only complex  $[\text{OsCl}_5(\text{H}_2\text{O})]^-$  could recently be isolated by solvent extraction with TBP [2]. Solvent extraction is used for recovery of rhenium from scrub sulphuric acid [3]. Data on solvent extraction of partly hydrolysed Os(IV) chloro complexes could be useful for explanation of the behaviour of osmium in the process of rhenium extraction from sulphuric acid scrub solutions.

## EXPERIMENTAL

Glass column having inner diameter of 35 mm was filled with diethylaminoethyl cellulose (DEAE 23 SS, Serva, Germany) as gel and used for ion exchange chromatography. The height of the ion exchanger layer was 500 mm. The sulphuric acid of  $1 \text{ mol} \cdot \text{L}^{-1}$  concentration was applied as eluent with flow rate of  $10 \text{ mL} \cdot \text{h}^{-1}$ .

UV-Vis spectra of the Os(IV) complexes were recorded on a Perkin Elmer Lambda 40 spectrophotometer in water solutions of sulphuric acid and in organic solutions (decane) in presence of TOA or TBP.

Electrodialysis of osmium-containing sulphuric acid solutions was carried out using a five chamber laboratory set (Figure 1) supplied with strong basic anion exchange AMX membranes and strong acidic cation exchange CMX membranes (Berghof, Germany). The volume of each chamber was 200 mL. Initial osmium-containing solutions were placed into the middle chamber *M*. Cathode chambers *K<sub>1</sub>*, *K<sub>2</sub>* and anode chamber *A<sub>1</sub>* was filled with 0.3 M  $\text{H}_2\text{SO}_4$ . Anode chamber *A<sub>2</sub>* was filled with 0.3 M  $\text{Na}_2\text{SO}_3$ . The time of an electrodialysis was 48 h at voltage of 12 V and current strength of 0.3 A.

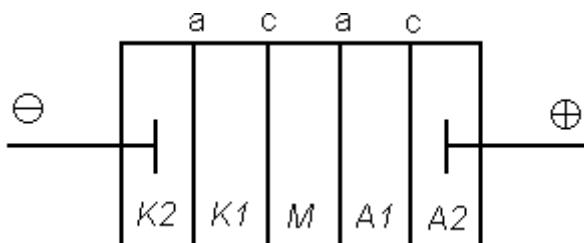

Figure 1. Schematic view of electrodialysis set.

*a* – anion exchange membranes; *c* – cation exchange membranes; *M* – middle chamber for initial solution; *K<sub>1</sub>*, *K<sub>2</sub>* – cathode chambers; *A<sub>1</sub>*, *A<sub>2</sub>* – anode chambers.

Experiments on solvent extraction of Os(IV) complexes were carried out at 20 °C. Tri-n-octyl amine and tri-n-butyl phosphate were supplied by Merck, Germany. n-Decane was used as diluent. To prevent the third phase formation, 10 % (vol.) of octanol-1 was added as modifier in a decane solution of tri-n-octylamine.

## RESULTS AND DISCUSSION

The key factors which determine composition of osmium complexes in industrial sulphuric acid scrub solutions are the concentrations of sulphur dioxide and chloride in such media. In the absence of chloride ions in the solution, the sulphur dioxide reacts with osmium tetroxide as reduction agent as well as the ligand. Sulphito complexes of Os(VI)  $[\text{OsO}_2(\text{SO}_3)_{4-x}(\text{HSO}_3)_x]^{2-}$  and  $[\text{OsO}_2(\text{SO}_3)_2(\text{H}_2\text{O})_2]^{2-}$  are formed in this instance [4]. However, such situation is never realised in industrial solutions, which always contain at least  $0.04 - 0.10 \text{ mol} \cdot \text{L}^{-1}$  of chloride. In the presence of chloride, sulphur dioxide acts as a reduction agent, and the reduction of  $\text{OsO}_4$  leads to Os(IV) complexes featuring chloride, hydroxide and aqua ligands.

Water solutions containing  $3 \text{ mol} \cdot \text{L}^{-1}$  of  $\text{H}_2\text{SO}_4$ ,  $0.04 \text{ mol} \cdot \text{L}^{-1}$  of  $\text{NaCl}$  and  $0.01 \text{ mol} \cdot \text{L}^{-1}$  of  $\text{Na}_2\text{SO}_3$  were used in preliminary experiments as a model of scrub sulphuric acid. Osmium tetroxide ( $2.3 \times 10^{-5} \text{ mol}$ ) was added to such solutions (100 mL) at 95 °C. The reaction mixture was heated for 20 min and afterwards cooled to 20 °C. For this mixture, a sharp absorption maximum was observed in the UV-Vis spectrum at 362 nm ( $\epsilon = 7.0 \times 10^3 \text{ L} \cdot \text{mol}^{-1} \cdot \text{cm}^{-1}$ ) (Figure 2a). The characteristic absorption for Os(VI) sulphito complexes in the area of 700 -

1000 nm [4] was not found in the UV-Vis spectrum. The obtained reaction mixture (*vide supra*) was contacted with 10 mL of a 0.1 M solution of TOA in decane in order to extract osmium. The extraction was relative low (12 %), but the osmium concentration in the organic extract allowed to record the UV-Vis spectrum of the extracted material. The absorption maximum observed at 349 nm (Figure 2c) indicates the presence of the anionic complex  $[\text{OsCl}_5(\text{H}_2\text{O})]^-$  in the organic phase. After extraction, the UV-Vis spectrum of the water phase (Figure 2 b) remained without variation in the position or intensity of the respective absorption band at 362 nm, which can be attributed to the Os(IV) aquachlorohydroxo complexes  $\text{cis}-[\{\text{OsCl}_2(\text{OH})(\text{H}_2\text{O})_2\}_2(\mu-\text{OH})]^+$  [5].

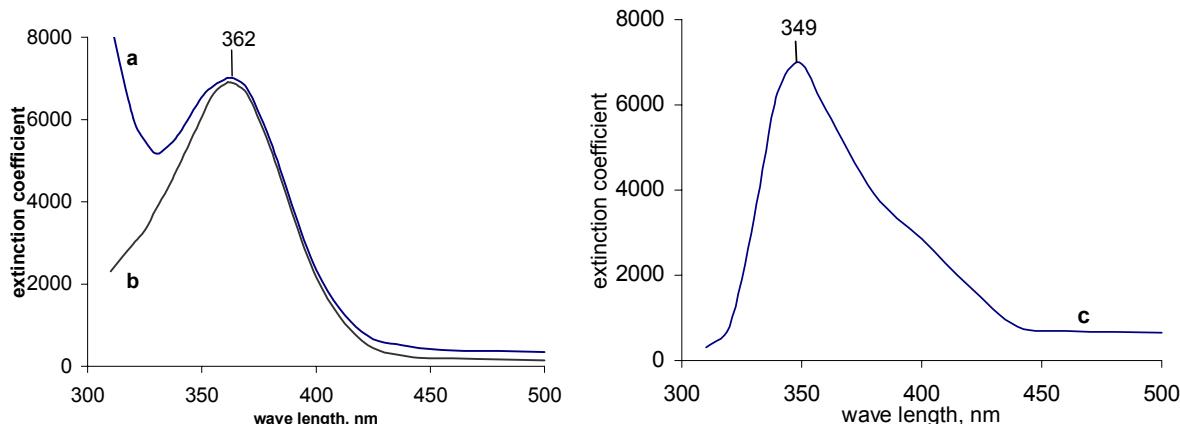

Figure 2. The electronic absorption spectra of initial osmium-containing model solution (a), raffinate after extraction with TOA (b), and organic extract (c).

The chloro complexes of Os(IV), e.g.,  $\text{cis}-[\{\text{OsCl}_2(\text{OH})(\text{H}_2\text{O})_2\}_2(\mu-\text{OH})]^+$  (1),  $\text{trans}-[\{\text{OsCl}_2(\text{OH})(\text{H}_2\text{O})_2\}_2(\mu-\text{OH})]^+$  (2),  $\text{fac}-[\{\text{OsCl}_3(\text{OH})(\text{H}_2\text{O})\}_2(\mu-\text{OH})]^-$  (3),  $\text{fac}-[\text{OsCl}_3(\text{OH})_2(\text{H}_2\text{O})]^-$  (4),  $\text{fac}-[\{\text{OsCl}_3(\text{OH})(\text{H}_2\text{O})\}_2(\mu-\text{O})]^{2-}$  (5),  $[\text{OsCl}_5(\text{H}_2\text{O})]^-$  (6) and  $[\text{OsCl}_6]^{2-}$  (7) were synthesized as described above by reduction of  $\text{OsO}_4$  in 3.0 M  $\text{H}_2\text{SO}_4$  in presence of 1.0 M  $\text{Na}_2\text{SO}_3$  and 0.5 or 1.0 M NaCl, respectively. To separate the diverse products from the reaction mixture, ion exchange gel chromatography was applied. The obtained chromatograms are shown in Figure 3. Seven different chloro complexes are found to be present in the reaction solution with concentration of NaCl being 1.0 mol $\times$ L $^{-1}$  (Figure 3a). The UV-Vis spectra of the appropriate fractions from the chromatographic separation were compared with literature data [5]. This allowed us to identify the structures of the formed osmium chloro complexes. The reaction solution obtained from the reduction of  $\text{OsO}_4$  with NaCl concentration of 0.5 mol $\times$ L $^{-1}$  shows four osmium chloro complexes, which could be separated by chromatographic technique (Figure 3b). The bulk of osmium is present as the *cis*- (1) or *trans*- (2) isomer of cationic  $[\{\text{OsCl}_2(\text{OH})(\text{H}_2\text{O})_2\}_2(\mu-\text{OH})]^+$ . However, the content of anionic species, e.g.,  $\text{fac}-[\{\text{OsCl}_3(\text{OH})(\text{H}_2\text{O})\}_2(\mu-\text{OH})]^-$  (3) and  $[\text{OsCl}_5(\text{H}_2\text{O})]^-$  (6) is significant lower than the cationic ones.

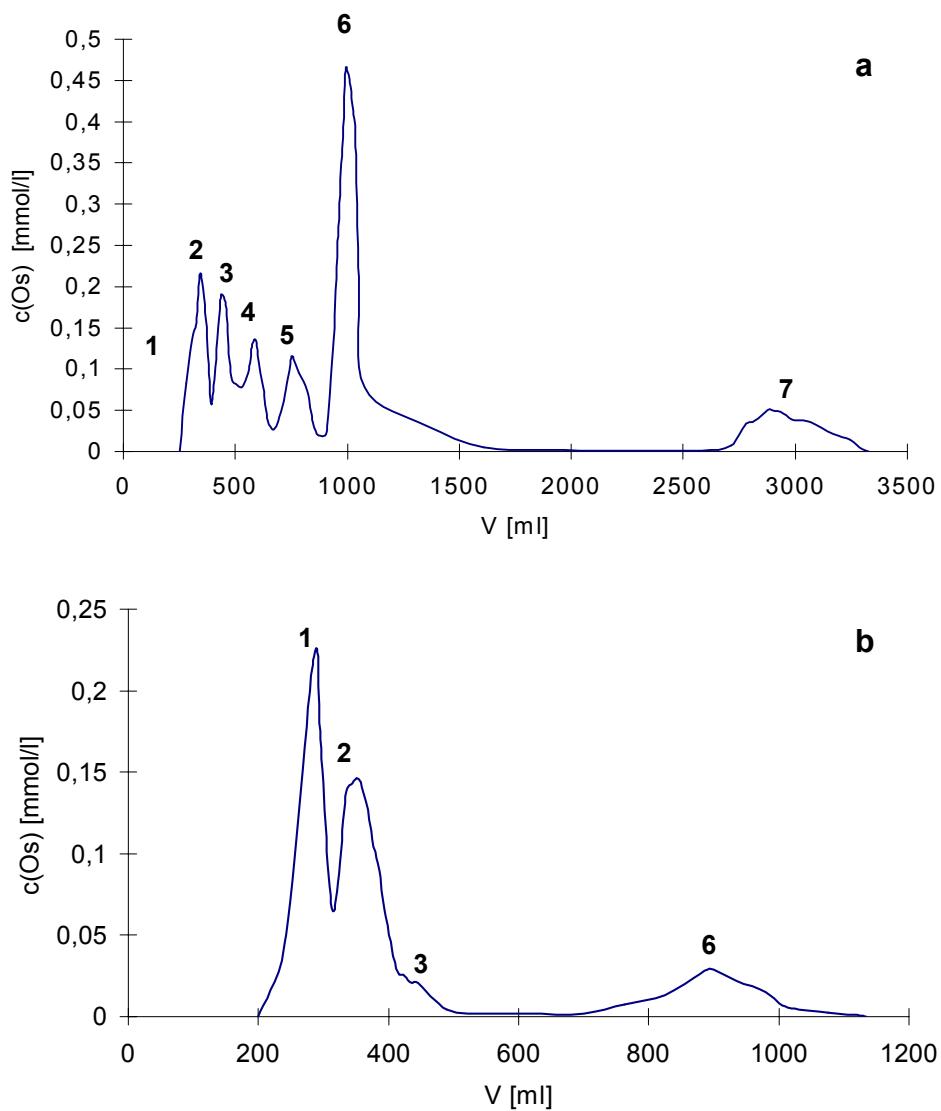

The charges of the corresponding Os(IV) aquachlorohydroxo complexes 1 – 5 were determined by Müller *et al.* on the base of the behaviour of these species in ion exchange chromatography processes [5]. To confirm this data, a separation of the respective complexes 1 – 6 using electrodialysis technique was carried out. The same osmium-containing solutions, which were applied for ion exchange chromatography (3.0 M  $\text{H}_2\text{SO}_4$ , 1.0 M  $\text{Na}_2\text{SO}_3$ , 0.5 or 1.0 M NaCl) were diluted 10 times with distilled water and treated by electrodialysis in a five chamber set (Figure 1). The dilution of the appropriate mixtures was necessary, since a transfer of osmium complexes through ion exchange membranes was completely inhibited in 3.0 M  $\text{H}_2\text{SO}_4$ . Such dilution seems to be admissible seeing that the UV-Vis spectra of the diluted solutions remain invariable at least for a weak. This indicates that a hydrolysis of the corresponding Os(VI) complexes does not take place in the diluted

solution and their structures remain without variation. The initial solution was placed in the chamber *M* of the electrodialysis set (*vide supra*). After 48 h of electrodialysis, only traces of osmium were found in this chamber. The solutions from chambers *K1* and *A1* were characterized by using UV-Vis spectroscopic methods. Spectroscopic data (Table 1) indicate that complexes **1** ( $\lambda_{\max} = 363$  nm) and **2** ( $\lambda_{\max} = 371$  nm) are indeed cationic; electrodialysis as well as ion exchange chromatography indicate the absence of neutral osmium complexes.

*Table 1. Absorption maxima of osmium-containing solutions from electrodialysis.*

[Cl] <sup>a)</sup> , mol·L <sup>-1</sup>	$\lambda_{\max}$ , nm		
	Initial solution	chamber <i>K1</i>	Chamber <i>A1</i>
0.5	360	364	355
1.0	376	371	380

<sup>a)</sup> Chloride concentration in solution, which was used as medium for  $\text{OsO}_4$  reduction.

*Figure 3. Ion exchange chromatograms of products obtained by the  $\text{OsO}_4$  reduction in  $\text{H}_2\text{SO}_4$  solutions in presence of 1.0 M NaCl (a) or 0.5 M NaCl, respectively.*

The chromatographic fractions with maximal concentration of isolated complexes were used for the preparation of initial aqueous solutions for solvent extraction. Concentrations of H<sub>2</sub>SO<sub>4</sub> and NaCl in initial aqueous phase were adjusted using 5 M H<sub>2</sub>SO<sub>4</sub> and 3 M NaCl. The corresponding chloro complexes of Os(IV) **1 – 6** were extracted from sulphuric acid media with a 0.1 M TOA solution in decane or a TBP solution (50 % vol.) in decane. The data on the extraction conditions and on the distribution coefficients (D<sub>Os</sub>) are summarised in Table 2. Within this Table, the complexes are arranged in order of egress of the corresponding fractions from the chromatographic column. Complexes **1** and **2** could not be extracted with both extractant due to their positive charge.

It was found that the chloride concentration effects the extraction of complex **3**. The presence of extracted HCl in the organic phase is a condition of coextraction of complex **3**. In contrast, increasing the chloride concentration inhibits the extraction of complex **6** with TBP as well as with TOA. Anionic complexes **4** and **5** are not extracted with TBP but can be extracted with TOA.

## CONCLUSIONS

The reduction of OsO<sub>4</sub> in sulphuric acid solutions in the presence of chloride ions lead to the formation of cationic as well as anionic aquachlorohydroxo complexes of Os(IV). It appeared that the respective cationic complexes prevail in solution, having low concentration of chloride ions. The distribution coefficient of the corresponding osmium complexes **3 – 7** could be determined by solvent extraction with TOA or TBP.

## ACKNOWLEDGEMENT

This work was partly supported by the Deutschen Akademischen Austauschdienst (DAAD; A. M.) and the Deutschen Forschungsgemeinschaft (DFG). We also would like to express our appreciation to Degussa-Hülls AG for the very generous gift of OsO<sub>4</sub>.

## SOLVENT EXTRACTION AND HYDROCHEMICAL PREPARATION OF GOLD POWDERS WITH DITHIZONE DERIVATIVES

María Guadalupe Sánchez-Loredo and Manfred Grote\*

Universidad Autónoma de San Luis Potosí, San Luis Potosí, México

\*University of Paderborn, Paderborn, Germany

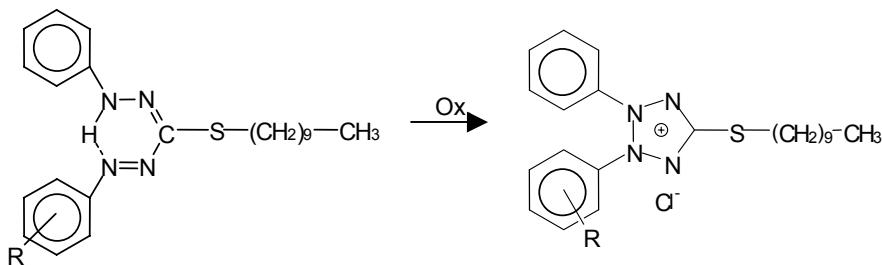

Solvent extraction of gold by S-decyldithizone **D-H** and its carboxylic acid derivatives was studied as a function of equilibration time, organic phase diluent, metal and hydrochloric acid concentrations. During the loading stage the chelating extractants were oxidized to the corresponding 2H-tetrazolium salts. Only from S-decyldithizone phases the loaded gold can be sufficiently re-extracted by thiourea. Both the non-acidic **D-H** and the ortho-carboxyl substituted extractant **D-oC** could be simultaneously stripped and fully regenerated by aqueous solutions of ascorbic acid or sodium borohydride. Gold was recovered as fine particles, which were characterised by means of scanning electron microscopy. The powder morphology was directly affected by the composition of the organic phases and the aqueous reducing media applied.

### INTRODUCTION

Solvent extraction has become an attractive alternative to traditional refining methods for the selective recovery of gold and other noble metals. Gold is normally removed from solution using solvating reagents [1]. Particularly reagents with incorporated sulphur have received much attention in the extraction of gold from chloride media [2,3]. According to Demopoulos, the metal could be recovered directly from the organic solvent by a precipitation method called hydrolytic stripping [4]. Also cementation or reduction with sulphur dioxide or hydrogen were applied [4]. Ultra-fine gold particles were obtained by utilising a water/oil micro-emulsion [5,6].

The present study on the behaviour of gold towards S-decyl derivatives of dithizone is based on results of earlier investigations: It was found that S-decyldithizone (**D-H**) and its ortho-, meta- and para-monocarboxyl substituted derivatives (**D-oC**, **D-mC** and **D-pC**, Figure 1) dissolved in organic solvents became progressively oxidised by mixtures of precious and base metal salt solutions when Au(III) was also present [7,8]. The molecular structure of the S-decyldithizone reagents represents the electrochemically reversible redox system of formazans (reduced form) and tetrazolium salts (oxidised form) [9]. It is to assume that the oxidation of the extractants by interactions with Au(III) could be reversed by reducing stripping agents.

Consequently in the present work the main characteristics of affinity of these dithizone derivatives towards Au(III) in acidic chloride medium were investigated. Stripping of gold by means of complexing and reducing agents was also studied.

## EXPERIMENTAL

### Reagents

The synthesis of the extractants is described elsewhere [7,8,10]. All chemicals used were of reagent grade quality. Gold feed solutions were prepared dissolving the required amount of the sodium salt of the tetrachloro complex (Degussa AG) in the selected acid medium. All aqueous phases used for extraction experiments were presaturated with the organic diluent *p*-xylene or chloroform. The standard solutions of Au(III) were prepared from commercial stock solution (Spex Industries Inc.).

### Extraction

Solvent extraction experiments were carried out at 20°C in 60 cm<sup>3</sup> separatory funnels shaken mechanically using a Bühler Co. shaker at a fixed frequency of 140 min<sup>-1</sup>. 10 cm<sup>3</sup> of the organic phase containing the extracting agent in the diluent were shaken with an equal volume of the aqueous phase containing the metal ion in 0.1, 1 or 3.5 mol/dm<sup>3</sup> HCl solutions. The metal ion and extractant concentrations were 0.1 mmol/dm<sup>3</sup> and 1 mmol/dm<sup>3</sup>, respectively. After a certain time of shaking (20 min, 1 h, 2 h, 4 h and 24 h), the two phases were allowed to separate and, if necessary, centrifuged. The metal concentrations of the aqueous phases were determined by DC-plasma emission spectrometry (Spectraspan 7, Thermo Jarrell Ash), and the organic phase metal content was calculated by mass balance.

### Stripping

In order to carry out the stripping experiments, metal loading was performed by shaking 50 cm<sup>3</sup> of gold salt solution (0.1 mmol/dm<sup>3</sup> in 0.1 mol/dm<sup>3</sup> HCl) with an equal volume of reagent solution (1 mmol/dm<sup>3</sup> in *p*-xylene) for 24 h. The metal loaded organic phase was separated and washed with 50 cm<sup>3</sup> of 0.1 mol/dm<sup>3</sup> HCl (15 min shaking). 10 cm<sup>3</sup> of the organic phase were transferred into a separatory funnel and contacted with an equal volume of 2 mol/dm<sup>3</sup> HClO<sub>4</sub>, 0.5 mol/dm<sup>3</sup> NaSCN or thiourea (Tu) solution (5% Tu (w/v) in 0.1 mol/dm<sup>3</sup> HCl).

Reductive stripping experiments were performed, firstly, by contacting 200 cm<sup>3</sup> of the organic phase (1 mmol/dm<sup>3</sup> of **D-H** and **D-oC** in *p*-xylene) with 100 cm<sup>3</sup> of the gold feed solution (5 mmol/dm<sup>3</sup> Au(III) in 0.1 mol/dm<sup>3</sup> HCl). In order to monitor the oxidation of the extracting reagents (spectrophotometrically, using a Lambda 13 Perkin Elmer Instrument), and the extraction process (by plasma emission spectrometry), 1 cm<sup>3</sup> aliquots of both phases were collected in intervals during the 24 h loading stage. A first fraction of elementary gold was formed during this stage. Therefore, prior to the subsequent reducing stripping procedure the phases were filtrated and allowed to separate.

The gold powders were filtered, washed with 500 cm<sup>3</sup> of acetone, 500 cm<sup>3</sup> of distilled water and weighed after drying. The residual gold was recovered from the loaded organic phase using one of the following reducing agents: oxalic acid (50 mmol/dm<sup>3</sup> in water), ascorbic acid (4, 50 and 100 mmol/dm<sup>3</sup> in water), or sodium borohydride (50 mmol/dm<sup>3</sup> in water, 0.1 mol/dm<sup>3</sup> HCl, 1 mol/dm<sup>3</sup> NaCl or 2.5 g/dm<sup>3</sup> NaOH). By 24 h shaking of 50 cm<sup>3</sup> of these solutions together with a 50 cm<sup>3</sup>-aliquot of gold-loaded organic phase in a separatory funnel elementary gold precipitated, which was isolated and finally treated as described above.

The morphology, size and purity of the gold powders obtained were determined by scanning electron microscopy (SEM) using an XL-30 microscope (Philips, Netherlands), and a DX-4I (EDAX) EDS analysis (energy-dispersive X-ray spectrometry).

## RESULTS AND DISCUSSION

### Solvent Extraction Experiments

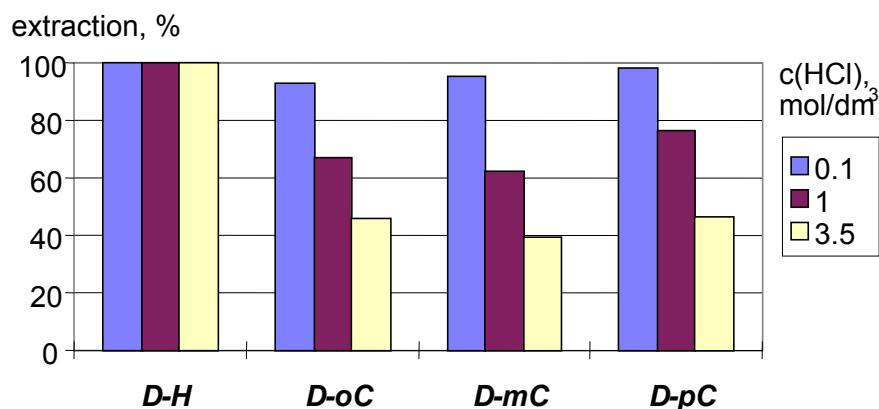

Dissolved in *p*-xylene or chloroform, the originally deep red coloured, chelating S-decyldithizone compounds are oxidised by aqueous Au(III) solutions to the corresponding yellow tetrazolium salts, ion-pairing cationic heterocycles [8,10]. It seems that the extraction reaction involves some kind of metal reduction to the Au(I) oxidation state, and depending on the metal concentration, to elementary gold. The change from the dithizone to the tetrazolium salt was monitored by the *UV-Vis* spectrum of the organic phase (in *p*-xylene). On prolonged extraction time the intensities of the absorbances at 543 and 422 nm (**D-oC**) as well as 550 and 415 nm (**D-H**) diminishes while a concomitant rise at 324 (**D-oC**) and 321 nm (**D-H**) appears. In case of the extractant **D-oC**, the oxidation product formed was identified as S-decyl-[2-(2'-carboxyphenyl)-3-phenyl-2H-tetrazolium-5-thiolate], which was isolated and its structure confirmed spectroscopically [10]. Simultaneously formation of gold particles occurred at higher concentrations of Au(III) (>0.5 mmol/dm<sup>3</sup>). Most of the metallic powder was concentrated at the aqueous/organic interface. The precipitates obtained in both extractant systems consisted of dense, irregularly shaped particles, with significant differences in the shape and size [11]. It was found by SEM analysis that extracting gold with the reagent **D-H** leads to gold particles of around 20-40 µm in size, partly agglomerated. A change to the extractant **D-oC** resulted in finer particles (<10 µm) and agglomerates also. The precipitates were irregular containing platelet particles grown by coalescence. Some particles were pyramidal, a common morphology for this metal.

In order to avoid precipitation of the elementary metal the following extraction studies described were carried out by using a feed solution containing 0.1 mmol/dm<sup>3</sup> Au(III). The effect of the diluent on gold extraction was investigated using chloroform and *p*-xylene (Table 1). The yield of metal extraction does not differ significantly, however, for all the substituted dithizonates slightly higher extraction efficiencies were obtained when the aliphatic diluent was used. By using the non-acidic **D-H** in *p*-xylene the extraction proceeds quite fast as the equilibrium was achieved in less than 20 min. In chloroform much more time is necessary (4 h). By contrast, in case of the carboxyl-substituted derivatives faster extraction was achieved by means of the aliphatic diluent. As an example, for the extractant **D-oC** the extraction equilibrium was achieved in 4 h using CHCl<sub>3</sub> as diluent, by using *p*-xylene the equilibration time had to be extended to about 24 h.

*Table 1. Influence of the diluent on gold extraction by S-decyldithizonates.  
c(HCl)=0.1 mol/dm<sup>3</sup>, shaking time: 24 h.*

Diluent	<b>D-H</b>	<b>D-oC</b>	<b>D-mC</b>	<b>D-pC</b>
<i>p</i> -xylene	≈100	93.2	95.1	98.1
Chloroform	≈100	≈100	99.2	99.2

The influence of increasing HCl concentration was also studied (Figure 2). Generally, with increasing acidity the extraction yields drops off for the acidic S-decyldithiones. On the other side, the extraction yields for Au(III) obtained with the unsubstituted derivative **D-H** is not dependent on hydrochloric acid concentration in the range of acidity investigated.

*Figure 2. Effect of hydrochloric acid concentration on extraction of Au(III). Diluent: p-xylene, shaking time: 24 h.*

### Stripping

Several reagents were tested for gold stripping. Coordinating ligands, like thiourea and thiocyanate, have been used, as well as perchloric acid, which displaces metal ions via ion exchange mechanism. However, stripping using perchloric acid solutions did not appear feasible as the extent of gold re-extraction was not higher than 1 %. Table 2 shows recovery data determined by using aqueous solutions of thiourea and thiocyanate. A sufficient recovery of gold from the loaded organic **D-H** phase was possible by applying a 5 % (w/v) thiourea solution in 0.1 mol/dm<sup>3</sup> HCl.

*Table 2. Recovery of gold using 5 % (w/v) thiourea-solution in 0.1 mol/dm<sup>3</sup> HCl and 0.5 mol/dm<sup>3</sup> NaSCN. Shaking time: 24 h.*

	<b>D-H</b>	<b>D-oC</b>	<b>D-mC</b>	<b>D-pC</b>
Thiourea	89.2	78.9	14.1	9.2
NaSCN	11.1	17.5	8.6	8.6

From the results obtained during the extraction and stripping experiments the superior effectiveness of **D-H** as extractant for gold is obvious.

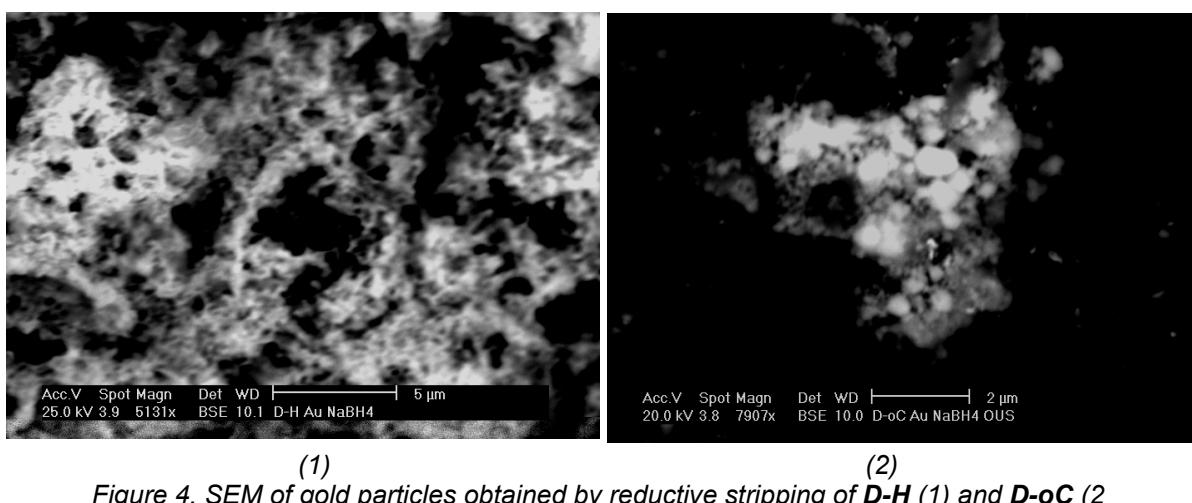

### Reductive Stripping

In order to perform the reductive stripping experiments, the extractant phases containing the S-decyldithiones **D-H** and **D-oC** in *p*-xylene were loaded with Au(III) for 24 h. As soon as the loaded organic extractants, being oxidised to tetrazolium salts, were contacted with aqueous reducing reagents a dramatic reaction occurred, indicated by a colour change of the yellow organic phase to deep red: the chelating molecules were reductively rebuilt and the precious metal extracted could be recovered as a black powder of elementary gold. When an oxalic acid solution was added, a part of the gold precipitated instantly as a very finely divided powder that is hard to handle, mostly plated on the internal walls of the funnel. UV/Vis-spectrophotometry revealed that regeneration was not complete even after 7 days shaking.

However, better results were obtained by using ascorbic acid as reducing agent. For example, 24 h were enough to reach an almost complete regeneration of the extractant **D-H** using 50 mmol/dm<sup>3</sup> of ascorbic acid dissolved in water. No residual amount of metal in the organic phase could be detected after chemical attack and analysis. The precipitates obtained were examined by SEM to determine their morphology and particle size and also data for determining the purity of the gold particles. Figure 3 shows SEM photographs of powders prepared by the ascorbic acid treatment of a loaded **D-oC** phase as mentioned above. A few particles are pyramidal, but most of them are spherical. The images obtained reveal aggregates consisting of nano-size subunits. The diameter of these subunits depends on the extractant applied. The values varied in the range of 220 to 280 nm (**D-H**) and 100 to 190 nm (**D-oC**).

Sodium borohydride has been widely used to reduce a variety of metal cations to the metallic state. In this work, optimum results were achieved by using NaBH<sub>4</sub> in alkaline solution. Particularly in the case of the non-acidic **D-H** precipitation of gold and regeneration of the organic extractant was extremely fast. Less than ten minutes were required for complete regeneration and quantitative metal recovery, compared to about eight hours when the carboxyl-substituted **D-oC** was used. In both cases the recovery of the metal was acceptable and no plating effects on the walls were observed. Figure 4 shows SEM-photographs of the gold particles, which revealed the powders to consist mostly of amorphous particles with some variation in size, composed from spherical subunits, which coalesced irreversibly and formed larger granules.

In general, the precipitation products were larger and showed broader size distribution. The size ranges of **D-H** and **D-oC** systems were 240 to 425 nm and 136 to 205 nm respectively, showing the strong influence of the acidic carboxyl group of the organic molecule on nucleation and growth and thus morphology and size of the gold particles.

## CONCLUSIONS

The extraction of gold by means of S-decyldithizone derivatives was studied. The extraction properties are significantly affected by substitution on one of the aromatic rings, and particularly the non acidic extractant **D-H** showed superior extraction and stripping properties. Ascorbic acid and sodium borohydride were used to prepare gold powders by reductive stripping. Almost quantitative gold recovery and good extractant regeneration was feasible. Particularly the use of the ortho-substituted **D-oC** as extractant, and ascorbic acid as reducing agent, allows to obtain nano-crystalline gold powders.

## ACKNOWLEDGEMENTS

## THE APPLICATION OF SOLVENT EXTRACTION TO THE REFINING OF GOLD

Richard A. Grant and Valerie A. Drake

Johnson Matthey Technology Centre, Reading, United Kingdom

Gold is treasured for its colour, ductility and resistance to corrosion and appears to have been the first metal known and used by Mankind. Its uses in medicine, dentistry and decoration date back to the Ancient Egyptians and Chinese. Today, its principle uses are in investment, coinage, jewellery, electronics, dentistry and decorative coatings. This paper discusses the application of solvent extraction to the production of high-purity gold which has potential advantages over conventional refining techniques. A wide range of reagents have been reported in the literature for the extraction of gold but these have limitations particularly with selectivity and ease of stripping. We have identified the simple commercial alcohol, 2-ethylhexanol, as offering significant advantages including high selectivity over other metal impurities, the ability to be stripped with water at ambient temperatures, high capacity and low cost. The development of a continuous solvent extraction process is described and initial pilot plant results are presented.

### INTRODUCTION

Johnson Matthey is the world's largest refiner of gold and is also a major refiner of the Platinum Group Metals (PGM) and silver. The group is also the world's largest manufacturer of high purity small gold bar products for investment and jewellery manufacture. The Company both refines gold from mining operations around the world and recycles secondary (scrap) material. To serve this worldwide business, Johnson Matthey has refining operations located in the UK; Salt Lake City, USA; Toronto, Canada; Melbourne, Australia and Hong Kong.

Johnson Matthey Chemical Division's UK Refinery at Brimsdown in North London recovers Precious Metals (PM) from a wide variety of inputs and produces separate semi-refined concentrates containing gold, silver and the PGM. These are then transferred to a second Refinery at Royston near Cambridge for purification and subsequent conversion into either metallurgical or chemical products. The main gold concentrate comes from the Brimsdown Silver Process and has a typical composition of 89% Au, 9% Ag, 1% PGM and <1% Cu and BM. Other potential feeds are Dore bullion from mining operations (85% Au and 15% Ag), Carat Gold mostly from jewellery scrap (62% Au, 9% Ag, 1% PGM and 28% Cu) and "Good Delivery" gold bars for upgrading (>99.5% Au and <0.5% Ag).

The refining of gold traditionally relies on two processes which both date back to the 19<sup>th</sup> Century. The purification of molten gold by passing chlorine through it was first reported by Thompson [1] in 1838. A process based on this principle was patented by Miller in 1867 and put into commercial practice at the Sydney Mint [2]. As is often the case this technique is therefore known as the Miller Process. It exploits the fact that at around 1100°C gold chloride is not stable unlike most base metal (BM) chlorides. Some such as copper, iron, lead and

selenium are gaseous at this temperature and therefore volatilise. Others such as silver chloride are molten and collect as a slag layer on top. The PGM chlorides are unfortunately also unstable at these temperatures. Consequently the Miller Process is restricted to the refining of materials that do not contain these metals such as the gold from the Witwatersrand deposit in South Africa. The process also does not give a complete separation and so, without further purification, is limited to the production of "Good Delivery" gold (>99.5%). Its main advantages are that it is very quick and has quite low operating costs.

The second traditional process is the Wohlwill electrolysis. This was developed in 1898 at the Norddeutsche Affinerie in Hamburg [3]. Here the impure gold is cast into anodes which are electrorefined using an HCl/H[AuCl<sub>4</sub>] electrolyte. The gold dissolves and is then deposited in pure form on the cathode. Although high purity gold (>99.95%) can be readily achieved, the Wohlwill electrolytic process is slow and relatively inefficient. As a result it has a high inventory and is expensive to operate. Its major advantage, in addition to the production of high purity gold, is that it can be used to refine gold containing limited amounts of the PGM.

The introduction of solvent extraction for the refining of gold offers potential benefits over both the Wohlwill and Miller processes, particularly in terms of improved purity, a reduction in metal inventory and flowsheet simplification.

### SOLVENT EXTRACTION CHEMISTRY OF THE PRECIOUS METALS

Gold and the other PM (e.g., Pt, Pd, etc.) are most conveniently and effectively bought into aqueous solution in hydrochloric acid under oxidising conditions. In aqueous solution gold generally has two stable oxidation states, Au(I) and Au(III). In chloride media, however, Au(I) is unstable and slowly disproportionates to Au(III) and the metal.

The PM form stable chloro-complexes and the Au(III) is present in solution as [AuCl<sub>4</sub>]<sup>-</sup>. It can therefore be readily extracted by anion-exchangers. The PGM, however, also form anionic complexes ([PdCl<sub>4</sub>]<sup>2-</sup>, [PtCl<sub>6</sub>]<sup>2-</sup>, [RhCl<sub>6</sub>]<sup>3-</sup>, etc.) as do a number of the BM (e.g., [CuCl<sub>4</sub>]<sup>2-</sup>). The solvent extraction reagent used must therefore be selective for gold.

The extraction of anionic complexes by anion-exchangers is strongly influenced by the size to charge ratio of the metal anion[4]. Thus for the PM the order of extraction is

Anion-exchange solvent extraction reagents can be divided into two classes. The first are strong-base extractants which either have a fixed cationic charge, such as quaternary ammonium salts (e.g., R<sub>3</sub>NCH<sub>3</sub><sup>+</sup>Cl<sup>-</sup>), or amines which protonate readily in contact with weak acid (e.g., R<sub>3</sub>NH<sup>+</sup>Cl<sup>-</sup>). These not only extract gold extremely strongly but also palladium and platinum, and so are non-selective. Stripping can also be a problem due to the very strong extraction.

The other class of reagents are weak-base or solvating extractants. These generally do not "protonate" but instead solvate protons enabling these to transfer into the organic phase to give cationic groups. Almost any reagent with an oxygen containing group (P=O, S=O, C=O, C-O-) is capable of acting as a solvating extractant and therefore a very wide range of strength of extraction is available. Due to the fact that the singly charged [AuCl<sub>4</sub>]<sup>-</sup> ion is so strongly extracted by anion-exchangers, gold extractants are generally selected from the very weak solvating reagents. The other Precious Metals are not extracted to any appreciable extent by these systems and so provide an excellent means of separating gold from the PM.

These very weak solvating extractants are generally those containing carbon-oxygen functional groups such as ethers, esters and alcohols. A tri-functional ether, di(ethyleneglycol)dibutyl ether ( $C_4H_9OC_2H_4OC_2H_4OC_4H_9$ , BUTEX) has been successfully commercialised by INCO at their Acton Refinery in the UK [5]. Although BUTEX has a high selectivity it has a number of significant disadvantages. Due to the low ratio (4:1) of the hydrophobic ( $CH_2$ ) groups to the hydrophilic (O) groups, BUTEX has a high aqueous solubility ( $3\text{ g l}^{-1}$ ). It also cannot easily be stripped. The purified gold is therefore recovered by direct reduction from the loaded organic in a two-phase reaction with an oxalic acid solution. Appreciable amounts of reagent are occluded in the product and solvent losses approach 4% per cycle. BUTEX is a low volume speciality chemical and therefore expensive. As a result operating costs are high.

The ketone, 4-methyl-2-pentanone (methyl iso-butyl ketone), has been used for a number of years by both Johnson Matthey and Anglo American Platinum Corporation [6] for the extraction of gold in their PGM Refineries. Although this also has a high solubility and has to be stripped by direct reduction, it is a large tonnage industrial chemical and therefore extremely cheap. It is a stronger extractant than BUTEX and therefore also usefully removes a number of BM contaminants of the PGM feed such as Fe, Sb Se, Sn and Te. A significant drawback is its low flashpoint ( $13^\circ C$ ) that necessitates stringent plant safety control.

The extraction of gold by a wide range of alcohols (e.g., *i*-pentanol [7],  $C_7 - C_9$  alcohols [7], decanol [8], butanol [9] and 4-methyl-2-pentanol [10]) has been reported in the literature. The Council for Mineral Technology (Mintek) investigated a number of alternative reagents to BUTEX [11]. They found that the alcohol, *i*-decanol, offered several advantages over BUTEX including having a higher selectivity over base metals and, as an industrial chemical, was readily available and low cost. Furthermore, because *i*-decanol is a sufficiently weak extractant, it was possible to strip the gold from the organic phase with water as at low acidity the solvation of protons by the extractant is reversed. Subsequent to the commencement of our own studies, Mintek developed the Minataur<sup>TM</sup> Process for the solvent extraction of gold [12, 13]. Very few details about the solvent extraction section of the process have been published by Mintek and the reagent used has not been disclosed.

The extraction of gold with *i*-decanol appeared very attractive. However a significant potential drawback was that efficient stripping of the gold was reported to require elevated temperatures ( $\geq 50^\circ C$ ). A number of alternative alcohols were therefore examined at the Johnson Matthey Technology Centre.

## EXPERIMENTAL

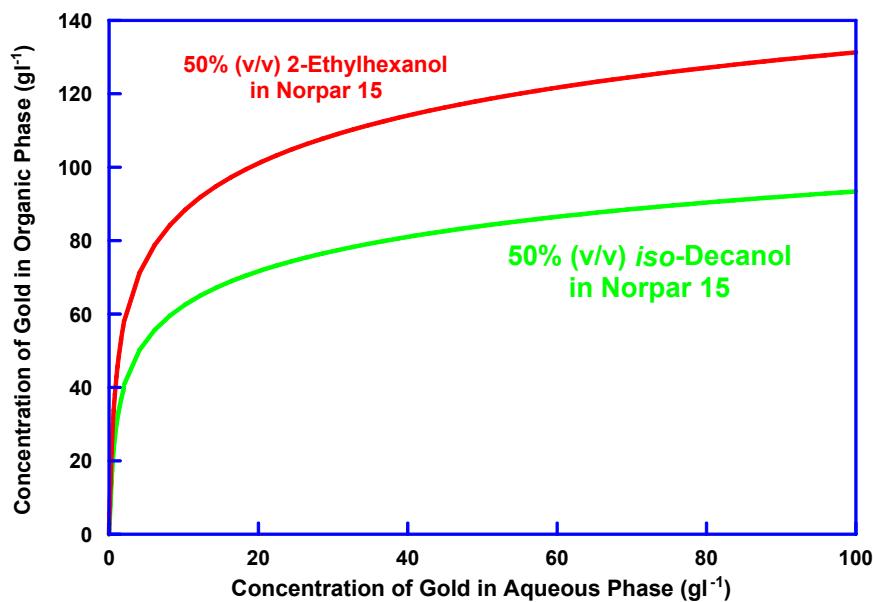

Solutions of the alcohols (50% v/v) in Norpar 15 (Exxon Chemicals) were contacted for two minutes with an equal volume of a feed containing  $120\text{ g l}^{-1}$  Au(III) in 6 M hydrochloric acid. The raffinate was separated and contacted twice more with equal volumes of fresh organic. The loaded organic from the first extraction was then stripped three times by contacting with an equal volume of water at either 23 or  $50^\circ C$ .

## DISCUSSION

The analytical results for the extraction of gold by three representative alcohols are presented in Table 1. As can be seen, 2-ethylhexanol proved to be a far stronger extractant than *i*-decanol but gave similar results to the straight chain alcohol, *n*-octanol. Distribution isotherms were then determined for the extraction of gold by 2-ethylhexanol and *i*-decanol. These confirmed that 2-ethylhexanol was a significantly stronger extractant and had a ca. 50% greater capacity than *i*-decanol (Figure 1). This is 20% higher than would be expected from the higher molar concentration of the 2-ethylhexanol solution as a result of its lower molecular weight.

*Table 1. The extraction of gold(III) from 6M hydrochloric acid by 50% (v/v) solutions of different alcohols in Norpar 15.*

Alcohol	Initial feed (mg l <sup>-1</sup> )	1 <sup>st</sup> Raffinate (mg l <sup>-1</sup> )	2 <sup>nd</sup> Raffinate (mg l <sup>-1</sup> )	3 <sup>rd</sup> Raffinate (mg l <sup>-1</sup> )
<i>i</i> -decanol	120000	48700	1350	0.2
<i>n</i> -octanol	120000	25000	500	<0.1
2-ethylhexanol	120000	25100	299	<0.1

*Figure 1. Distribution isotherms for the extraction of gold(III) at 23°C.*

The results for the stripping of gold from the loaded organic from the first extraction are presented in Table 2. These showed that at ambient temperatures 2-ethylhexanol was easier to strip than *i*-decanol, whilst *n*-octanol was difficult to strip even at elevated temperatures.

*Table 2. The stripping of gold(III) from loaded 50% solutions of different alcohols in Norpar 15 using water at different temperatures.*

Alcohol	Temperature	Loaded organic (mg l <sup>-1</sup> )	Organic After 1 <sup>st</sup> Strip (mg l <sup>-1</sup> )	Organic After 2 <sup>nd</sup> Strip (mg l <sup>-1</sup> )	Organic After 3 <sup>rd</sup> Strip (mg l <sup>-1</sup> )
<i>i</i> -decanol	23°C	70800	12700	453	16
<i>i</i> -decanol	50°C	70800	7260	72	0.4
<i>n</i> -octanol	23°C	94500	33800	9630	1360
<i>n</i> -octanol	50°C	94500	24200	2990	85
2-ethylhexanol	23°C	94400	13600	348	1.8

Although the results confirmed that stripping would be more efficient at elevated temperatures, this has a number of potential disadvantages. Heating the strip section would complicate the design of equipment, not least because it would be operating at a much closer temperature to the flash point of the diluent. Loss of diluent by evaporation and the rate of possible degradation of the organic would also be significantly increased.

McCabe-Thiele constructions were therefore carried out to determine whether a gold extraction process based on 50% (v/v) 2-ethylhexanol could be successfully operated at ambient temperatures. These showed (Figure 2) that with a phase ratio of 1:1, the extraction of gold from a typical 90  $\text{g l}^{-1}$  Au(III) feed would require three equilibrium counter-current stages to produce a raffinate containing <1  $\text{mg l}^{-1}$  Au.

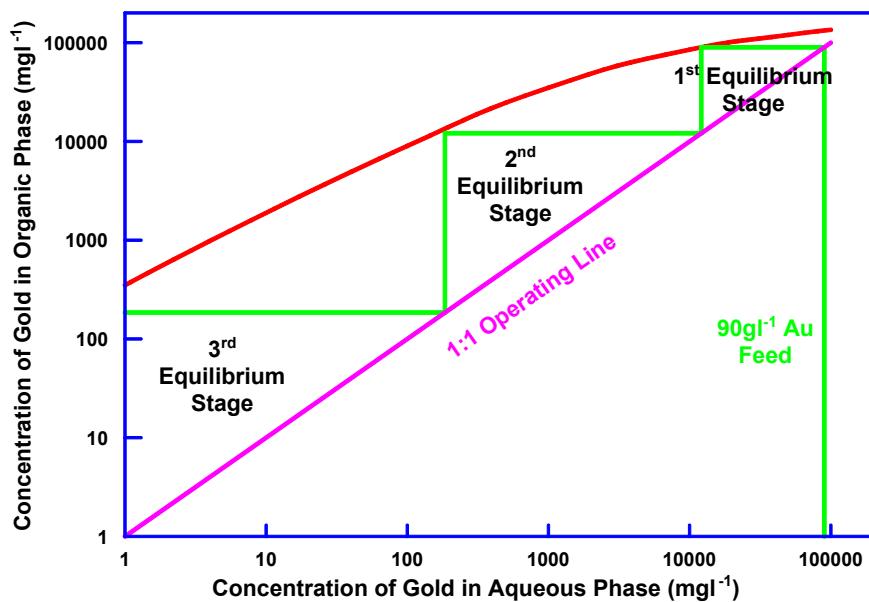

Figure 2. McCabe-Thiele construction for the extraction of gold by 50% 2-ethylhexanol.

Stripping the gold from this loaded organic to below 20  $\text{mg l}^{-1}$  Au (>99.98% strip) would require two equilibrium stages operating with a phase ratio of 1:2 (Figure 3). This level of gold recirculating in the stripped organic would not affect the number of extraction stages required.

Following further optimisation of the flowsheet, a series of pilot plant mixer-settler trials were carried out. These confirmed the promise of 2-ethylhexanol as a selective gold extractant. Typical analyses of the product streams are presented in Table 3. The level of extraction of gold achieved was >99.99%. The purity of the strip produced was >99.95%. Reduction of the gold from the strip using oxalic acid gave a further purification and produced a metal sponge of around 99.995% purity.

Table 3. Typical analyses of product streams from pilot plant trials.

	Feed ( $\text{mg l}^{-1}$ )	Raffinate ( $\text{mg l}^{-1}$ )	Strip ( $\text{mg l}^{-1}$ )
Au	150000	2.1	96000
Ag	200	95	< 2

Sb	20	10	< 2
Se	32	16	< 2
Te	125	67	< 2

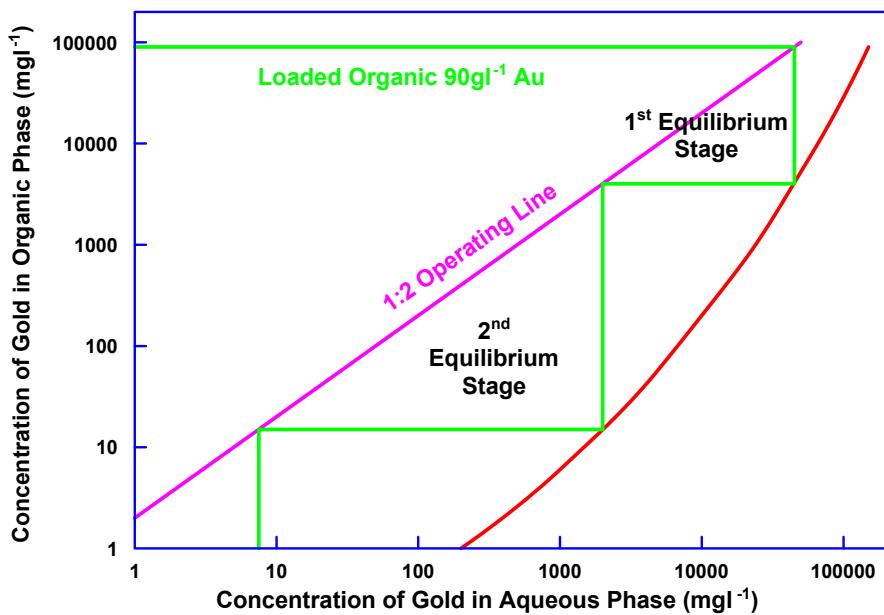

Figure 3. McCabe-Thiele construction for the stripping of gold from 50% 2-ethylhexanol.

## CONCLUSIONS

The refining of high purity gold by solvent extraction offers potential advantages over the traditional techniques such as the Miller and Wohlwill Processes. The industrial synthetic alcohol, 2-ethylhexanol, has been shown to have significant advantages over other potential gold extractants including high selectivity over other metals, the ability to be stripped with water at ambient temperatures, high capacity and low cost.

## PILOT-PLANT SOLVENT EXTRACTION OF COBALT AND NICKEL FOR AVMIN'S NKOMATI PROJECT

Angus Feather, Wendy Bouwer, Arnold Swarts\* and Vic Nagel\*\*

MINTEK, Randburg, South Africa

\*Anglovaal Mining Company Ltd., Johannesburg, South Africa

\*\*Bateman Engineering, Boksburg, South Africa

Avmin have developed a flowsheet for the refining of copper, nickel and cobalt from Nkomati concentrates. Cobalt is recovered from calcium-saturated solution using CYANEX® 272. Nickel is subsequently extracted using versatic acid. The loaded organic is stripped using spent electrolyte, producing advance electrolyte for recovery of nickel by electrowinning.

Cobalt was recovered with >99.5% extraction efficiency, reducing cobalt from 1.8 g/L to <10 mg/L. The cobalt/nickel ratio in the cobalt product solution was >1500. Nickel solvent extraction was optimised to recover 99%, reducing the nickel concentration from 32 g/L to <0.3 g/L, while minimising calcium deportment to the nickel electrowinning circuit.

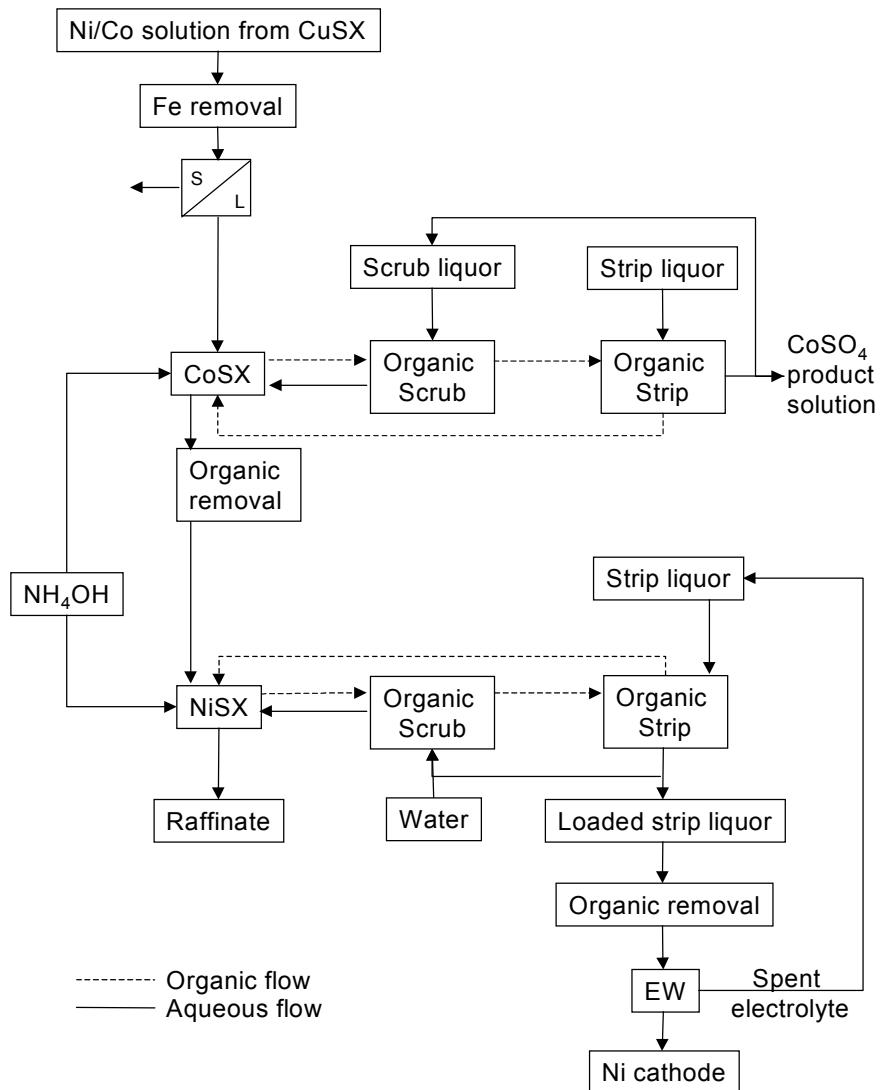

### PROCESS DESCRIPTION

In the flowsheet developed by Avmin for the Nkomati base metal refinery, copper, nickel, and cobalt from a sulphide flotation concentrate are dissolved using fine grinding, followed by pressure leaching. Copper is recovered from the leach liquor by solvent extraction (SX). A bleed stream of the copper SX raffinate is treated to remove iron by oxidation/precipitation, and then to recover cobalt and nickel in sequential SX unit operations.

After precipitation of iron from the copper SX raffinate, cobalt is recovered from solution using a phosphinic acid extractant, CYANEX® 272. The cobalt concentration in the nickel solution is reduced to enable the cobalt specification in the downstream nickel electrowinning (EW) to be met. Co-extracted nickel, calcium, and magnesium are scrubbed from the loaded organic phase using a portion of the loaded strip liquor (cobalt concentration of approximately 25 g/L). The scrubbed organic phase is stripped with dilute sulphuric acid to produce a cobalt sulphate solution. The form of the final cobalt product has yet to be decided.

Nickel is extracted from the calcium-saturated solution by SX using versatic acid. Co-extracted calcium and magnesium are scrubbed from the loaded organic phase using a portion of the nickel loaded strip liquor diluted with water to a nickel concentration of 3 g/L and a pH of 5.6. The scrubbed organic phase is stripped with spent electrolyte from the nickel EW operation.

Both SX plants were operated at ambient temperature as this was considered to be a “worst case scenario” in terms of settling characteristics, reaction kinetics, and nickel ammonium sulphate precipitation. The circuit was continuously run for 400 hours. Nickel was recovered from the advance electrolyte by standard divided-cell EW technology. Figure 1 shows the overall process flowsheet.

*Figure 1. Process flowsheet for treatment of Nkomati copper SX raffinate.*

## EQUIPMENT AND PROCEDURES

Conventional mixer-settler units, each with a mixer volume of 500 mL and settling area of 256 cm<sup>2</sup>, were operated in a countercurrent configuration. Solutions were pumped into the plant using peristaltic pumps. When required, stages were operated with internal recycle to maintain aqueous phase continuity in the mixers. Adjustment of pH in both SX circuits was achieved by the addition of 400 g/L NH<sub>4</sub>OH or 300 g/L H<sub>2</sub>SO<sub>4</sub> solution directly into the mixers. The NH<sub>4</sub>OH concentration was chosen based on Avmin's estimate of the concentration attainable from the lime boil ammonia recovery planned for the full-scale circuit. Control of pH in each stage was by the use of an ABB Commander 300 PID controller linked to a peristaltic pump and Foxboro pH meter and probe.

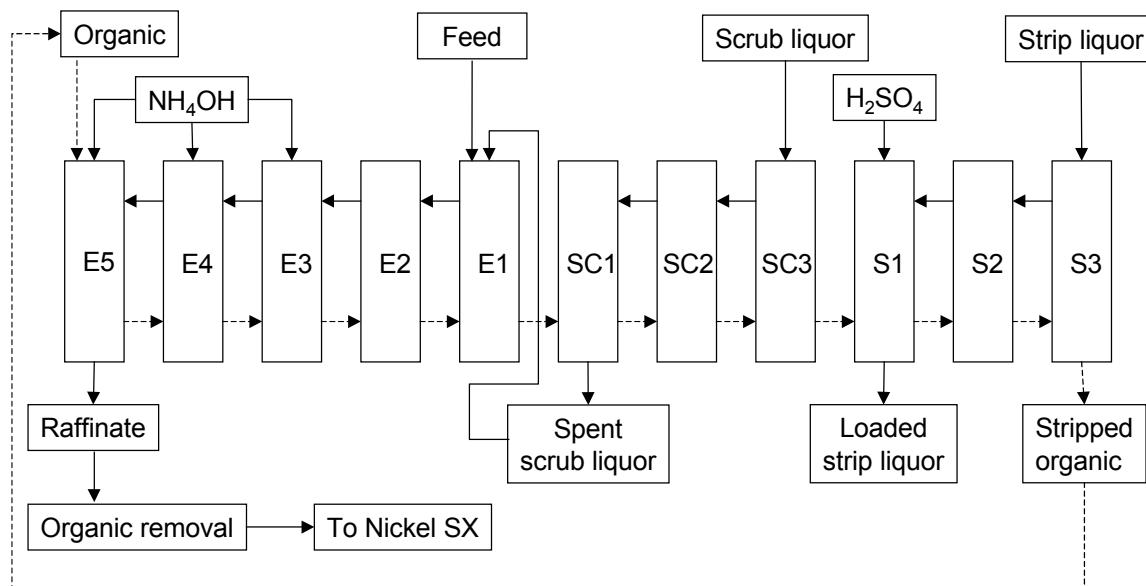

CYANEX 272 was supplied by Cytec, Canada, and versatic acid by Shell, South Africa. Both circuits used C<sub>12</sub>-C<sub>13</sub> *n*-paraffin (SasolChem, South Africa), an aliphatic hydrocarbon diluent.

## COBALT SOLVENT EXTRACTION

The feed solution to the cobalt SX was synthetically made up to represent Avmin's estimate of the cobalt SX feed. After 7 days operation, this was replaced by copper SX raffinate from a previous pilot campaign, which had been subjected to an iron removal step. The composition of the cobalt SX feed solution is shown in Table 1 and the circuit configuration in Figure 2.

*Table 1. Average composition of feed solution to cobalt SX.*

Element	Ni	Mn	Fe	Cu	Zn	Ca	Mg	Co
Concentration (g/L)	32.7	0.31	0.001	0.007	0.121	0.576	3.58	1.87

*Figure 2. Cobalt SX circuit configuration.*

### Extraction

The organic phase contained 7 vol.% CYANEX 272 and, with a phase ratio of 1, enabled the cobalt concentration to be consistently reduced to <10 mg/L. The pH was controlled in the last three stages to between 5.5 and 5.65, with the pH being slightly raised towards the end of the extraction bank to ensure low levels of cobalt in the raffinate. Some magnesium, calcium, and nickel were loaded in the last extraction stages, but progressively squeezed off the organic phase by cobalt in the incoming feed solution. Table 2 shows typical extraction efficiencies achieved for the various elements present in the feed solution.

*Table 2. Extraction efficiencies of major elements in the cobalt SX circuit.*

Element	Ni	Mn	Fe	Cu	Zn	Ca	Mg	Co
Extraction (%)	1.39	99.7	> 99.5	> 85	> 99.5	0.25	2.44	99.7

The  $\text{NH}_4\text{OH}$  consumption for cobalt extraction was 0.88 kg  $\text{NH}_4\text{OH}$  per kg of cobalt extracted, which represents 75% of the stoichiometric requirement. This low consumption has been noted during previous cobalt SX campaigns [1], and is thought to be due to the strong buffering effect of the high ionic strength of the aqueous solution. The consumption includes the  $\text{NH}_4\text{OH}$  required for the extraction of impurity elements such as copper, manganese, and zinc, as well as cobalt that is scrubbed off the organic phase in the scrubbing section and then re-extracted in the extraction stages.

### **Scrubbing**

The magnesium, calcium, and nickel in the loaded organic phase were scrubbed in three stages at an O/A ratio of approximately 52, using dilute cobalt (26 g/L) sulphate with a pH of 2.8. The scrub mixer-settler units were operated with internal recycle of aqueous phase, adjusted to ensure that the apparent phase ratio in the mixer was close to 1. This ensured that there was sufficient interfacial surface area for adequate mass transfer.

The optimised advance phase ratio and pH in the scrubbing section (pH 4.4 to 4.9) ensured that the following objectives were met:

- The magnesium, calcium, and nickel scrubbed from the loaded organic phase to meet the specification of the cobalt product solution;
- The cobalt in the spent scrub solution to be depleted by at least 50%; and
- Calcium concentration in the spent scrub solution to be below gypsum saturation level.

### **Stripping**

The scrubbed organic phase was stripped in three counter-current stages using dilute H<sub>2</sub>SO<sub>4</sub> (50 g/L). The pH in the first stage was controlled at 2 to ensure adequate stripping of impurities such as zinc, which are loaded in the extraction section and are not scrubbed off in the scrub section. Typical product solution composition is shown in Table 3.

*Table 3. Product solution from cobalt SX.*

Element	Concentration (g/L)	Element	Concentration (g/L)
Co	29.20	Fe	0.001
Ni	0.008	Zn	1.52
Cu	0.094	Si	0.001
Mn	3.98	Ca	0.003
Al	0.001	Mg	0.568

## **NICKEL SOLVENT EXTRACTION**

The raffinate from the cobalt SX plant was passed through a column of coal-based activated carbon (Montan Chemicals GRC 22) for the removal of dissolved organic from the solution. Table 4 shows the composition of a typical nickel SX feed, once the cobalt SX circuit had been optimised. The circuit configuration is shown in Figure 3.

*Table 4. Typical feed composition to nickel SX circuit.*

Element	Concentration (g/L)	Element	Concentration (g/L)
Ni	31.200	Zn	< 0.002
Co	0.005	Si	0.039
Cu	< 0.002	Ca	0.541
Mn	< 0.002	Mg	3.250

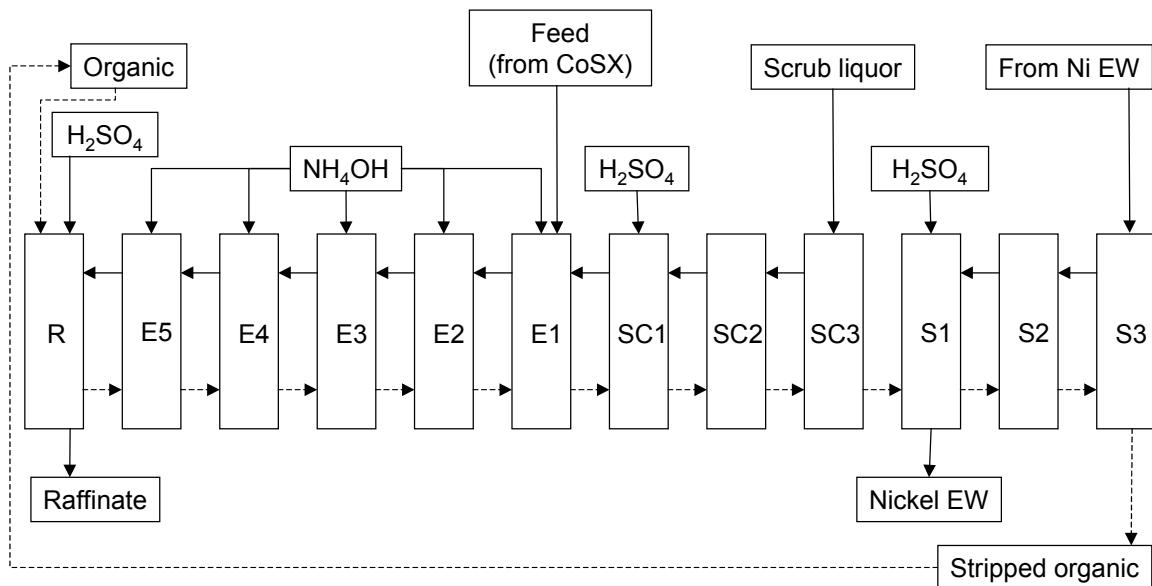

Figure 3. Nickel SX circuit configuration.

### Extraction

The objective in the extraction section was to achieve a nickel extraction efficiency of 99%, while minimising the co-extraction of calcium into the loaded organic phase to a level that could be scrubbed into a low scrub liquor flowrate without the precipitation of gypsum. No dilution was made to the extraction circuit, other than the neutralising base and the calcium-rich spent scrub liquor. The versatic acid concentration in the organic phase was 30 vol.%.

The nickel SX circuit was started with four extraction stages at the chosen pH profile. To achieve 99% extraction efficiency and improve nickel/calcium separation, a fifth extraction stage was added. The plant was operated to ensure that the calcium concentration in the aqueous phase of each stage was safely below the solubility limit of gypsum.

The main control mechanism was the organic-phase calcium profile. After optimisation of the pH profile, the target of 99% nickel extraction was achieved, and the co-extraction of calcium was limited to <3%. Figure 4 shows the aqueous and organic phase profiles of calcium and nickel across the extraction section.

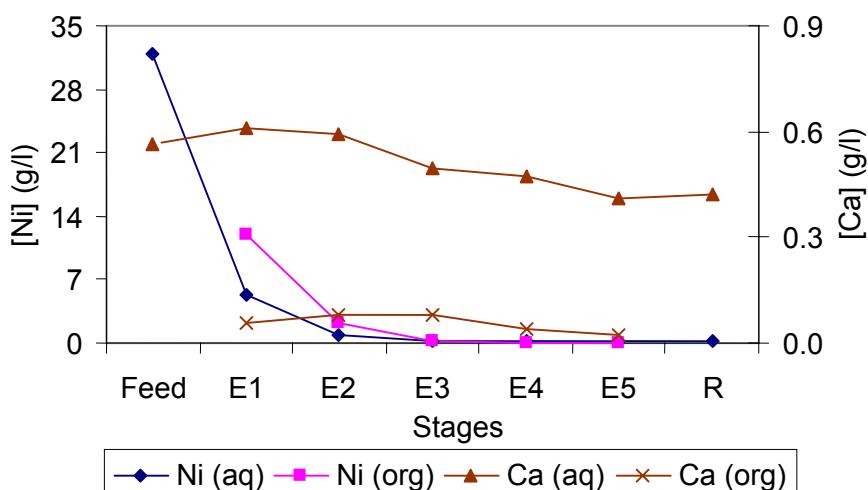

Figure 4. Nickel SX extraction profile.

Dissolved versatic acid was recovered from the raffinate by contacting the raffinate with the stripped organic phase. This operation was done in a separate reclamation mixer settler at a controlled pH of 3, reducing the versatic acid concentration in the raffinate to <25 mg/L.

### Scrubbing

The purpose of the scrubbing section was to minimise the transfer of calcium into the EW electrolyte circuit to such an extent that a bleed stream of <5% of the spent electrolyte would be sufficient to maintain the calcium concentration below the gypsum solubility limit. This meant that the calcium concentration on the scrubbed organic should be reduced to <9 mg/L. In order to scrub co-extracted calcium to this level, the correct pH profile across the scrubbing section is essential. To achieve this, the pH in the first scrubbing stage was maintained at 5.9 by the controlled addition of 300 g/L H<sub>2</sub>SO<sub>4</sub>.

### Stripping

The scrubbed organic phase was stripped in three stages using spent EW electrolyte. The steady-state compositions of the stripping solutions are shown in Table 5.

*Table 5. Composition of nickel SX stripping solutions.*

Element	Ni	Mn	Fe	Cu	Zn	Ca	Mg	Co
Spent (g/L)	66	0.003	0.001	0.001	0.001	0.21	0.29	0.05
Advance (g/L)	98	0.003	0.001	0.001	0.001	0.22	0.29	0.06

## CONCLUSIONS

The cobalt SX circuit was optimised to recover >99.5% of the cobalt in the feed stream with overall extraction of nickel <0.1%. The cobalt/nickel ratio of the loaded strip solution from this operation was >1500.

Nickel was recovered with >99% extraction efficiency in the second SX plant with overall calcium extraction into the nickel electrolyte circuit of <3%. Importantly, the nickel SX was optimised to prevent precipitation of gypsum or nickel salts in the extraction section.

## ACKNOWLEDGEMENTS

This paper is published by permission of Avmin and MINTEK. Start-up conditions for the nickel SX system were determined by John Preston. Pilot-plant control systems were optimised by Milton Summers. Cytec and Shell are thanked for providing the extractants.

# SEPARATION OF COBALT AND NICKEL BY SOLVENT EXTRACTION FROM SULFATE LIQUORS OBTAINED BY ACID LEACHING OF A PRODUCT FROM THE CARON PROCESS

**Elízabeth García Liranza, Aurora Moreno Daudinot, Roberto Viera Martínez,  
and Bernardo Rosales Bárzaga**

Laterite Research Center, Moa, Cuba

Laboratory-scale and miniplant studies have been conducted on the solvent extraction of cobalt from a liquor obtained by the sulfuric acid leaching of basic nickel - cobalt carbonate (a product of the Caron process for the treatment of lateritic ores).

Laboratory scale results showed that CYANEX 272 extracts 99% of cobalt and over 98% of zinc and manganese, with only 1.5% co-extraction of nickel. At miniplant scale, cobalt extraction was 99.7%, with nickel co-extraction below 1%, and over 98% extraction for other impurities. The Ni/Co ratio reached in the raffinate was 8166 and the Co/Ni ratio in the cobalt product solution was 528. Manganese was not separated from cobalt by solvent extraction.

## INTRODUCTION

Lateritic ore processing by reduction of the mineral and subsequent leaching in ammonium carbonate media (the Caron process) has been developed since the early 1940s at the Nicaro Plant in Cuba [1, 2]. Thereafter, similar processes were implemented at the Queensland Nickel plant in Australia (1974) [3, 4], at Companhia de Niquel Tocantins in Brazil (1981) [5, 6] and at the Punta Gorda Nickel plant in Cuba (1980s) [6].

The two Cuban plants currently running this process obtain nickel oxide as the main product in the form of sinter and a mixed nickel-cobalt sulfide, with a Ni/Co ratio of 2:1, as by-product.

Since the 1970s, studies have been carried out on the use of extraction by organic solvents for the separation of Ni, Co, Cu and Zn from sulfate and ammonium carbonate solutions, employing chelating and acidic extractants. A large amount of data has been obtained, serving as a basis for feasibility studies for the construction of a nickel-cobalt refinery based on the mixed sulfides from the ammoniacal process. By mid-1998, a small refinery with a capacity of about 30 t/y of cobalt as carbonate was designed and built at the Laterite Research Center, a product of reliable quality (99% purity) being obtained.

This paper presents a summary of the experimental results from laboratory and miniplant studies on a solvent extraction process for the selective recovery of cobalt from acid-leached basic nickel-cobalt carbonate.

## PROCESS DESCRIPTION

### Experimental

The laboratory and miniplant scale studies were carried out using an acid-leached basic nickel-cobalt carbonate solution obtained from the pilot-plant scale work. Impurities such as iron and copper were removed previously from the solution by precipitation using oxidation and neutralization methods. The chemical solution composition is shown in Table 1.

*Table 1. Chemical composition of the acid leached basic Ni-Co carbonate solution (g/L).*

Ni	Co	Fe	Zn	Cu	Mn	Ca	Mg	pH
92.63	3.53	0.004	0.193	0.001	0.643	0.12	0.628	4.3

Both studies were carried out with CYANEX 272 at 20% v/v (0.634 mol/L) in kerosene as hydrocarbon diluent. The sulfuric acid solutions employed were prepared from 98% reagent grade acid. Sodium hydroxide at 32% was used as the neutralizing agent.

Effect of pH, extraction isotherms, organic phase scrubbing, kinetics of cobalt extraction and stripping isotherms were determined in laboratory studies. All tests were carried out in beakers with mechanical agitation of the phases, after which the phases were separated in separating funnels. The pH control of the process was achieved by neutralizing the solvent with NaOH solution.

Once organic and aqueous phases were separated, stripping of the organic phase was carried out using 150 g/L sulfuric acid at unit phase ratio. Chemical analysis of the solutions was carried out by atomic absorption spectrophotometry. All the tests were done at room temperature (27- 29°C).

The miniplant consisted of ten mixer-settlers made of transparent acrylic. Each mixer was equipped with a digital speed control and a six-bladed turbine-type impeller to achieve the correct mixing of phases and pumping between stages. Aqueous and organic phases were pumped by using peristaltic pumps, and the flows were controlled by flowmeters. The dimensions of the mixer-settlers are given in Table 2.

*Table 2. Dimensions of the mixer-settlers.*

Dimensions	Mixer	Settler
Width	150 mm	150 mm
Length	96 mm	325 mm
Total height	228 mm	228 mm
Effective volume	2 736 cm <sup>3</sup>	9 360 cm <sup>3</sup>
Impeller diameter	55 mm	
Area	-	0.0487 m <sup>2</sup>

## RESULTS AND DISCUSSION

### Laboratory Test Work

#### *Effect of pH*

The variation in cobalt extraction with aqueous pH was studied at pH range from 1 to 6, O: A equal to 1, with 5 min. extraction time and 15 min. for stripping.

Figure 1 shows the extraction curves for the most relevant elements present in the feed solution. The maximum cobalt extraction is achieved at pH value 6, where 99.4% of cobalt is separated from the rest of the elements. Under these conditions about 3 % of nickel is co-extracted. The selectivity order showed by CYANEX 272 at pH 6 was:

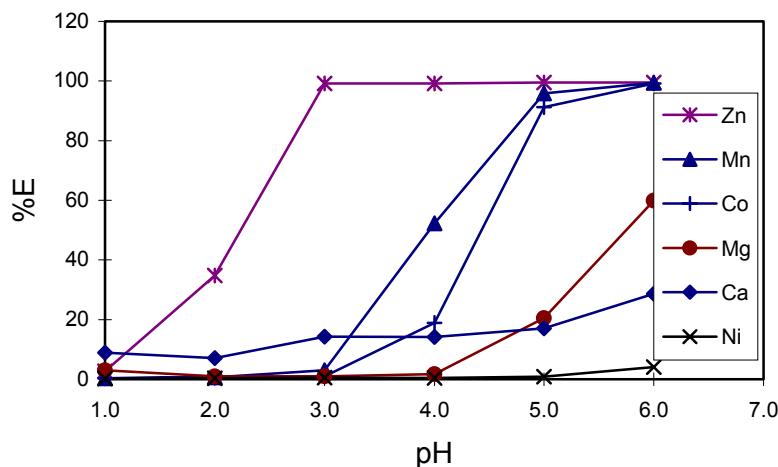

Figure 1. Extraction curves for CYANEX 272 at 20%, O:A = 1:1,  $t = 5\text{min}$ ,  $T = 28^\circ\text{C}$ .

#### Cobalt extraction isotherm

The extraction isotherm was obtained by contacting the phases at O:A ratios of 10, 5, 2, 1, 0.5, 0.25 and 0.1 (pH  $\sim 5.5$ ) at 5 min as extraction time. The results shown in Figure 2 indicate that three is the number of extraction stages required to separate more than 99% of cobalt.

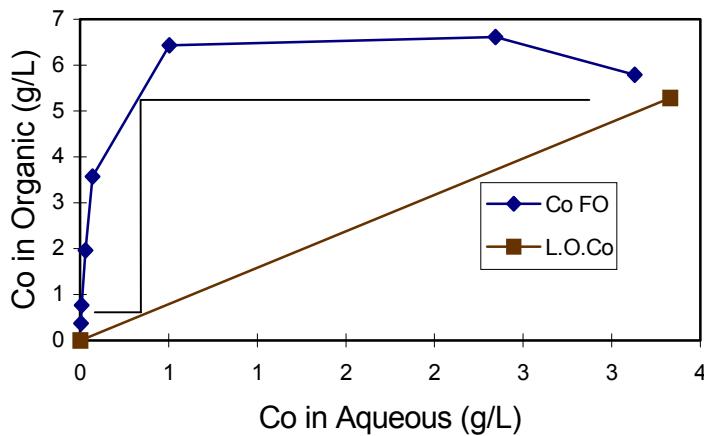

Figure 2. Extraction isotherm.  $T = 28^\circ\text{C}$ .

#### Organic phase scrubbing

To separate the co-extracted impurities (mainly nickel), tests for scrubbing of the organic phase with 20 g/L cobalt sulfate solutions were done at O:A ratios from 1 to 10. Under these conditions, the scrubbing efficiency for nickel was more than 98%. The scrubbing of calcium and magnesium was also effective, but manganese is scrubbed in smaller quantities. Figure 3 shows the effect of the phase ratios on the cobalt and nickel concentration in the loaded solvent.

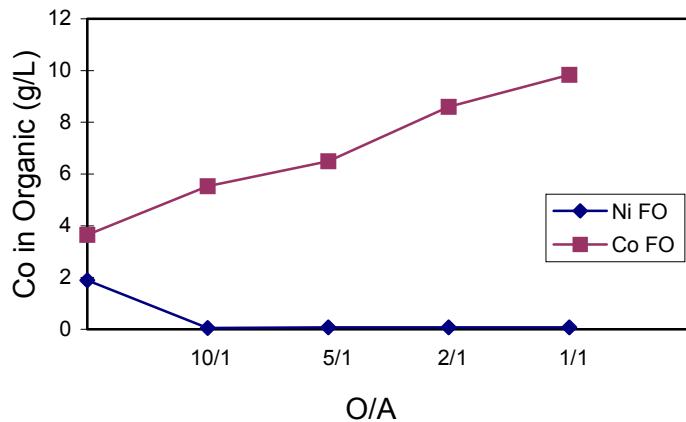

Figure 3. Effect of phase ratios O:A on organic scrubbing.

#### Kinetics of cobalt extraction

The effect of equilibrium time on cobalt extraction was studied at 1:1 phase ratio for times period of 30, 60, 90, 120 and 180 seconds. Figure 4 shows that cobalt extraction kinetics is very fast, reaching more than 97% extraction at pH values 5.4-5.5 in only 30 seconds. Nevertheless, there is no possibility of selecting cobalt extraction by controlling the extraction time, because all elements show rapid extraction kinetics.

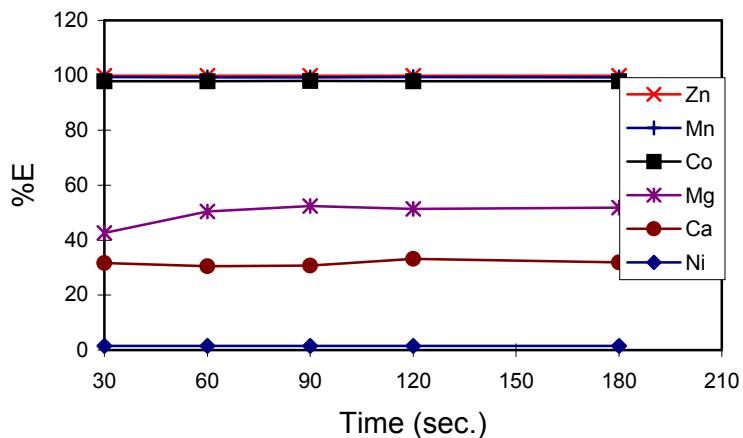

Figure 4. Extraction kinetics of elements. O:A = 1:1, T = 28°C.

#### Cobalt stripping isotherm

To determine the number of theoretical stages for cobalt stripping, experiments were carried out by using 10 to 1 O: A phases and 15 minutes of contact time. The cobalt-stripping isotherm (Figure 5) shows that two stages would recover more than 99% of loaded cobalt from the organic phase.

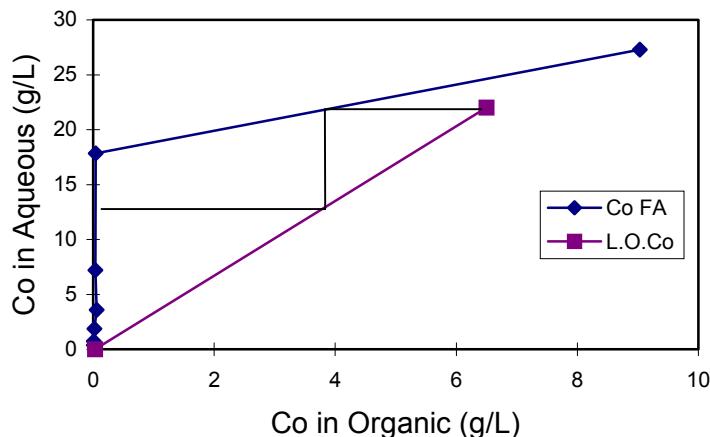

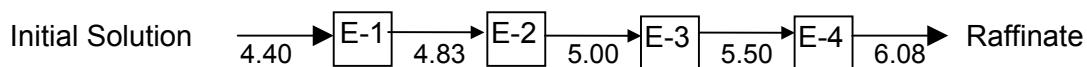

Figure 5. Cobalt stripping isotherm.  $T = 28^\circ\text{C}$ .

### Miniplant Run Test

The solvent extraction circuit was operated continuously for a total running time of 96 hours. This time  $2.13 \text{ m}^3$  of nickel-cobalt sulfate solution were treated. Organic and aqueous streams were sampled once every two hours. Chemical analyses were carried out by atomic absorption spectrophotometry.

### Extraction

The pH values across the extraction stages were controlled between 4.4 and 6.08 as shown in the following diagram:

Cobalt concentration in the raffinate was maintained below 0.012 g/L. The total extraction efficiencies for the elements are given in Table 3.

Table 3. Extraction efficiencies for the elements.

Elements	Ni	Co	Fe	Zn	Cu	Mn	Ca	Mg
Extraction (%)	0.23	99.67	92.7	99.6	98.7	99.3	3.7	25.6

### Organic phase scrubbing

Co-extracted nickel was scrubbed in two stages with 20 g/L cobalt sulfate solution, O: A  $\sim 8:1$  and at a pH of 5.5. Only nickel and part of the magnesium are scrubbed from the organic phase. Nickel and magnesium concentrations were reduced by 96.3 and 71.4%, respectively in the loaded organic phase, while iron, zinc, copper, manganese and calcium are reduced to a lesser degree, inferior to 30%. Table 4 shows the average concentrations of elements in the loaded and scrubbed organic phases.

Table 4. Chemical composition of loaded and scrubbed organic phases (g/L).

Elements	Ni	Co	Fe	Zn	Cu	Mn	Ca	Mg
Loaded phase	0.35	7.71	0.038	0.32	0.03	1.176	0.008	0.049
Scrubbed phase	0.013	7.84	0.03	0.29	0.021	1.13	0.007	0.014

### **Cobalt stripping**

Cobalt stripping was done by diluted sulfuric acid in three stages while iron, zinc, calcium and part of the others elements were stripped using a higher concentration of sulfuric acid than in the cobalt circuit. The total stripping efficiencies for the elements are given in Table 5.

*Table 5. Stripping efficiencies for the elements.*

Elements	Ni	Co	Fe	Zn	Cu	Mn	Ca	Mg
Stripping (%)	100	99.97	0.63	0.227	69.04	67.0	8.14	17.64

Table 6 shows the chemical composition of the final cobalt product solution from the run test.

*Table 6. Chemical composition of the final cobalt solution (g/L).*

Ni	Co	Fe	Zn	Cu	Mn	Ca	Mg
0.156	82.3	0.002	0.007	0.153	7.94	0.006	0.026

The manganese content was separated by treatment with sodium persulfate solution, giving 82 % manganese precipitation efficiency and only 0.5 % of cobalt co-precipitation.

## **CONCLUSIONS**

The results on the solvent extraction of cobalt from the nickel-cobalt sulfate leach liquor by CYANEX 272 shows the technical feasibility of this process. Impurity removal before and after the solvent extraction circuit is required, however.

Cobalt extraction was over 99% and nickel co-extraction was below 0.5%. The Ni:Co ratio was upgraded from 26.24 in the feed solution to 8 166 in the raffinate. In addition, a cobalt product solution with Co:Ni ratio equal to 528 was obtained.

## MODELLING METHODOLOGY FOR THE SIMULATION OF SOLVENT EXTRACTION PROCESSES - COBALT/NICKEL

Jörg Leistner, Astrid Görge\*, Werner Bäcker\*\*, Andrzej Górkak and Jochen Strube\*\*

Chair for Thermal Process Engineering, University of Dortmund, Germany

\*H.C. Starck, Goslar, Germany

\*\*Fluid Process Development, Bayer AG, Leverkusen, Germany

A modelling basis for the description of reactive extraction processes has been developed. As an example, the separation of cobalt from nickel by a commercial cation exchanger has been chosen, to take manifold effects into account. Different models have been created that are based on a small number of parameters for the description of mass transfer and thermodynamic or chemical equilibrium respectively. Simulation studies of mixer-settler combinations as well as columns have been carried out to improve process comprehension.

### INTRODUCTION

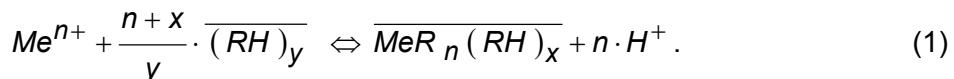

Process design in the field of multi-component extraction is strongly influenced by empirical procedures. Reasons for this are the strong ionic-interaction forces, high concentration ranges and several phenomena, which intensively affect the distribution in industrial applications. Therefore, the application of theoretical approaches to the separation of multi-component mixtures leads to failures in the prediction of phase equilibrium. Moreover, due to the complex flowsheet the amount of process and operating parameters that have to be optimised leads to a high number of experiments. In order to reduce experimental costs as well as expenditure for screening of process variants, detailed scale-up and process optimisation, simulation can be employed.

Either short cut or physico-chemical (rigorous) models are used in combination with numerical optimisation tools for a qualitative prediction of operating points based on lab scale experiments only. Short cut models are used for a first estimation of thermodynamic feasibility and economy evaluation of potential process alternatives and extraction media types. Rigorous models are applied for the next step in the design procedure in order to prove the experimental feasibility. The operating points simulated are validated during the first piloting studies and support than the quantitative prediction of further optimised operating points for a better process comprehension.

For this design strategy, the most important model parameters have to be determined by experiments like equilibrium data from shake out experiments, kinetic data from single drop apparatus and further investigations of drop behaviour. The complete model is used for the simulation of a continuous operating mixer-settler plant or a sequence of columns. The sensitivity of reactive extraction of cobalt and nickel with regard to individual model parameters will be illustrated by simulation studies. The complex separation behaviour of Co/Ni has been used as a test example.

## REACTIVE EXTRACTION OF COBALT AND NICKEL

The reactive extraction of n-valent metal cations,  $\text{Me}^{n+}$ , by ion exchangers, RH, is based on complex formation. Unfortunately, this complex formation is affected by many variables like the ionic strength and the concentration of the extractive agent. These dependencies complicate process modelling and simulation although the separation of cobalt and nickel by ion exchangers is a widely examined application in the field of hydrometallurgy [1-5]. Thus the complex structure or the number of associated extractive agent molecules can change due to the loading condition of the organic phase. At very high loading conditions even reversible polymerisation can occur [6]. To take these modifications into account the complex formation can be generalised as follows (Components in the organic phase are represented by a superscript bar.):

Depending on the solvent used, the cation exchanger usually forms dimers in aliphatic and monomers in aromatic dilutents, which is indicated by  $y$ . The number of additional ion exchanger molecules is represented by  $x$ , due to the coordination number of the complex formed. Nevertheless, equation 1 is still a simplification because possible formation of polynuclear or mixed complexes of cobalt and nickel are neglected as well as the saturation of coordination compounds by different anions or water molecules. However, this simplified description has been chosen because within certain operating ranges the influence of these parameters is constant and can be summed up as an assumption which has been proven.

Responding to equation 1 the reaction equilibrium can be described by the law of mass action for each metal by an equilibrium constant  $K_{\text{ex}}$ , if the stoichiometry is constant for the considered concentration range:

$$K_{\text{ex}} = \frac{\left[ \overline{\text{MeR}_n(\text{RH})_x} \right] \cdot [\text{H}^+]^n}{\left[ \text{Me}^{n+} \right] \cdot \left[ \overline{(\text{RH})_y} \right]^{n+x/y}}. \quad (2)$$

From equation 2 an expression for the distribution coefficient  $D$  can be derived:

$$D = K_{\text{ex}} \cdot \left[ \overline{(\text{RH})_y} \right]^{n+x/y} \cdot 10^{-n \cdot \text{pH}}. \quad (3)$$

This correlation connects the main regulating variables in reactive extraction processes with the distribution of metals in both phases. These are the equilibrium constant, the pH-value and the concentration of the free extractant.

## MODELLING

The equipment that is used in the field of extraction can be divided into two main groups: mixer-settlers and columns. In general there are two kinds of models for these equipments: stage models and models that take fluid dynamic non idealities into account.

**Mixer-settler combinations** have an overall stage efficiency near one. Therefore stage models can be used for feasibility studies with thermodynamic equilibrium, which is represented by equation 1, or in consideration of mass transfer resistance.

**Columns** can be described either by stage models or models which consider hydrodynamic behaviour, for example back-mixing, like the dispersive plug flow or drop population models. To take non idealities of fluid dynamic into account dispersive plug flow model has been chosen:

$$\frac{\partial}{\partial t} c_j^d = D_{ax}^d \cdot \frac{\partial^2 c_j^d}{\partial z^2} - u^d \cdot \frac{\partial c_j^d}{\partial z} - k_{eff} \cdot \frac{6}{d_{drop}} \cdot (c_j^d - c_j^{d,eq}) \quad (4)$$

$$\frac{\partial}{\partial t} c_j^k = D_{ax}^k \cdot \frac{\partial^2 c_j^k}{\partial z^2} + u^k \cdot \frac{\partial c_j^k}{\partial z} + k_{eff} \cdot \frac{\varepsilon}{(1-\varepsilon)} \cdot \frac{6}{d_{drop}} \cdot (c_j^d - c_j^{d,eq}) \quad (5)$$

The boundary conditions for this partial differential equation are derived by Danckwerts [7]. The models require several parameters depending on their complexity. They can be assigned to the following modelling phenomena: chemical and thermodynamic equilibrium, mass transfer, chemical reaction kinetic and hydrodynamics.

## DETERMINATION OF MODEL PARAMETERS

In order to simulate extraction processes the main regulating parameters, which are the equilibrium constant and the mass transfer coefficient, have to be determined.

### Equilibrium Constant $K_{ex}$

Shake out experiments were carried out under isothermal condition in closed Erlenmeyer flasks. Metal concentrations were analysed by atomic absorption spectroscopy as described by Manski [8]. The equilibrium constants are determined using the well-known slope-analysis method.

### Mass Transfer Coefficient $k_{eff}$

To determine the mass transfer coefficient a single drop cell was used (see [9] for a detailed description). The following photos (Figure 1) illustrate the dependency of the mass transfer of the relevant parameters of influence which are the concentration gradient, the drop diameter and its Reynolds number during one experiment with constant physical and chemical properties (density, viscosity, surface tension). The pH is adjusted in the feed solution and measured after exposition and removal.

Figure 1. Mass transfer experiment.

The intensive blue-coloured cobalt complex is formed at the interface. As the complexes are extracted by the continuous organic phase, the volume of the drop decreases. The experiments indicate a strong influence of pH to the drop size as well as simultaneous extraction of water into the unsaturated organic phase.

## VALIDATION

A countercurrent laboratory-scale mixer-settler cascade consisting of 8 extraction units, each with a mixer volume of 500 ml and settling area of 250 cm<sup>2</sup>, was used to validate the model. The pH was adjusted by addition of base into the mixers. A comprehension between simulated and measured Co and Ni concentrations of inlet and outlet as well as measured and simulated pH-values is represented by Figure 2. The model prediction corresponds within the accuracy of measurement. Therefore, the model is used for simulation studies as follows. Further validation studies with other sets of operating parameters will be done.

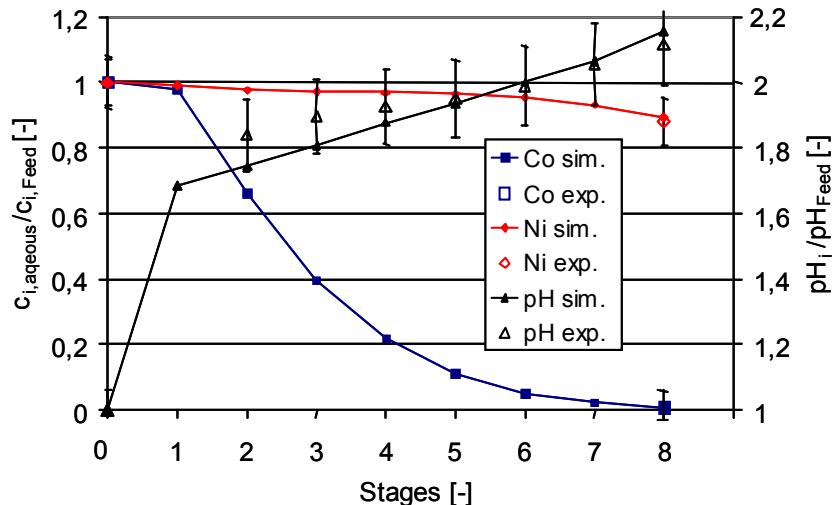

Figure 2. Experimental vs. simulated concentration profiles.

## SIMULATION STUDIES

A whole reactive extraction process with extraction, scrubbing and back-extraction units has been modelled within a flowsheet simulator to carry out the principal simulation studies. Under the condition that external streams like feed, scrub and back-extraction are constant, the pH-values in every stage of the extraction cascade have been optimised. Thus the constraints for special yields and a purity for cobalt of 99,5% in the re-extract are met. The results for these simulation studies are shown in Figure 3.

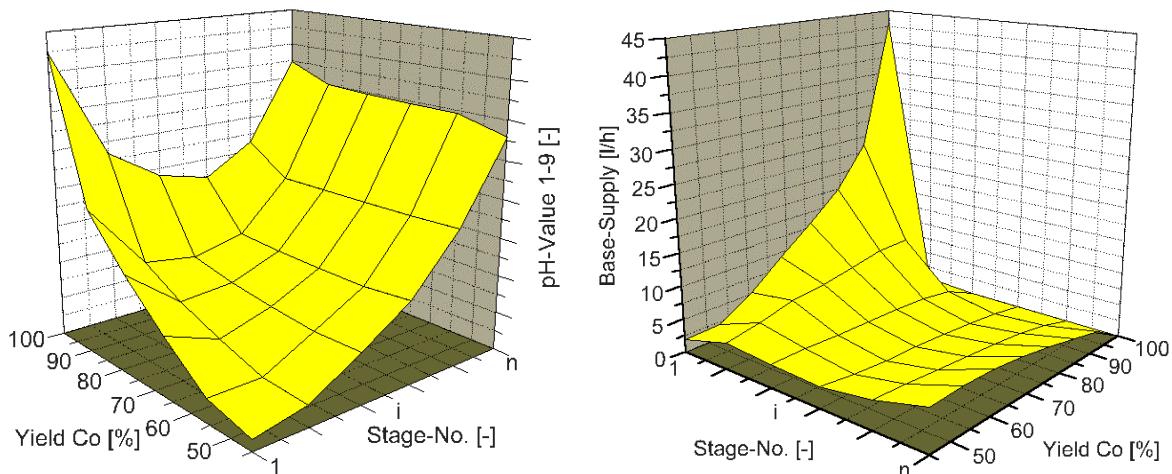

Figure 3. Comparison between optimised pH-values and required base volumes.

At a required yield for cobalt of 50 percent the pH-values increase linearly along the extraction cascade. If more cobalt should be extracted from the feed-solution the gradient in the cascade changes. The reason for this is that the mass transfer is shifted to the first stage, where the feed-solution is contacted for the first time with the extractant in the cascade.

To obtain these pH-values, different amounts of base must be fed to the single stages. The required base volumes are an indicator for mass transfer, since for every metal ion that is extracted, a stoichiometric amount of protons is released. That is the reason why the total amount of base increases linearly with the extraction yield.

At low yields the amount of base for every stage is almost equal. The small deviations are caused by different additional extractant flows to the stages. In the end, at a yield of 100 percent the whole amount of base is fed to the first stage, and the others lose importance.

The decisive difference between a mixer-settler cascade and a column is that the pH-values in a column can not be influenced as easily as in a mixer-settler cascade. To obtain a certain required yield, the pH-values at the entry have to be chosen high enough to ensure the neutralisation of released protons. In Figure 4 a simulation study for a laboratory scale column illustrates the concentration gradients of standardised component concentrations plotted against the column length. All concentrations are referred to the concentration of the leaving protons.

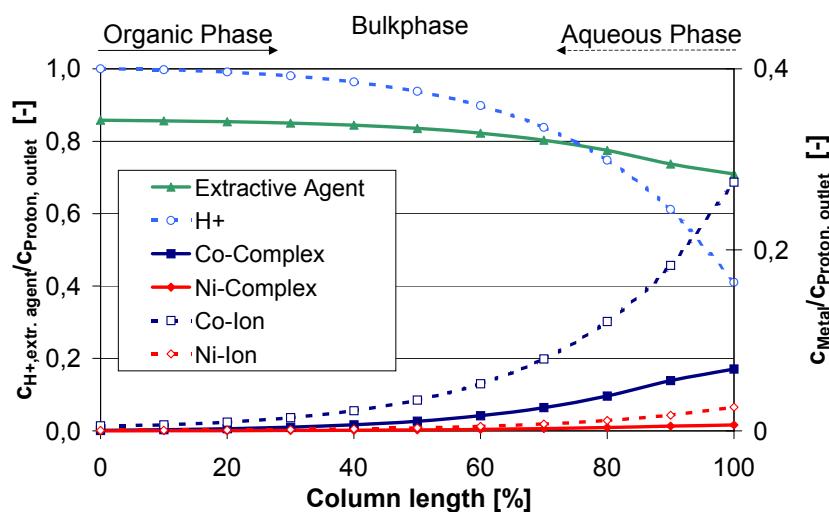

Figure 4. Simulated concentration profiles.

The solid lines represent the continuous phase concentrations and the broken lines the concentrations in the dispersed phase. At the first contact of aqueous and organic phase a large amount of metal cations is extracted and protons are set free equally. This amount of substance lowers the distribution coefficients due to the law of mass action, as can be seen in Figure 5.

Simultaneously the mass transfer decreases from its maximum value, at the top of the column to its minimum value at the bottom. The concentration gradients of both metals decrease in a very similar way, because no selective influence can be carried out inside the column. In a mixer settler cascade in which the amount of base or the concentration of the extractive agent can be changed easily at each stage, the separation factor can be modified in a much broader range than within an extraction column. Therefore, process parameters at the inlet like the selection of phase ratio, extractive agent concentration and pH-value become much more important in operating extraction columns than in mixer settler cascades, and have to be chosen carefully.

## CONCLUSIONS

A modelling approach for the complex separation of Co and Ni has been derived and implemented in models with different assumptions. Stage and dispersive plug flow models were used as an approximation for mixer-settlers and columns.

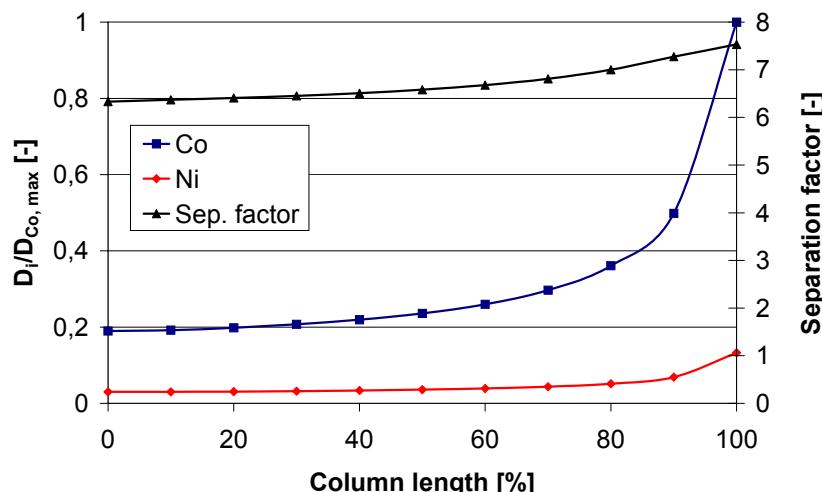

Figure 5. Distribution coefficients for cobalt and nickel.

The required model parameters were determined in laboratory-scale experiments. The objective of the described design strategy is to support feasibility studies and economy evaluation as well as piloting.

Furthermore, the design approach requires the knowledge on chemical equilibrium and mass transfer in multi-component and multi-reaction systems. The sensitivity analysis indicated that the equilibrium constant and the pH-values are the most important parameters. Experiments and simulations have proven the feasibility of the described simplified models as a first design approach. Further model validations and model improvements will be done.

Based on this modelling approach, process development and design are enhanced.

## ACKNOWLEDGEMENTS

The authors would like to thank H.C. Starck AG for support, and would like to acknowledge the support of the research groups from Bayer AG Technical Development, Leverkusen, especially Dr. M. Traving and Dr. E. Dikow, as well as R. Manski and Prof. H.-J. Bart of the chair of thermal separation technology at the University of Kaiserslautern for their collaboration in the project.

## COBALT-NICKEL SEPARATION BY SOLVENT EXTRACTION IN CUBA

Aurora María Moreno Daudinot and Elízabeth García Liranza

Laterite Research Center, Moa, Holguín, Cuba

In recent years, many plants have included solvent extraction in their processes to replace the cobaltic hydroxide or cobalt sulfide precipitation methods, due to the high selectivities and separation factors attainable.

In 1998 the Laterite Research Center introduced the results obtained during three years of research, and a small-scale plant was constructed at Moa, Cuba, in order to treat cobalt – nickel mixed sulfide by atmospheric and pressure leaching, purification, removal of cobalt by solvent extraction, and precipitation of cobalt and nickel carbonates.

The small-scale refinery treats a mixed sulfide, and produces Co 30 and Ni 60 ton/year contained in carbonates.

### INTRODUCTION

Several refineries in different countries throughout the world are in operation at present in order to obtain pure nickel and cobalt from matte, minerals or sulfides as raw material [1, 2].

Solvent extraction is the technology that is most advisable for carrying out the difficult process of separating metals with similar physicochemical characteristics contained in aqueous liquors. During the last twenty five years of the past century there has been a marked tendency to devise processes using solvent extraction such as: Nippon Hitachi Cobalt Refinery, Sumitomo's Niihama Nickel Refinery, Anaconda's Murrin Murrin, Bulong Nickel/Cobalt Project, and Cawse Nickel Operations [1, 3]. Solvent extraction technology has also been introduced into processes such as Falconbridge Nikkelverk a/s Kristiansand Refinery, Societe Le Nickel, and the Queensland Nickel Yabulu Refinery [1,4]; as well as replacing the hydroxide precipitation process at Companhia de Níquel Tocantins and Outokumpu Harjavalta Metals Oy [5, 6].

After three years of research and laboratory and bench scale experiments, the design criteria and the feasibility analysis were obtained. Then a small-scale refinery was erected in Cuba, in 1998, which started applying solvent extraction process at miniplant scale using nickel and cobalt mixed sulfide, obtained as a by-product from an ammoniacal leaching process.

## PROCEDURES

### Lab Scale

To separate cobalt from nickel, phosphoric (D2EHPA), phosphonic (PC 88A, P 507) and phosphinic solvents (CYANEX 272, CYANEX 301 and CYANEX 302) were tested with cobalt – nickel mixed sulfide leach liquors [7, 8]. Extraction pH curves and extraction isotherms were determined for all these reagents. Different solutions were used to scrub the extract to determine the optimum concentration and pH for the scrubbing, and stripping isotherms were also determined. Kinetic studies were also carried out for each of the stages: extraction, scrubbing, stripping, and solvent regeneration.

### Bench Scale

Once the lab scale researches were finished, CYANEX 272 was chosen as the organic reagent able to separate cobalt from nickel with a high separation factor (>7000) [9]. Calcium and magnesium were rejected and remained in the aqueous phase (raffinate). This solvent does not show any problems with stripping the extracted cobalt, and allows a cobalt product with a Co: Ni ratio of over 3000 to be obtained.

Experimental results obtained at lab scale such as extraction pH, number of stages, speed of stirring for aqueous and organic phases, extraction kinetics, speed of phase separation, and so on were introduced to bench scale. The necessary number of stages, flows rates and phase ratios, recycles, regenerated organic phase neutralization, and solvent losses were verified and fixed.

In this stage, the design parameters for the scaling of the bench results to miniplant scale were obtained. During operation at bench scale, cobalt and nickel liquors with high purity were obtained, to produce salts utilized in ceramics, military techniques and at the Animal Nutrition Institute in Cuba.

## DESCRIPTION OF CUBAN SMALL-SCALE REFINERY

The project for the construction of the refinery as such to small scale, capable of processing the nickel – cobalt mixed sulfide as a product of ammonium carbonate process in order to obtain basic cobalt and nickel carbonate of high purity, was performed with the parameters obtained at bench scale. The flowsheet of the Cuban small-scale refinery for nickel and cobalt is shown in Figure 1.

The mini-refinery was erected in the Investigations Area of the Laterite Research Center with the assistance and protection of Unión del Níquel. The investigators of this center carried out the calculations and design for the mini-refinery project, culminating in December 1998 with the Basic Industry minister's approval. Operations started in January 1999, reaching design capacity by the end of the first semester, and commercializing high purity nickel and cobalt carbonate.

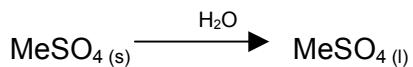

The mini-refinery is made up of three principal areas: leaching and purification, solvent extraction and final product.

### Leaching and Purification

Ni – Co mixed sulfide has the following composition (%):

Ni	Co	Fe	Mn	Cu	Zn	MgO	CaO
14 – 17	7 – 8.5	1 – 1.4	0.025 – 0.05	1.3 - 3	0.01 – 0.03	2.0	0.03

The following sulfate solution is obtained by atmospheric leaching with 80% efficiency:

The slurry containing solid sulfide is fed into a supplied compressed-air horizontal autoclave, and the following reactions take place for the different elements. Efficiency in this oxidation reaction is 99%.

### Removal of Impurities

The iron precipitation is carried out at 80°C by addition of limestone, thereby removing iron and copper from the liquor. Then the copper is separated from the liquor by means of sodium sulfide.

The efficiency of impurity removal is superior to 99%. The partially purified solution is filtered and adjusted with sodium hydroxide in order to feed to the solvent extraction circuit. The chemical composition in g/L is:

Ni	Co	Fe	Mn	Cu	Zn
25.2	12.8	0.005	0.002	0.001	0.018

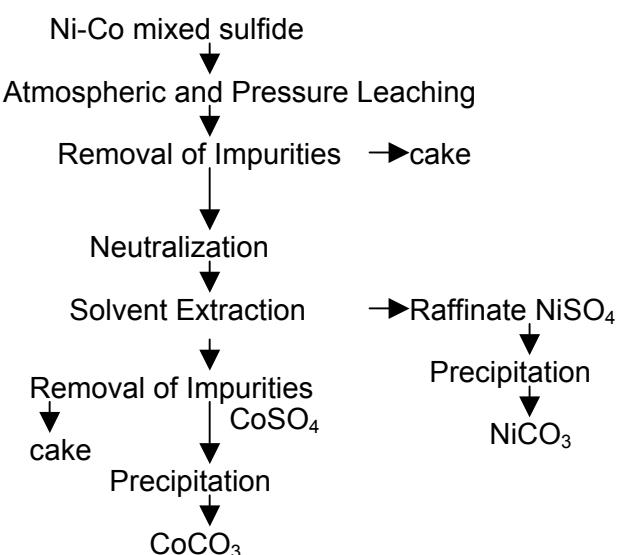

Figure 1. Flowsheet of the Cuban Nickel Refinery.

### Solvent Extraction

The system consisted of 9 stages. The extraction, scrubbing and stripping stages are performed in mixer settlers in countercurrent flow, and the organic phase: aqueous phase ratio in the settlers is 1 throughout the solvent extraction process.

CYANEX 272 is the organic reagent utilized at 20 % diluted in kerosene. The organic acid solution is neutralized with sodium hydroxide solution, as the following reaction:

The behavior of the individual metals in the organic phase through the solvent extraction circuit is shown in Figures 2 and 3.

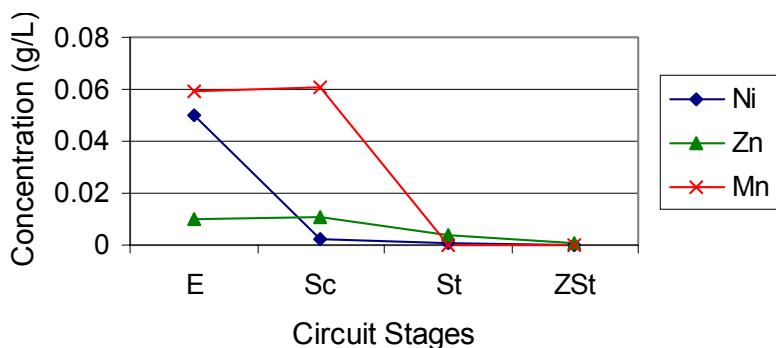

Figure 2. Metals behavior through the solvent extraction circuit.

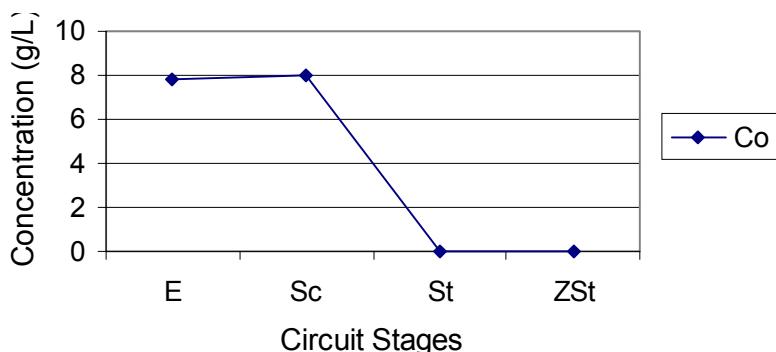

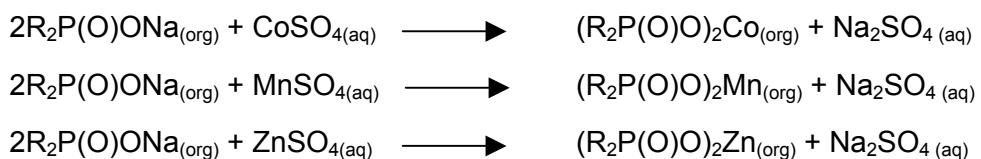

Figure 3. Cobalt behavior through the solvent extraction circuit.

### Extraction

The purified liquor enters the first mixer settler in the extraction stages of solvent extraction circuit. Solvent CYANEX 272 enters the last mixer settler. Three stages are sufficient to remove cobalt from nickel with pH 6.0, whilst nickel remains in the aqueous phase or raffinate. The extraction of manganese and cobalt in this stage is >99.5%.

The reactions for this manganese and cobalt extraction process are:

### Scrubbing

The extract containing over 99% of zinc, manganese and cobalt, and 0.35% of the coextracted nickel is scrubbed in two stages by a cobalt-containing solution in sulfate medium, to eliminate nickel, with an efficiency of 96%. This reaction is described as follows:

The spent scrubbing liquor is recycled to the extraction stages of the system, and the scrubbed extract continues to the stripping stages.

### Stripping

Stripping takes place at controlled pH, and the manganese and cobalt loaded during extraction are stripped in three stages with sulfuric acid, both metals are liberated due to the high hydrogen ion concentration in the aqueous phase.

The cobalt liquor product contains manganese as an impurity. The composition in g/L of the cobalt sulfate product is as follows:

Co	Ni	Fe	Mn	Cu	Zn
62 - 65	0.005 – 0.01	0.01	0.06	-	0.01

### Zinc Stripping

The partially stripped organic phase contains zinc, and this is removed by means of concentrated sulfuric acid solution, giving a clean organic phase, ready again for neutralization. The reaction that takes place between partially stripped solvent and concentrated acid solution is:

The purified nickel and cobalt liquors pass through a carbon column, to clean off soluble solvent, then leave the solvent extraction area.

Manganese is removed by using a strong oxidant, separating 85% with 0.5% loss of cobalt. A product liquor of 99% purity and the following chemical composition in g/L is obtained:

Co	Ni	Fe	Mn	Cu	Zn
61.6 – 64.7	0.005 – 0.01	0.01	0.009	-	0.01

### Final Product

The carbonate in both cases (cobalt and nickel) is obtained in three stages by a precipitation process using sodium carbonate addition at elevated temperature. The obtained slurry is passed to the thickeners, and then the thickened slurry is filtered and washed to eliminate the entrained sodium sulfate.

Products containing 60 ton/year of nickel and 30 ton/year of cobalt are obtained with the following composition in percent.

Basic Nickel Carbonate					
Ni	Co	Fe	Mn	Cu	Zn
47-49	0.16	0.01	-	0.005	0.002
Basic Cobalt Carbonate					
Co	Ni	Fe	Mn	Cu	Zn
48-49	0.05	0.05	-	0.015	0.03

## BATEMAN PULSED COLUMN PILOT-PLANT CAMPAIGN TO EXTRACT COBALT FROM THE NICKEL ELECTROLYTE STREAM AT ANGLO PLATINUM'S BASE METAL REFINERY

Victor Nagel, Mark Gilmore\* and Sean Scott\*\*

Bateman Engineering Limited, Boksburg, South Africa

\*Anglo Platinum, Rustenburg, South Africa

\*\*Mintek, Randburg, South Africa

An extended pilot-plant campaign was completed at Anglo Platinum's base metal refinery to evaluate the technical feasibility of using the Bateman Pulsed Column for the removal of cobalt from the nickel sulphate electrolyte produced at the refinery. A conventional Cyanex 272® solvent-extraction system was employed and the Bateman Pulsed Column was successfully evaluated for the extraction and stripping of cobalt.

The extraction of cobalt from the nickel feed solution was successfully evaluated at a flux of 50 m<sup>3</sup>/m<sup>2</sup>/h and the cobalt concentration in the feed was reduced from 250 to below 10 mg/L. The average Co:Ni and Co:Mg ratios on the loaded organic were 15.5 and 9.5, respectively.

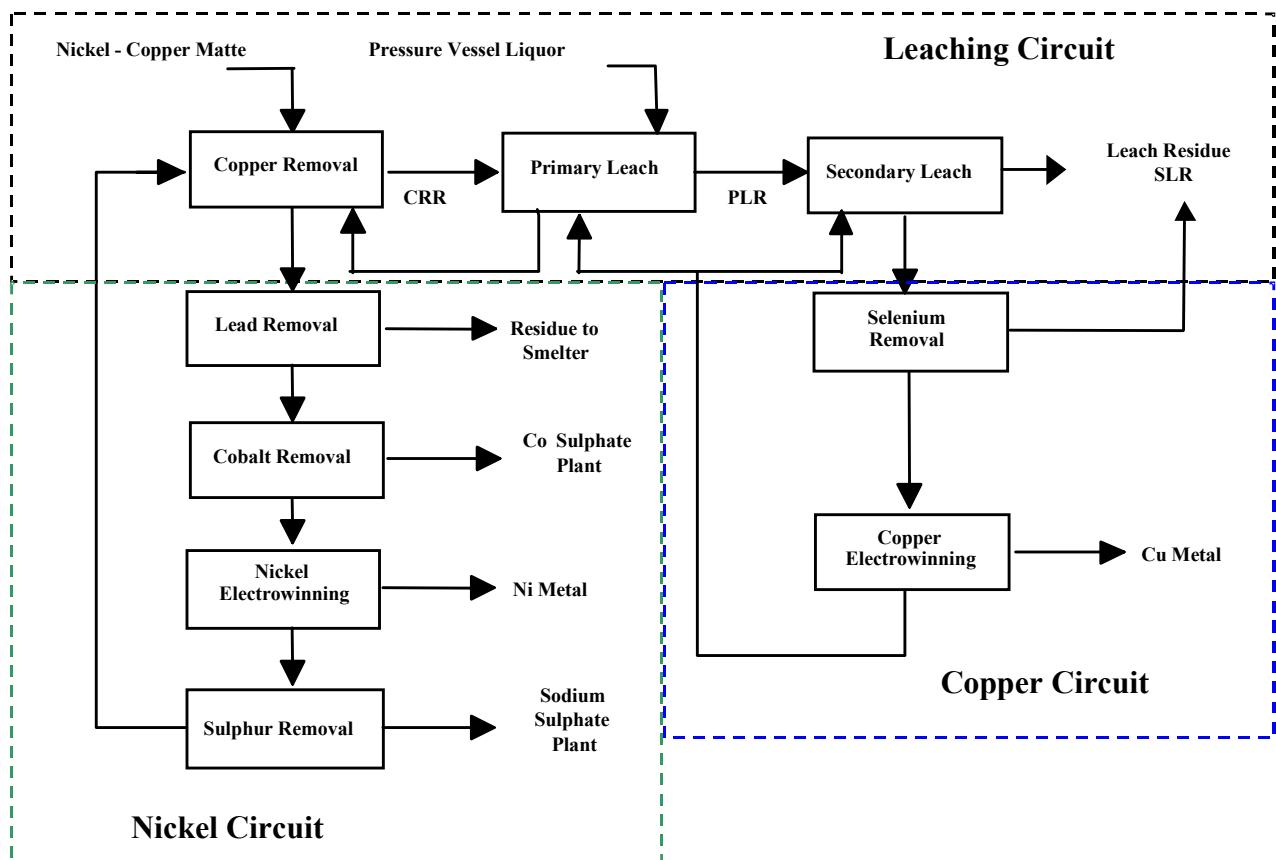

The stripping of cobalt from the loaded organic was successfully evaluated at a flux of 25 m<sup>3</sup>/m<sup>2</sup>/h. The cobalt concentration of the loaded organic was consistently reduced from approximately 0.8 to 0.05 g/L (>95% stripping efficiency) and a loaded strip liquor containing approximately 12 g/L cobalt was produced.

### INTRODUCTION

Anglo Platinum declared a R12 billion expansion in February 2000 to increase its platinum production from 2 million to 5 million oz of platinum over a time period of 5 years. This expansion would include the establishment of a number of new mines, concentrators and a new smelter exploiting the eastern limb of the Bushveld Complex. Where appropriate, the existing operations would be de-bottlenecked to meet the increased production. The increase in platinum production would yield an associated increase in base metals, which will surpass the nominal capacity of the existing Rustenburg Base Metal Refinery (BMR), in the year 2003. It was decided that the BMR would be de-bottlenecked in line with the anticipated platinum expansion.

The BMR is a medium sized base metal refinery and has a nominal capacity of 21,000 tpa nickel, 12,000 tpa copper, 2000 tpa cobalt sulphate and 55,000 tpa sodium sulphate crystal. A simplified process flow diagram is indicated in Figure 1.

Currently the major bottlenecks in the production of nickel cathode are the nickel electrowinning operation as well as the cobalt removal stage. The process currently employed to remove cobalt from the nickel stream is an outdated Outokumpu process [1].

*Figure 1. Simplified process flow diagram of Anglo Platinum's BMR.*

The nickel hydroxide used in the separation process is manufactured internally by electrolytic means. This process is labour intensive, extremely costly and utilises approximately 7% of the potential nickel plating capacity. Anglo Platinum decided to evaluate the use of alternative technology for the removal of cobalt. A solvent extraction (SX) process using Cytec's organophosphinic acid reagent, Cyanex 272® was identified as the most likely technology.

Anglo Platinum commissioned Bateman and Mintek to run a 5-week pilot-plant campaign to evaluate the use of Cyanex 272®. The Bateman Pulsed Column (BPC) was identified as the preferred contacting equipment as it offered many advantages to Anglo Platinum when compared with conventional mixer settlers. Two main advantages are its limited footprint and reduced solvent inventory requirement. Space is currently a constraint at the BMR. The main perceived disadvantage of the BPC is that it has never been used before commercially in an industrial application for the extraction of cobalt using Cyanex 272®.

## PROCESS DESCRIPTION

The process tested during the campaign was a conventional Cyanex 272® cobalt SX circuit, comprising cobalt extraction, nickel and magnesium scrubbing, and cobalt stripping. As only one pilot BPC was available for the campaign, a combination of mixer settlers and the BPC were used for the evaluation of the individual extraction and stripping steps.

When evaluating the BPC for extraction, conventional mixer settlers were used for the scrubbing and stripping of the loaded organic. Co-extracted nickel was scrubbed from the loaded organic using a 45 g/L cobalt scrub solution originating from the BMR cobalt circuit, while the scrubbed organic was stripped with dilute sulphuric acid to produce a concentrated cobalt solution.

When the stripping performance of the BPC was being evaluated, three parallel banks consisting of three mixer settlers each were used for extraction. The mixer settlers were used to generate the cobalt-loaded organic while the BPC was used to strip the loaded organic and to produce the cobalt product solution. Dilute sulphuric acid was used as the strip liquor.

## EXPERIMENTAL

### Solutions and Reagents

The feed solution used during the campaign originated from the BMR, and is representative of the feed solution to be produced in the expanded refinery. A representative composition of the feed solution used during the campaign is shown in Table 1.

*Table 1. Average composition of the feed solution.*

Element	Concentration (g/L)	Element	Concentration (g/L)
Ni	67.5	Zn	< 0.005
Co	0.12 – 0.27	Ca	0.147
Cu	< 0.005	Mg	0.444
Mn	< 0.005	Na <sub>2</sub> SO <sub>4</sub>	120 – 140
Fe	< 0.005	pH	6.1 – 6.2

The organic phase used consisted of Cyanex 272<sup>®</sup> (2.2 – 4.5 vol.%) in an aliphatic diluent C<sub>12</sub>-C<sub>13</sub> *n*-paraffin (SasolChem). A 40 g/L H<sub>2</sub>SO<sub>4</sub> solution was used as strip liquor. Diluted product liquor originating from RBMR's cobalt recovery D<sub>2</sub>EHPA SX circuit was used as the scrub liquor to remove co-extracted nickel and magnesium from the loaded organic. The scrub liquor consisted of 45 g/L cobalt and trace amounts of nickel, calcium and magnesium.

### Equipment

The BPC used during the campaign consisted of two settlers, one passive and the other active depending on the phase continuity being tested and a 6-7 meter 100-mm ID contacting section. The contacting section was made up of 1-meter glass column lengths each fitted with PVDF (polyvinylidene fluoride) internals arranged in a disc-and-doughnut configuration. The pH along the length of the column was monitored and controlled by the addition of H<sub>2</sub>SO<sub>4</sub> or NaOH to various ports along the column. NaOH was also added directly into the organic phase before it entered the column during the extraction tests.

Conventional mixer settlers were used for the extraction, scrubbing and stripping duties as required.

## RESULTS AND DISCUSSION

### Extraction

Hydrodynamic tests were conducted to determine the conditions which would maximise the flux (combined flowrates divided by the flow area of the column), mixing intensity (combination of the frequency and stroke length of the mechanical pulsator) and the extraction efficiency attainable in the BPC. The hydrodynamic tests indicated that the BPC could be run at a higher mixing intensity at an equivalent flux without flooding, when the

continuity of operation was organic. This meant that the BPC could be run at higher fluxes in this continuity and a full-scale BPC would have a smaller diameter when compared with a BPC run in an aqueous continuity. As the extraction of cobalt is dependent on pH, the initial operating philosophy was to run the BPC aqueous continuous as this would facilitate the measurement and control of the pH along the length of the BPC.

The initial conditions tested were a flux of  $40 \text{ m}^3/\text{m}^2/\text{h}$ , an O:A of 0.4 and a mixing intensity of 126 cm/min. Initial results indicated that the cobalt concentration in the raffinate was high at 50 mg/l. To reduce the concentration, the operating flux was decreased to  $25 \text{ m}^3/\text{m}^2/\text{h}$ , the mixing intensified to increase the organic phase holdup and the height of the BPC lengthened to increase the residence time of the two phases in the column. The O:A ratio was also raised to ensure that there was sufficient capacity available on the organic phase. These attempts resulted in the cobalt concentration in the raffinate decreasing but it still exceeded the target of <10 mg/L. The initial conclusion drawn was that mass transfer was the limiting factor. No further testwork under aqueous-continuous conditions were done.

The initial concern with operating the organic continuity was that it would be difficult to control the pH along the length of the BPC. During the trials this was found not to be the case as the high aqueous hold ups achieved (~20-30%) ensured that sufficient aqueous phase was present to allow pH to be measured. Online measurements were regularly compared to aqueous samples taken along the length of the BPC to confirm the accuracy of the online readings.

During the extraction tests the extractant was converted to the sodium salt with approximately 400 g/L NaOH in a mixer settler to decrease the NaOH addition requirement to the BPC. During this preloading/conversion a brown wax-like substance formed. Analysis by Cytec of the substance indicated that it was an iron-contaminated sodium phosphinate gel and that its formation was reversible. This substance formed throughout the campaign and was attributed to the high concentration of NaOH used. Initially the Cyanex 272<sup>®</sup> concentration did not decrease but as the campaign progressed, the Cyanex 272<sup>®</sup> concentration decreased from 4.5 % to approximately 2.5 vol. %.

The results achieved during the organic continuous hydrodynamic tests did not give a clear indication of the conditions at which the BPC could be run at, as the Cyanex 272<sup>®</sup> concentration had decreased to 2.5 vol. % and there appeared to be insufficient capacity available on the extractant. The Cyanex 272<sup>®</sup> concentration was increased to 4.5 vol. % and the BPC was run under three different sets of conditions as indicated in Table 2.

*Table 2. Operating conditions for the extraction of cobalt – organic continuous.*

Flux ( $\text{m}^3/\text{m}^2/\text{h}$ )	30	40	50
Feed flowrate (L/min)	2.91	3.97	4.92
Organic flowrate (L/min)	1.02	1.27	1.62
Spent scrub flowrate (mL/min)	7.5	10.5	13
Mixing intensity (cm/min)	152	152	122-152

The increased concentration together with the organic continuity mode of operation resulted in the cobalt concentration in the raffinate decreasing to below 10 mg/L under all conditions tested. Once the raffinate specification was being met for the flux of 50 on a continuous basis, attempts were made to improve the Co:Ni and Co:Mg ratios in the loaded organic phase by controlling the pH in the top section of the column by the addition of 200g/L H<sub>2</sub>SO<sub>4</sub>. This was deemed necessary as the feed solution entering the column was at a pH of 6.2 and resulted in the pH in the upper sections of the BPC being around 5.8. A lower pH was deemed to be necessary as this would have increased the selectivity of the Cyanex 272<sup>®</sup> for cobalt over nickel and magnesium.

Large delay times between the point where the pH was measured and the point where the H<sub>2</sub>SO<sub>4</sub> was introduced resulted in the pH decreasing to levels as low as 5.2. This adversely effected the raffinate cobalt tenors achieved but did result in the selectivity of the system increasing. Before the addition, the average Co:Ni and Co:Mg ratios were 13 and 7; after the addition, these ratios increased to 25 and 14.5, respectively. This increase reduced the load on the scrubbing circuit and increased the overall selectivity of the circuit. Selected results produced during this period are shown in Table 3 and a typical profile along the length of the BPC is indicated in Table 4.

The scrubbing of the organic phase was not successful during the campaign, as the residence time in the mixer settlers was inadequate to allow for sufficient scrubbing of the co-extracted nickel and magnesium. Further testwork after the campaign indicated that Co:Ni and Co:Mg ratios in excess of 1000 are achievable in three to four scrubbing stages with a residence time in the mixers in excess of 4 minutes.

### Stripping

The hydrodynamic tests indicated that the column could be run at a flux of 25 – 30 m<sup>3</sup>/m<sup>2</sup>/h - in an aqueous-continuous mode of operation, at various mixing intensities and at an O:A of approximately 20. The results of some of these tests are indicated in Table 5.

Following the optimisation test, the BPC was run for a period of 24 hours at a flux of 25, a mixing intensity of 176 and O:A of approximately 20. During this period an average cobalt stripping efficiency of 96% was achieved with the stripped organic phase exiting the column at between 17 - 40 mg/L cobalt. Typical loaded strip liquor (LSL) compositions are shown in Table 6. The high level of nickel and magnesium in the LSL can be attributed to the fact that the loaded organic was not scrubbed prior to being fed to the BPC for stripping.

*Table 5. Optimisation results.*

Test	Flux m <sup>3</sup> /m <sup>2</sup> /h	Mixing intensity (cm/min)	Dispersed phase hold-up (%)	[Co] (g/L)			Co Stripping (%)

## CONCLUSION

The technical feasibility of using a BPC for the extraction of cobalt from the nickel feed solution and stripping of the cobalt loaded organic was successfully proven during an extended pilot-plant campaign.

The extraction tests indicated that the BPC could be operated at a higher flux at an equivalent mixing intensity when run organic continuous. An aqueous continuity favoured the measurement and control of pH in the BPC but a cobalt concentration of < 10 mg/L in the raffinate could not be consistently produced. When running the column organic continuous, the cobalt concentration of the raffinate was reduced to below 10 mg/L. The operating conditions used in the column were a flux of 50 m<sup>3</sup>/m<sup>2</sup>/h, an O:A ratio of 0.33, 3.5-4.5 vol. % Cyanex 272<sup>®</sup> in C<sub>12</sub>-C<sub>13</sub> n-paraffin and a 7 m contacting height. The average Co:Ni and Co:Mg ratios on the loaded organic phase were 15.5 and 9.5, respectively, and were increased to 25 and 14.5 when the pH at the top of the column was suitably controlled. On a full-scale plant 4-5 scrubbing stages would be necessary to achieve the required Co:Mg ratio of 500-1000:1.

The stripping tests conducted indicated that the BPC could be run at a higher flux at an equivalent mixing intensity when run organic continuous. However to ensure efficient stripping of the cobalt loaded organic, the column had to be run with an aqueous continuity. Operating the column at a flux of 25 m<sup>3</sup>/m<sup>2</sup>/h and an average O:A ratio of approximately 20, the cobalt concentration of the loaded organic was consistently reduced from approximately 0.8 g/L to 0.05 g/L (stripping efficiency of >95%) and a LSL was produced containing on average 12 g/L cobalt. This concentration can be raised to suit downstream process requirements by increasing the O:A ratio and the acid concentration in the strip liquor.

## EXTRACTION EQUILIBRIUM OF Zn(II) AND Ni(II) WITH LIX 984

M. T. Draa and M. Benamor

Department of Chemical Engineering, University of Bejaia, Bejaia, Algeria

The solvent extraction of Ni(II) and Zn(II) with LIX 984 dissolved in heptane was investigated. Extraction experiments were carried out varying the pH and metal concentration of the aqueous phase and the extractant concentration in the organic phase. The selectivity series for the extraction of these metals from nitrate media based on the  $\text{pH}_{50}$  was found to be Ni ( $\text{pH}_{50} = 3.75$ ) > Zn ( $\text{pH}_{50} = 5.5$ ).

The experimental data obtained were treated numerically. Ni(II) and Zn(II) extraction by LIX 984 could be explained by the formation of  $\text{NiR}_2$  and  $\text{ZnR}_2$  organic complex species. The values of the equilibrium constants for these extraction reactions were  $\log K_{\text{ex1}} = -5.69$  for Ni(II) and  $\log K_{\text{ex2}} = -9.50$  for Zn(II). Nickel stripping by acidic solution was also studied and it was found that 1 M  $\text{HNO}_3$  can strip Ni(II) to the extent of 99%.

### INTRODUCTION

Solvent extraction is widely used in the extraction of a number of non-ferrous metals. In the case of a multi-metal system, there are two basic process approaches for metal separation [1, 2]: sequential-selective extraction stripping and co-extraction-selective stripping. This latter is reported to be more economical [2]. Nickel and zinc are often present together in a number of raw materials, and liquid effluents. Thus, their recovery/separation presents an important industrial problem.

LIX reagents are powerful extractants for copper [3]. While there is ample published data on copper extraction with current LIX reagents such as LIX 860 (2-hydroxy-5-dodecylsalicylaldoxime), LIX 84 (2-hydroxy-5-nonylacetophenone oxime) and LIX 984 (equivolume mixture of the two) [4, 5], there is very little information on the extraction of nickel and zinc using these extractants.

The aim of this work is to study the extraction of these metals from nitrate solution using the commercially available LIX 984 as extractant. The influences of aqueous pH and extractant concentration are discussed, and a simple model explaining the extraction mechanism is developed.

### EXPERIMENTAL

#### Reagents

LIX 984, an equivolume mixture of 5-dodecylsalicylaldoxime and 5-nonyl-acetophenone oxime, was supplied by Cognis. It was used as received by diluting it to the desired concentration in heptane.

A stock solution (1 g/l) of zinc(II) and nickel(II) was prepared from  $\text{ZnNO}_3 \cdot 5\text{H}_2\text{O}$  and  $\text{NiNO}_3 \cdot 6\text{H}_2\text{O}$  (Prolabo) in double distilled water, respectively. Working solutions for extraction consisted of 0.1 M ( $\text{Na}^+$ ,  $\text{H}^+$ ,  $\text{Zn}^{2+}$ ) $\text{NO}_3^-$ . The total nitrate concentration was kept constant at 0.1 M. The aqueous pH was adjusted by changing different fractions of  $\text{HNO}_3$  and  $\text{NaNO}_3$  as required. All other chemicals used were of analytical grade.

A  $10^{-3}$  M solution of 4-(2-pyridylazo)resorcinol (PAR) (Fluka) was prepared for the spectrophotometric determination of Ni(II) and Zn(II).

### Apparatus

A Shimadzu UV-2101PC double beam UV-VIS spectrophotometer was used for absorbance measurement. For pH measurements, a 3420 electrochemistry analyzer (Jenway) with combined glass-saturated calomel electrode was used.

### Extraction Procedure

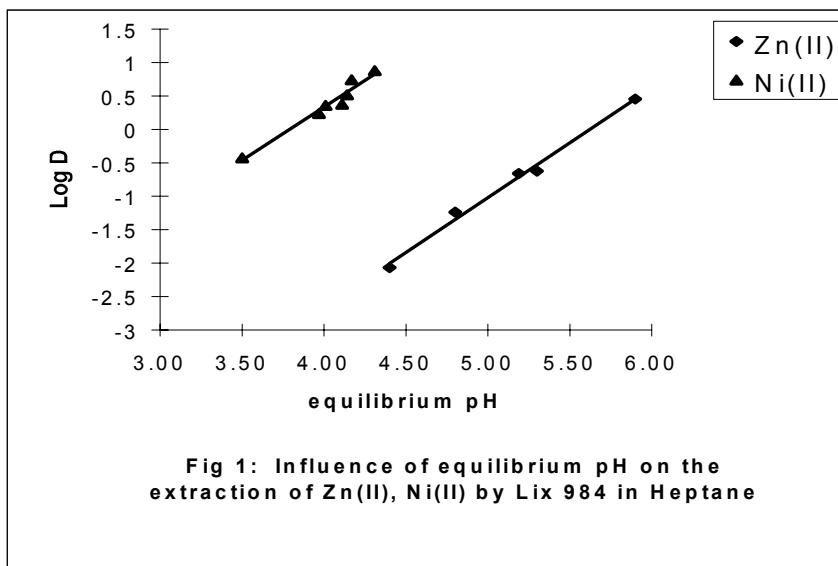

Suitable aliquots of the aqueous phase containing the desired concentration of the metal and sodium nitrate 0.1 M ( $\text{Na}^+$ ,  $\text{H}^+$ ,  $\text{M}^{2+}$ ) $\text{NO}_3^-$  were equilibrated with an organic phase containing the extractant LIX 984 dissolved in heptane. The initial pH of the aqueous phase was adjusted to the desired value by adding dilute  $\text{HNO}_3$  solution. Extraction was carried out in separating funnels at unit phase ratio for 20 min. Initial experiments indicated that a contact time of 10 min is sufficient to reach equilibrium. After phase disengagement, the aqueous phase was separated and its equilibrium pH was measured.

Metal concentration in the aqueous phase was estimated by spectrophotometric determination with PAR as follows. For both metals, the pH of the solution was adjusted by adding  $2\text{ cm}^3$  of a buffer of pH 6 (acetate buffer) and adding  $1\text{ cm}^3$  of  $10^{-3}$  M aqueous PAR. The absorbance of the complex was measured at 490 nm for zinc and 495 nm for nickel against a reagent blank prepared analogously. The concentration of metal in the organic phase was calculated from the difference between the metal ion concentration before and after extraction. All the extraction experiments were conducted at room temperature.

## RESULTS AND DISCUSSION

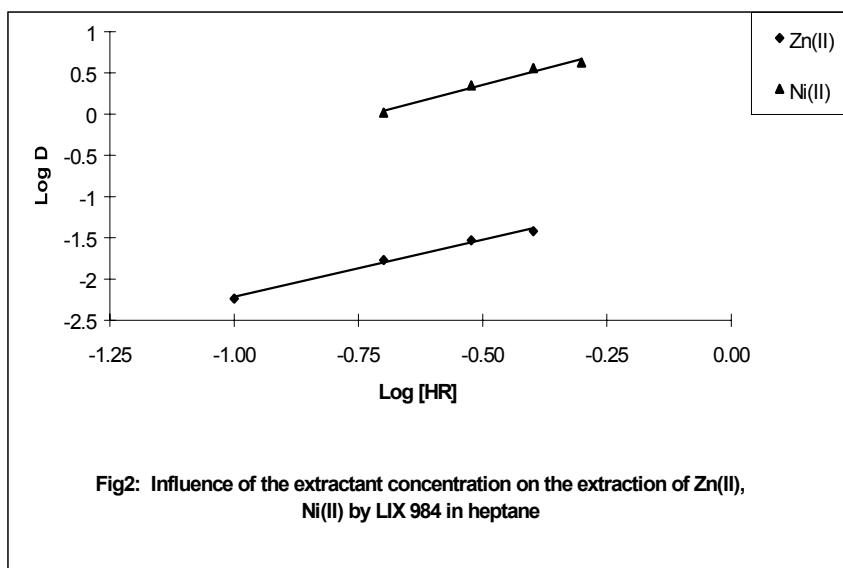

### Effect of pH

The effect of aqueous solution pH has been investigated by keeping the metal concentration constant (10 mg/l) using 10 % v/v LIX 984 in heptane. The results shown in Figure 1 indicate that Zn(II) is poorly extracted in comparison to Ni(II), the  $\text{pH}_{50}$  values corresponding to 50% extraction are equal to 3.75 and 5.5 for Ni(II) and Zn(II), respectively. For both metals, the extraction increases with increasing aqueous equilibrium pH. From the slope of the plot of  $\log D$  vs. pH, it is inferred that two protons are involved in the extraction of Zn(II) and Ni(II).

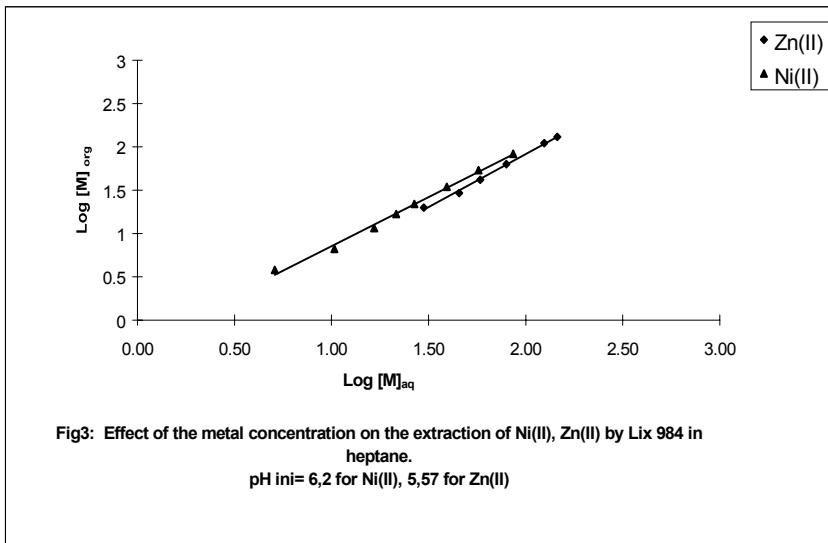

### Effect of Extractant Concentration

The effect of LIX 984 concentration (10%v to 50%v) on the extraction of Zn(II) and Ni(II) has been studied at constant metal ion concentration (10 mg/l), and a constant initial aqueous pH of 6 (Figure 2). In both cases, the distribution ratio D increases linearly with an increase in the concentration of LIX 984 and, from the slope of the log-log plot, it is inferred that two molecules of LIX 984 are associated with the extractable complexes.

### Effect of Metal Ion Concentration

The effect of metal ion concentration on the extraction process has been investigated using 40% v LIX 984 in heptane for Zn(II) and Ni(II) (Figure 3). The metal concentration varied from 5 to 100 mg/l for Ni(II) and from 20 to 150 mg/l for Zn(II). The initial aqueous pH was maintained constant at 6.2 for Ni(II) and 5.57 for Zn(II). The plot of the equilibrium organic phase metal concentration  $\log [M]_{org}$  against the aqueous metal concentration  $\log [M]_{aq}$  is linear, with a slope close to unity for both metals, indicating that only mononuclear species are extracted into the organic phase for both cases.

### Extraction Equilibrium

It is generally accepted that the reaction between divalent metal and chelating molecules proceeds at the oil-water interface [6]. The chelating extraction is an acid-base reaction in which the oxime molecules donate protons in exchange of metal ions. The reaction is described by:

$$K_{ex} = \frac{[MR_2_{(org)}][H^+]^2}{[M^{2+}][RH]_{org}^2} \quad (2)$$

where RH represents hydroxime molecules, and the subscripts 'aq' and 'org' to the aqueous, and organic phase, respectively. From Equation (1), we can define the equilibrium constant  $K_{ex}$  as

This equilibrium constant is based on the assumption that both phases are ideal, and concentration could be used instead of activity. This assumption is only valid in the case of low species concentration [4].

Chelating extractants often form dimers, but only in nonsolvating diluents. They exist as monomers in solvating diluents such as aromatic hydrocarbon and chloroalkanes. The degree of hydroxime dimerization depends strongly on the extractant concentration. Hydroxime dimerization can be ignored in solution of aliphatic or aromatic hydrocarbon up to a concentration of 0.01 and 0.1 M, respectively [6].

The value of  $K_{ex}$  was obtained numerically through the minimization of the sum square of errors U defined by:

$$U = \sum (\log D_{exp} - \log D_{cal})^2 \quad (3)$$

where  $D_{exp}$  is the experimental metal distribution coefficient and  $D_{cal}$  is calculated by assuming the validity of Equation (1). The free extractant concentration  $[HR]$  is supposed to equal to total concentration  $[HR]_t$ . This calculation was carried out by using Microsoft Excel. The standard deviation is calculated by:

$$\rho(\text{Log D}) = (\text{U}/\text{N}_p)^{1/2} \quad (4)$$

where  $N_p$  is the difference between the total number of data points and the total number of equilibrium constants calculated.

In the first attempt, and following the slope analysis results, the value of  $n$  was varied between 0 and 2. Table 1 shows the best formulation for the metal/LIX 984 complexes, together with the calculated equilibrium constants obtained for both metals. This result partly agrees with the one obtained by Rodriguez *et al.* [7] who investigated the solvent extraction of some metals with LIX 984 dissolved in *n*-heptane and suggested the formation of  $\text{NiR}_2$  in the case of nickel and a mixture of  $\text{ZnR}_2$  and  $\text{ZnR}_2 \cdot 3\text{HR}$  in the case of zinc in the organic phase.

*Table 1. Results of the best formulation obtained in the Zn(II) / LIX 984 system and Ni(II) /LIX 984 system from various model species.*

Species	$\log K_{\text{ex}}$
$\text{ZnR}_2$	-9.5
$\text{NiR}_2$	-5.69

### **Effect of Acid Concentration on Stripping of Nickel from the Loaded Organic Phase**

Stripping studies were carried out to re-extract nickel from the loaded organic phase at varying concentrations of  $\text{HNO}_3$  (Table 2). The pH of the stripping phase ranged from pH 0.75 to pH 2.75. It was found that the percentage stripping of nickel increases with increasing acid concentration and reaches quantitative stripping for  $\text{HNO}_3$  concentration of 1 M.

*Table 2. Effect of  $\text{HNO}_3$  concentration on nickel stripping.*

$\text{HNO}_3$ (M)	0.001	0.01	0.03	0.10	0.17	0.31	0.56	1
Stripping (%)	14	52.1	63.4	80.6	90.54	95	98	> 99

### **CONCLUSION**

The solvent extraction of Ni(II) and Zn(II) with LIX 984 dissolved in heptane was studied. Extraction experiments were carried out varying the pH and metal concentration of the aqueous phase and the extractant concentration in the organic phase. These results show that zinc is poorly extracted in comparison to nickel. The selectivity series for the extraction of these metals from nitrate media based on the  $\text{pH}_{50}$  was found to be Ni ( $\text{pH}_{50} = 3.75$ ) > Zn ( $\text{pH}_{50} = 5.5$ ).

The experimental data obtained were treated numerically. Ni(II) and Zn(II) extraction by LIX 984 could be explained by the formation of  $\text{NiR}_2$  and  $\text{ZnR}_2$  organic phase complexes. The values of the equilibrium constants for these extraction reactions were  $\log K_{\text{ex1}} = -5.69$  for Ni(II) and  $\log K_{\text{ex2}} = -9.50$  for Zn(II).

Nickel stripping by acidic solution was also studied and it was found that 1 M  $\text{HNO}_3$  can strip Ni(II) to the extent of 99%.

## ACKNOWLEDGMENTS

We are grateful to Cognis (Germany) for kindly donating the LIX 984 sample.

# THE EFFECT OF ORGANOPHOSPHORIC EXTRACTANT CONCENTRATION AND INITIAL PHASE VOLUME RATIO ON COBALT(II) AND NICKEL(II) EXTRACTION

Darko Maljković and Zdenka Lenhard

Faculty of Metallurgy, University of Zagreb, Sisak, Croatia

Extraction and separation of cobalt(II) and nickel(II) with the commercial organophosphorus extractants MOOP, Cyanex 272 and Cyanex 302 were investigated. Within the scope of the investigations the effect of the initial extractant concentration (2.5 - 20 vol. %) and the initial phase volume ratio of the organic phase to the aqueous phase [0.5 and 1] on metal concentration in the organic phase was examined. Samples containing single metals or their mixture in sulphate solution were treated with the extractant, using kerosene as diluent, at initial pH = 8 and 25°C. Noticeable differences in dependence of metal extraction on extractant concentration and initial phase volume ratio as well as a significant mutual action of cobalt and nickel were observed. Under given experimental conditions the highest separation factors were found with Cyanex 302 at 2.5 and 20 % per volume.

## INTRODUCTION

Within the scope of study of application of commercial organophosphorus extractants for extraction and separation of cobalt(II) and nickel(II) from lateritic ore or from used hard metal the properties of Cyanex 272, Cyanex 302 and MOOP were examined. Extraction with those extractants was investigated previously by the authors, among others, extraction with Cyanex 272 from real and prepared samples, effect of different diluents and third phase appearance [1,2], mutual action of cobalt and nickel and third phase appearance for extraction with MOOP [3,4] as well as the behaviour of the extraction system containing Cyanex 302 [5]. All investigations were carried out with the extractant concentration 10 vol. % as a favoured level in literature. It seemed appropriate to investigate the influence of extractant concentration over a broader range than in the experiments of Tait with Cyanex 272 and Cyanex 302 [6]. Investigations were carried out with lower metal concentrations ( $c_{Co}^i = 0.09 - 0.7 \text{ g.dm}^{-3}$ ,  $c_{Ni}^i = 1.9 - 9.0$ ) and a lower nickel to cobalt ratio (16 - 21) than it was found in literature [6-9]. The cobalt concentrations reported in literature were from 0.4 to 2  $\text{g.dm}^{-3}$ , and those of nickel from 7 to 100  $\text{g.dm}^{-3}$  and the ratio of nickel to cobalt from 17 to 50. The experimental conditions as described in literature differed also in regard to diluent, use of modifier and pre-treatment of extractants (purification, conversion to Na-salt).

In this paper the results of investigation into the effect of extractant concentration on the behaviour of extraction systems containing commercial extractants, Cyanex 272, Cyanex 302 and MOOP, for low concentrations of cobalt and nickel, are presented.

## EXPERIMENTAL

### Materials

The extractants were Cyanex 272, Cytec, Canada, containing 85% bis (2,4,4-trimethylpentyl) phosphinic acid, Cyanex 302, Cytec, Canada, containing 84% bis (2,4,4-trimethylpentyl) mono thiophosphinic acid and Mono octyloctan phosphonate, MOOP, Bayer, Germany containing 97.5% of pure compound mono(2-ethylhexyl) phosphonic acid (2-ethylhexyl) ester. All extractants were used without further purification. Kerosene, INA, Croatia having a density (20°C) of 0.80 served as diluent in all experiments. All other chemicals were analytical reagent grade.

### Procedure

Samples containing a single metal, cobalt(II) or nickel(II), or a mixture of the two were prepared by dissolving metal sulphates in diluted sulphuric acid and by neutralisation with ammonium hydroxide to the required pH value. The examinations were carried out in graduated cuvettes (15 cm<sup>3</sup>). Cobalt(II) and nickel(II) concentrations were 0.15 g.dm<sup>-3</sup> (2.5x10<sup>-3</sup> M) and 2.3 g.dm<sup>-3</sup> (3.9x10<sup>-2</sup> M) and they corresponded to those in pre-treated leach liquors of lateritic ore. The initial pH value chosen on the basis of previous investigations was 8.0 in all experiments. The initial phase volume ratios of the organic phase to the aqueous phase (*r*) were 0.5 and 1.0. After the addition of the extractant (2.5 - 20 vol. % or approximately 0.08 - 0.6 M) diluted in kerosene samples were thermostated for 15 minutes at 25 ± 0.1°C, and after that, vigorously shaken four times for 30 seconds at 2-minute intervals. In between shakings the systems were thermostated.

### Methods of Analysis

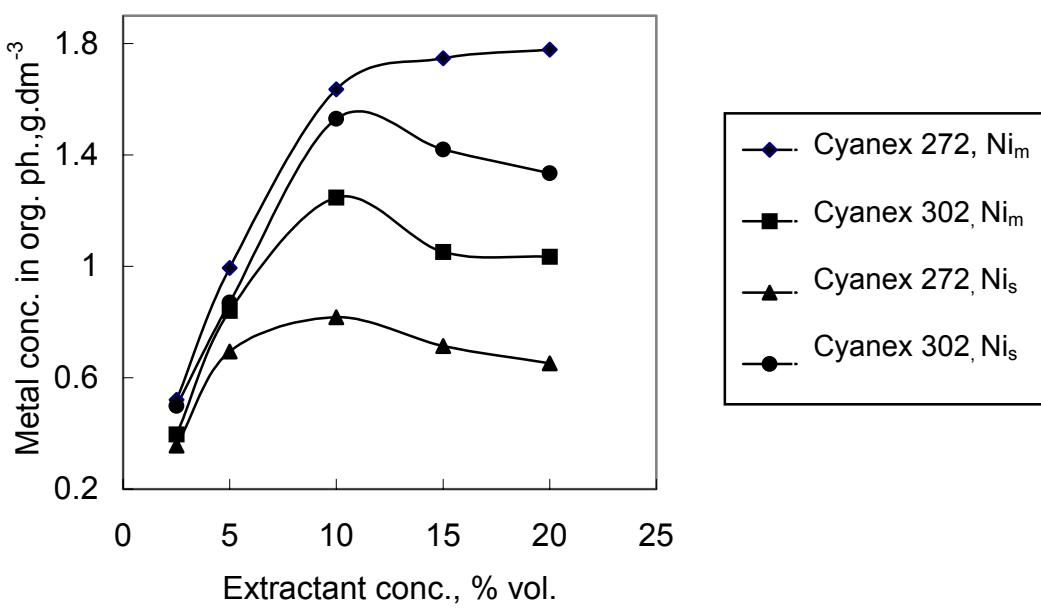

Concentration of cobalt (using nitroso-R salt) and nickel (using dimethylglyoxime and K<sub>2</sub>S<sub>2</sub>O<sub>8</sub>) were determined by measurement of absorbance at 530 nm and 464 nm, respectively.

## RESULTS AND DISCUSSION

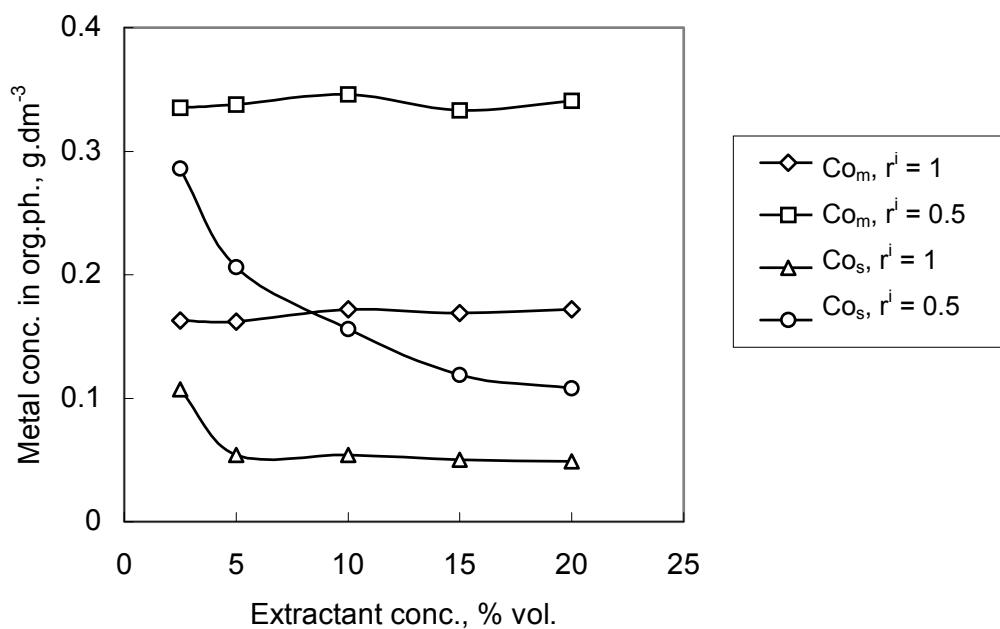

The effect of initial concentration of the extractant on cobalt(II) and nickel(II) concentrations in the organic phase ( $c_0^{\text{Co}}$ ,  $c_0^{\text{Ni}}$ ), as well as calculated distribution ratios ( $D_c$ ) and separation factors ( $\alpha$ ) at two different initial phase volume ratios were examined in samples containing a single metal or a mixture of metals.

In samples containing only cobalt, the best extraction was found with Cyanex 272 over Cyanex 302 and MOOP in the full range of extractant concentrations. In samples containing only nickel the metal was extracted better with MOOP than with Cyanex 302 and Cyanex 272. Concentration of metal in the organic phase was, as expected, always higher at the initial phase volume ratio 0.5 for all extractants, but for nickel, it always decreased with increase in extractant concentration, and for cobalt, it achieved a maximum value at extractant concentration between 5 and 15 vol. %.

Extraction of metals from samples containing a mixture compared to that from samples containing single metals differed.  $c_0^{\text{Ni}}$  obtained from a mixture with Cyanex 272 was significantly higher (e.g., at  $c_e = 10\%$  it was about 100 per cent higher), with Cyanex 302 significantly lower (Figure 1), and with MOOP slightly lower.  $c_0^{\text{Co}}$  obtained from a mixture was always higher than from samples containing a single metal, and the highest difference was observed with Cyanex 302 (e.g., at  $c_e = 10\%$  it was about 120 per cent higher). Additionally, for both metals, at the initial phase volume ratio 0.5, the difference increased with increase in extractant concentration. The effect of Cyanex 302 concentration on cobalt concentration in the organic phase is shown in Figure 2.

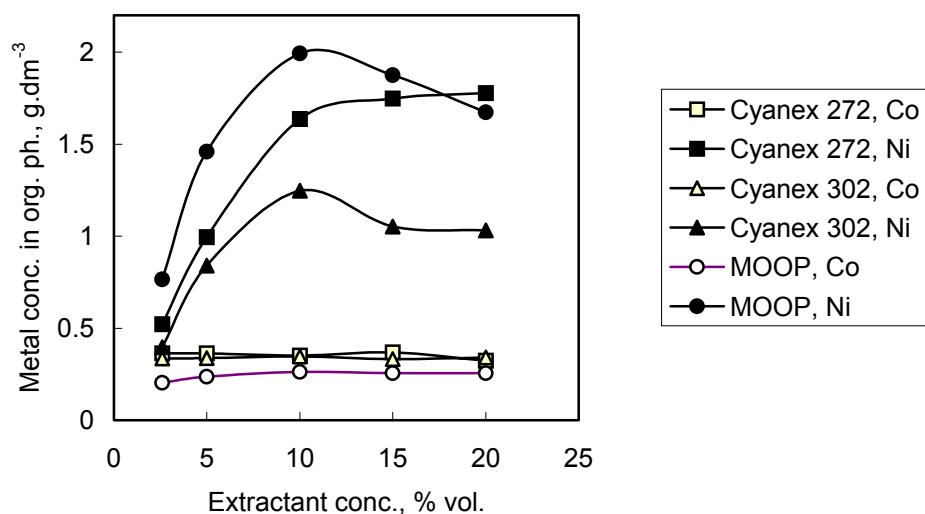

**Figure 1.** Effect of Cyanex 302 and Cyanex 272 concentration on nickel(II) extraction In the organic phase and comparison of extraction from samples containing a single metal ( $Ni_s$ ) and a mixture with cobalt(II) ( $Ni_m$ ) [  $pH^i = 8$ ,  $c^i_{Ni} = 2.3 \text{ g.dm}^{-3}$ ,  $c^i_{Co} = 0.15 \text{ g.dm}^{-3}$ ,  $r^i = 0.5$  ].

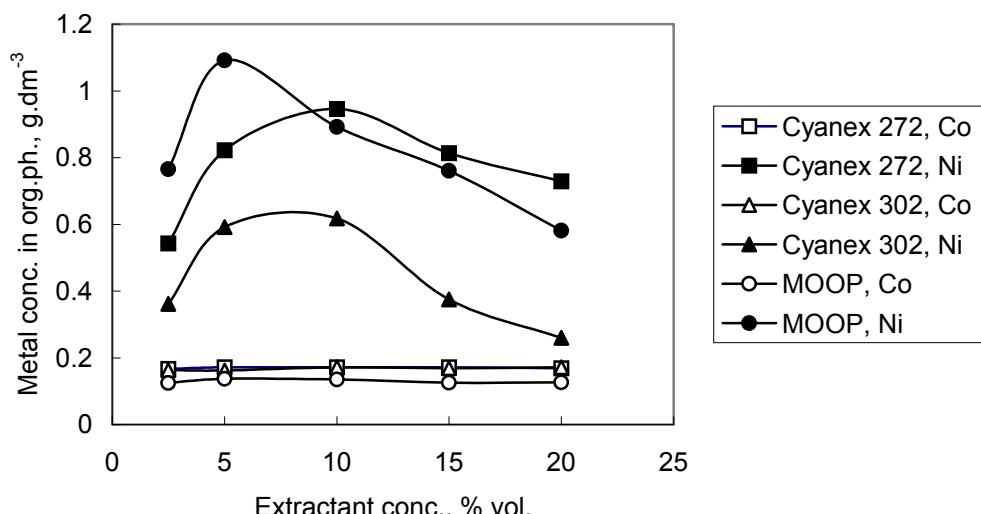

**Figure 2.** Effect of Cyanex 302 concentration on cobalt(II) concentration in the organic phase at different initial phase volume ratios and comparison of extraction from samples containing a single metal ( $Co_s$ ) and mixture with nickel(II) ( $Co_m$ ). [  $pH^i = 8$ ,  $c^i_{Ni} = 2.3 \text{ g.dm}^{-3}$ ,  $c^i_{Co} = 0.15 \text{ g.dm}^{-3}$  ].

In Figures 3. and 4 results of extraction from a mixture of metals with different extractants at two initial phase volume ratios are compared.

Extractant concentration produced a stronger effect on extraction of nickel than on extraction of cobalt at both investigated initial phase volume ratios. At the initial phase volume ratio 0.5, the highest nickel concentration in the organic phase was obtained with MOOP over Cyanex 272 and Cyanex 302 in the full range of extractant concentrations, except at 20 vol. % where MOOP and Cyanex 272 reached the same value. Significant influence of extractant concentration was observed. Under identical conditions cobalt concentration was not influenced by a change in extractant concentration, and higher concentrations were obtained with Cyanex 272 and Cyanex 302.

*Figure 3. Effect of concentration of different extractants on cobalt(II) and nickel(II) concentration in the organic phase  $r = 0.5$ . [  $pH^j = 8$ ,  $c_{Ni}^j = 2.3 \text{ g} \cdot \text{dm}^{-3}$ ,  $c_{Co}^j = 0.15 \text{ g} \cdot \text{dm}^{-3}$  ].*

*Figure 4. Effect of concentration of different extractants on cobalt(II) and nickel(II) concentration in the organic phase at  $r = 1$ . [  $pH^j = 8$ ,  $c_{Ni}^j = 2.3 \text{ g} \cdot \text{dm}^{-3}$ ,  $c_{Co}^j = 0.15 \text{ g} \cdot \text{dm}^{-3}$  ].*

At the initial phase volume ratio 1, metal concentrations in the organic phase were generally lower than at initial phase volume ratio 0.5, and the effect of extractant concentration was similar, *i.e.*, it was present for nickel and absent for cobalt. The only difference concerned nickel extraction, as the highest nickel concentration in the organic phase at extractant concentrations over 10 vol. % was achieved with Cyanex 272.

Results obtained could be explained only partly by increase in the number of organic sites, by increase in extractant concentration, and, by a higher content of metal in the system at the initial phase volume ratio 0.5.

Presented results differ from those of Tait [6] who obtained increased concentration of both metals in the organic phase as a result of increase in extractant concentration. However, higher metal concentrations, a modifier and a different type of diluent were used.

The change in equilibrium pH in the systems prepared at initial pH 8, as a result of change in extractant concentration, was also measured. Decrease in equilibrium pH with increase of extractant concentration at constant initial pH depended not only on the extractant, but also on the type of the metals present, and on their concentration.

The highest distribution ratios of cobalt were achieved with Cyanex 302 at the initial phase volume ratio 0.5. At all extractant concentrations they were over 110. These distribution ratios were much lower than the maximum distribution ratio reported previously [4] for lower cobalt concentrations at the same initial pH. The distribution ratio of cobalt calculated for Cyanex 272 at the same initial phase volume ratio increased with increase in extractant concentration and achieved the highest value ( $D_c^{Co} = 108$ ) at extractant concentration 20 vol. %. In all other cases the effect of extractant concentration was evident to a greater or lesser extent, but highest distribution ratios of cobalt were below 60. As expected, on the basis of changes in metal concentrations in the organic phase, the distribution ratio of nickel was strongly influenced by extractant concentration. In all systems its maximum value was between extractant concentration 5 and 15 vol. %. The highest distribution ratios for nickel were achieved with MOOP ( $D_c^{Ni} = 1.45$ ,  $c_e = 20$  vol. %) and Cyanex 272 ( $D_c^{Ni} = 1.27$ ,  $c_e = 20$  vol. %) at the initial phase volume ratio 0.5.

The separation factors ( $\alpha$ ) as a result of changes of distribution ratios, mostly those of nickel, also show significant changes with increase in extractant concentration. In the case of Cyanex 272 and Cyanex 302, at both initial phase volume ratios, the minimum value of separation factor appeared at extractant concentration between 5 and 15 vol. %.

Table 1 shows the highest separation factors obtained with Cyanex 302 and Cyanex 272 and corresponding experimental conditions. The separation factors obtained with MOOP were between 15 and 36 in all cases.

*Table 1. Separation factors for Cyanex 302 and Cyanex 272.*

r	$C_e$ , % vol.	$\alpha_{Co/Ni}^{Co}$	
		Cyanex 272	Cyanex 302
0.5	2.5	233	558
	20.0	85	196
1.0	2.5	139	429
	20.0	122	330

## CONCLUSIONS

Comparison of metal extraction from samples containing a mixture of metals and those with a single metal confirmed the existence of a mutual effect of metals, noticed in our previous investigations of similar systems. Extraction was influenced by extractant concentration, but the extent and mode of that effect were different, and depended among others, also on the initial volume ratio and on the type of metal. Results showed that under given experimental conditions Cyanex 302 was a better extractant for the separation of cobalt from nickel at all extractant concentrations and both investigated initial volume ratios, than Cyanex 272 and MOOP.

## ACKNOWLEDGEMENT

Financial support of this investigation by the Ministry of Science and Technology of the Republic of Croatia Grant No 124003 is kindly acknowledged. Authors thank Prof. Dubravka Maljkovic for her useful discussions concerning the experiment design and the preparation of this paper. Supply of samples of extractants by Cytec Canada Inc. (Cyanex 272 and Cyanex 302) and Bayer AG, Germany, (MOOP) is greatly appreciated.

## NOMENCLATURE

### Symbols

c - concentration, g.dm<sup>-3</sup>

D<sub>c</sub> - distribution ratio

r - volume ratio of the organic to the aqueous phase

α - separation factor

### Subscripts and superscripts

Co - of cobalt

Ni - of nickel

e - of extractant

i - initial

m - extracted from mixture of both metals

o - in the organic phase

s - extracted from sample containing single metal

## OPTIONS FOR COPPER(II) AND ZINC(II) EXTRACTION FROM CHLORIDE MEDIA WITH BI-FUNCTIONAL EXTRACTANTS

Aleksandra Borowiak-Resterna, George Kyuchoukov\* and Jan Szymanowski

Poznan University of Technology, Poznan, Poland  
\*Bulgarian Academy of Sciences, Sofia, Bulgaria

Extraction of copper(II) and zinc(II) from acidic chloride solutions with mixtures of two extractants: a basic or solvating one and a chelating extractants are discussed. The processes for recovery and separation of copper(II) from zinc(II) are proposed. The processes consist of the following steps: extraction from chloride media with the formation of metal chlorocomplex ion pair or solvate, scrubbing of chloride ions with an aqueous solution of appropriate pH with simultaneous transfer of the metal ion to the chelate, traditional stripping with sulphuric acid and conditioning of the basic extractant. Both effective recovery and separation of metal ions with simultaneous change of the system from the chloride to sulphate one can be achieved. A bi-functional extractant, such as derivatives of 8-hydroxyquinoline, can also be used in place of a mixed extractant system.

### INTRODUCTION

Hydroxyoximes are well known extractants and are widely used to recover copper(II) from dilute acidic sulphate solutions [1].  $\beta$ -diketones are used for the extraction of copper(II) from ammoniacal etching solutions obtained in circuit board manufacture [1]. Both hydroxyoximes and  $\beta$ -diketones are chelating reagents (HL). The stable chelate complexes are formed and extracted, but the reaction is reversible and equivalent amounts of protons are liberated.

As a result, the reagents are not convenient for the processing of concentrated copper(II) solutions which can be obtained by the leaching of sulphide ores, e.g., with  $FeCl_3$  or  $CuCl_2$ . In this case the leaching solution (pH 3) can contain 0.2-1.0 M copper(II) and ferric ions and 4-6 M  $Cl^-$ . Under such conditions copper(II) is mainly in the form of chlorocomplexes and can be effectively extracted with solvating reagents (S) [2].

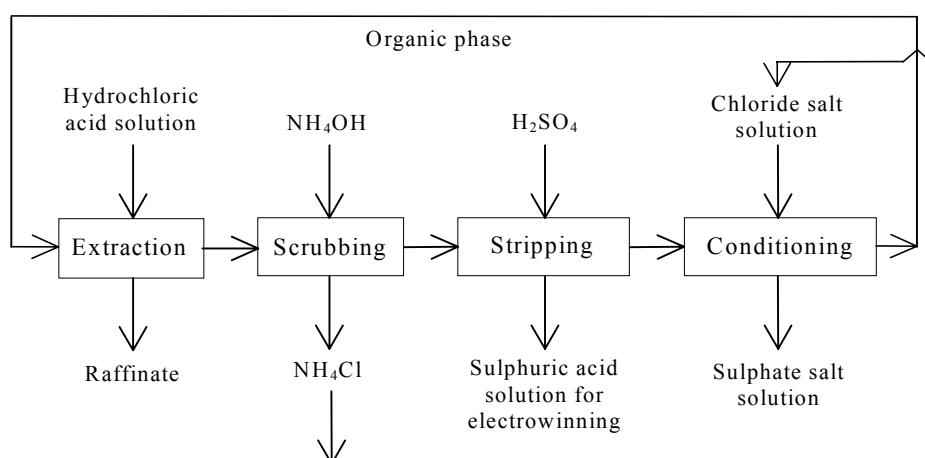

Such a commercial reagent, ACORGA CLX 50, was produced by ZENECA (now Avecia) and the CUPREX process was developed based on it [3]. The main drawback of the extraction of copper(II) from chloride solutions with solvating reagents is the stripping with water and subsequent electrowinning from chloride media. Reactive granules of copper with well-developed surface area are produced instead of traditional copper sheets.

In this paper possibilities are explored to recover copper(II) from acidic chloride solutions with mixed extractants, or with a bi-functional extractant, to obtain loaded sulphate solution suitable for classical electrowinning of the metal. Leaching of copper sulphide ores and etching of copper covered goods can give such chloride solutions. In the first case the solution also contains large amounts of iron. Chloride leaching is also important for processing of ores and wastes containing zinc alone and alloys of copper and zinc. Thus, depending on the system the extractant must be selective for copper over iron or zinc and effectively extract metal species from highly concentrated chloride solutions at appropriate acidity of the aqueous feed. Proprietary extractants and model compounds synthesised mainly by the authors are considered. The proposed processes and conditions are the results of the author's own investigations.

### CONCEPTUAL FLOWSHEET FOR RECOVERY OF METAL CHLORO-COMPLEXES

A conceptual flowsheet for a process based on the use of mixed extractants (one basic or solvating and one chelating reagent) or a bi-functional extractant is shown in Figure 1.

*Figure 1. Flowsheet of the process proposed for metal(II) recovery from chloride media with simultaneous change of the system from chloride to sulphate.*

In the extractant systems the basic or solvating reagent can extract metal ions present in the form of anionic chloro-complexes or neutral chloro-complex, respectively. When the organic phase is then scrubbed with an aqueous solution the complex is decomposed and liberated chloride anions are transferred to the aqueous phase, while the metal cations remain in the organic phase as complexes with the chelating reagent. In such a case, a traditional stripping with sulphuric acid of appropriate concentration and then conventional electrowinning can be carried out. Depending on the type of reagent used to extract copper from chloride solutions the process can be selective (a solvating reagent) or not-selective (a basic reagent) with respect to iron(III) or zinc(II). Depending then on the type of the chelating reagent and the type of metal, water at different adjusted pH must be used for scrubbing of chloride ions to prevent the simultaneous stripping of metal ions.

## SOLVENT-EXTRACTION CHEMISTRY

Most of the common metal ions form chloro-complexes in chloride media. At comparable conditions the chloro-complex formation constants change in the following order:  $\beta_i(\text{Fe}) > \beta_i(\text{Zn}) > \beta_i(\text{Cu})$ . This means that negatively charged chloro-complexes are more readily formed with iron(III) and zinc(II) than with copper(II). This results in a poor selectivity for zinc(II), and especially for copper(II) extraction from highly concentrated chloride media with basic extractants carried out in the presence of iron(III). However, it also reveals some possibilities for separation of zinc(II) from copper(II).

The basic extractant is easily protonated in a contact with an acidic aqueous chloride solution:

This means that the amine hydrochloride can be decomposed by a decrease of the acidity and/or chloride content in the aqueous phase. The amine hydrochloride can bind the second molecule of the hydrochloric acid transferring it to the organic phase:

The reaction is favoured by a high concentration of the hydrochloric acid [4]. A basic extractant can also be protonated in a contact with aqueous acidic solutions containing metal chloro-complexes. The reaction can occur even more readily than reaction (4), especially for  $\text{ZnCl}_4^{2-}$ :

A basic extractant treated with a sulphuric acid solution gives two products:

The equilibrium of these two reactions depends on the concentration of sulphuric acid. In low acidity, depending on the basicity of amine, reaction 7 is favoured. However, when treated with 1 *M* sulphuric acid ammonium hydrogensulphate is mainly formed. It can bind the second molecule of sulphuric acid.

Hydrogensulphate or sulphate forms can be readily transferred to the chloride form by treating with a chloride solution, e.g., with 2.8 *M* NaCl solution:

Metal chlorocomplexes can be extracted by the amine hydrochlorides according to reaction:

The reaction with  $\text{MCl}_3^-$  and the neutral chlorocomplex  $\text{MCl}_2$  are also possible, e.g.:

The amine metal chlorocomplex can also bind one additional molecule of hydrochloric acid, i.e.,  $\text{MCl}_4(\text{HB})_2 \cdot \text{HCl}$  [5].

The amine metal chlorocomplex can be decomposed by treating with an aqueous solution of low concentration of chloride ions. The extractant can also undergo deprotonation.

The scrubbing of the metal cation to the aqueous phase can be neglected when the organic phase contains appropriate quantities of a chelating extractant (or an acidic extractant); and the acidity of the aqueous phase is low enough to permit the formation of the chelate according to reaction similar to Equation (1). The process can be described as follows:

When a solvating extractant is used instead of an amine the protonation of the reagent can be avoided but the extraction must be carried out from weakly acidic solutions (Equation (2)).

### TECHNOLOGICAL ASPECTS

Various extractants can be selected for extraction (Table 1). The following parameters should be considered: compatibility of structure and properties, including the mutual reactivity and extraction capacity, selectivity and kinetics of extraction, compatibility of extractants to the composition and acidity of the aqueous phase in each step of the separation process, physicochemical properties of solutions in each separation step, molar ratio of extractants, their concentrations in the solvent and the phase volume ratio.

*Table 1. Extractants and process conditions.*

Extractants	Extraction	Scrubbing	Stripping
ALAMINE 336/LIX 54 Synergistic mixture	Up to 130 g/L Cu(II), 3 M HCl and 7 M Cl <sup>-</sup>	Equilibrium pH 6 - 7	Even 0.04 M H <sub>2</sub> SO <sub>4</sub>
ACORGA CLX 50/LIX 54	pH 3, 4-6 M Cl <sup>-</sup> Selective in respect of Fe(III)	Equilibrium pH ≥ 6 - 7	Even 0.04 M H <sub>2</sub> SO <sub>4</sub>
N,N,N',N'-tetrahexyl- pyridine-3,5-dicarboxamide /2-hydroxy-5-t-octylbenzo- phenone oxime	pH 3, 0.1 - 6 M Cl <sup>-</sup> Selective in respect to Fe(III)	Water	1.7 M H <sub>2</sub> SO <sub>4</sub>
N,N,N',N'- tetrahexylpyridine-3,5- dicarboxamide/1- phenyldecane-1,3-dione	pH 3, 5 - 6 M Cl <sup>-</sup> Selective in respect of Fe(III)	Equilibrium pH ≥ 3.8	0.25 M H <sub>2</sub> SO <sub>4</sub>
KELEX 100 or LIX 26 Zn/Cu separation	Up to 130 g/L Cu(II), 3 M HCl and 7 M Cl <sup>-</sup>	Equilibrium pH 2 - 9 for Cu(II) and 7 - 8 for Zn/Cu separation	2.8 M H <sub>2</sub> SO <sub>4</sub>

The extractants used must not react with each other. Their co-association via hydrogen bonding should also be avoided. A mixture of ALAMINE 336 and LIX 860 can be given as an example of an incompatible pair of extractants. Using this mixture for extraction of copper(II) from acidic chloride solutions an important drop in extraction capacity is observed [4]. Reagents having an appropriate selectivity, especially with respect to iron(III) should be used, *i.e.*, the use of a solvating reagent instead of alkylamines is favoured, permitting the selective extraction of copper(II) and zinc(II) in the presence of iron(III).

Kinetics of extraction should not be worse with the mixed extractants. Again, it means that the concentrations of the active forms of extractants should not be decreased. A good compatibility of reagents should also be assured in the scrubbing and stripping steps.

In scrubbing, chloride ions must be qualitatively washed out but metal ions should be completely transferred from the metal ion pair, or solvate, to the chelate. The removal of chloride ions can be easily accomplished using an aqueous solution at relatively broad range of acidity. However, to obtain full chelation the acidity of the scrubbing solution must be adjusted to the extraction ability of chelating extractant. The limiting pH of the scrubbed solution depends both on extractant and on the metal ion considered, and a higher and lower pH is needed for the scrubbing of chloride ions from the organic phase containing zinc(II) and copper(II), respectively.

In stripping, besides the transfer of the metal ions to the acidic sulphate solution, the undesired protonation of the basic extractant occurs. The solvating extractant (e.g., ACORGA CLX 50) can also be protonated depending on the basicity of the nitrogen atom in the pyridine moiety and the concentration of sulphuric acid. The phenomenon should not result in any precipitation of the extractant and emulsification of the system. A good and quick separation of phases must be obtained in each step of the process.

Molar ratio of extractants, their concentrations and volume phase ratio are important for two reasons. First, the chelating reagent must be able to bind the metal ion released in the scrubbing from the metal ion pair, or from the solvate. Moreover, the chelation must compete kinetically with the scrubbing. A use of a small excess of the chelating reagent (10 mol%) is recommended. Second, the separation of metal ions is easier near the capacity of extractants. The crowding effect permits the dismissal of metal ions weakly bound by the extractant. The concentration of the extractants and/or the phase volume ratio can be adjusted to achieve a high loading of the organic phase.

## EXTRACTION WITH MIXED REAGENTS

### **ALAMINE 336-LIX 54 [4, 6-8].**

ALAMINE 336 and LIX 54 are the basic and chelating extractants, respectively. The extractants are mutually compatible and useful for the recovery of copper(II) from hydrochloric acid etching solutions obtained in circuit printed board manufacture (130 g/L copper(II), 2.8-2.9 M HCl and 7 M Cl<sup>-</sup>). A strong synergistic effect is observed. 30% solution of ALAMINE 336 in kerosine extracts about 16 g/L copper(II) from the etching solution. LIX 54 does not extract copper(II), but a 30:70 mixture of ALAMINE 336 and LIX 54 extracts ~20 g/L copper(II). The synergistic effect is especially strong when copper(II) is extracted from 1 M HCl. In such a case, the mixture of reagents permits the extraction 10 g/L copper(II), whilst individual components extract only negligible amounts of copper(II). Scrubbing must be carried out with an ammoniacal solution to obtain the equilibrium pH 6-7. The stripping can be carried out with a very diluted sulphuric acid (even 0.04 M at the equilibrium). However, the concentration of 1.5 M is recommended to obtain the acidity typical for electrowinning. The mixture can also be used to separate copper(II) from zinc(II) [9].

### **ACORGA CLX 50-LIX 54 [10]**

ACORGA CLX 50 acts as a solvating reagent at pH 3 and efficiently extracts neutral chloro-complex of copper(II) from solutions containing 4 - 6 M Cl<sup>-</sup>. An equimolar mixture of ACORGA CLX 50 and LIX 54 extracts copper(II) in comparable amounts to ACORGA CLX 50 from aqueous chloride solutions above 2 M at pH 3. At lower concentrations of chloride ions an important coextraction of copper(II) by LIX 54 is also observed. The scrubbing of chloride ions must be carried out with an ammonia solution to neutralise hydrogen cations liberated in chelation with LIX 54. The equilibrium pH cannot be lower than 6. The system is suitable for practical applications in the presence of large amounts of iron(III).

### **N,N,N',N'-tetrahexylpyridine-3,5-dicarboxamide (a) / 2-Hydroxy-5-t-octylbenzophenone oxime (b) [11]**

The equimolar mixture of an amide analogue of CLX 50 (a, above) and a LIX 65 type oxime (b, above) permits effective extraction of copper(II) from chloride media and the transfer of copper from solvate ( $\text{CuCl}_2\text{B}_2$ ) to the chelate ( $\text{CuL}_2$ ) by scrubbing with water. The effect of chloride concentration on the extraction of copper(II) is almost negligible. However, at low ( $0.1 \text{ M}$ ) chloride concentration copper is mainly bound with the oxime in the chelate (74 %) and at high ( $5 - 6 \text{ M}$ ) chloride concentration with the amide in the solvate (92 %). The oxime is a strong enough extractant to bind copper(II) when the organic phase is scrubbed with water. In this case only 5 - 16 % of copper(II) with respect to that present in the aqueous feed is transferred back with chloride ions to the aqueous phase, while 58 - 51 % remains in the organic phase in the form of the chelate, and the rest in the form of the chloro-complex solvate. Although copper is successfully transferred from the solvate to the chelate the system needs additional washing of the organic phase before recycling for extraction. Sulphuric acid (170 g/l) must be used for stripping. In such a case some protonation of the pyridine function and its deprotonation must be obtained before recycling the organic phase. In another case the reagent would complex iron chloro-complexes in the form of an ion pair. As a result, the system is not suitable for recovery of copper(II) in the presence of iron(III).

### **N,N,N',N'-tetrahexylpyridine-3,5-dicarboxamide (a) / 1-Phenyldecane-1,3-dione (c) [11]**

The equimolar mixture of (a, above) and a LIX 54 type dione (c, above) permits effective extraction of copper(II) from chloride media and the transfer of copper(II) from the solvate to the chelate; by scrubbing with an ammoniacal solution. In this case, when the ammoniacal solution is used for scrubbing only small amounts of copper(II) (3 - 6 %) are transferred back to the aqueous phase. The equilibrium pH after scrubbing cannot be lower than 3.8 and 5.7 for the concentration of chloride ions in the initial feed equal to  $5 - 6$  and  $0.1 - 1 \text{ M}$ , respectively. Copper(II) can be then stripped with dilute sulphuric acid solutions containing at least 25 g/L  $\text{H}_2\text{SO}_4$ . At such concentration of sulphuric acid a significant protonation of the pyridine function is not observed. The use of the system for recovery of copper(II) from chloride solutions is proposed.

## **EXTRACTION WITH BIFUNCTIONAL EXTRACTANTS KELEX 100 AND LIX 26**

The 8-hydroxyquinoline derivatives, KELEX 100 and LIX 26, can act as a chelating extractant (Equation (1)), or as a basic extractant after protonation (Equation (9)). The reagent must be used with a modifier (about 15 v/v% octanol) to avoid the formation of the third phase. The process was developed to recover copper(II) from etching solutions containing 120 g/L copper(II),  $2.9 \text{ M HCl}$  and  $6.8 \text{ M Cl}^-$  [5, 12-14]. The recovery of copper(II) and zinc(II) from brass leaching solutions is also possible. An ammonium solution must be used for scrubbing of chloride from organic solution containing copper(II) with the equilibrium pH changed in the broad range from 2 to 9. In the case of the organic phase loaded with zinc(II) the equilibrium pH must be adjusted to 7-8 [13, 14]. Stripping of copper(II) and zinc(II) can be carried out in one stage with  $2.8 \text{ M H}_2\text{SO}_4$ . A lower concentration of sulphuric acid can be also used, especially for the stripping of zinc(II), e.g.,  $0.5 \text{ M}$ . In such a case KELEX 100 is only slightly protonated. The organic phase must then be treated with waste hydrochloric acid solution to obtain full protonation and the scrubbing of sulphate ions. Thus, it is more convenient to use more concentrated sulphuric acid for stripping and then  $4.7 \text{ M NaCl}$  or  $\text{NH}_4\text{Cl}$  for the replacement of sulphate by chloride anion.

The separation of copper(II) from zinc(II) can be accomplished at the stage of extraction, scrubbing or stripping. The separation at the extraction stage, chemically easier to accomplish, is technologically less attractive because two parallel loops for copper and zinc streams have to be considered for the next stages. Thus, technologically and economically

the most attractive option is the separation in the stripping stage. The separation can be accomplished by the selective stripping of zinc(II) with the equilibrium sulphuric acid concentration in the range of 0.1 - 0.5 M. The stripping of zinc(II) is not complete below 0.1 M, while the stripping of copper(II) is observed above 0.75 M. Thus, the initial concentration for the stripping of zinc(II) should be in the range 0.25 - 0.8 M. Copper(II) can be stripped with 3 M sulphuric acid. Two stages for complete stripping are needed. Sulphuric acid of lower concentration can also be used but more stages are needed.

## CONCLUSION

Mixed extractants containing a basic or solvating extractant with a chelating extractant permits the recovery of copper(II) and zinc(II) from acidic chloride solutions with the change from a chloride to a sulphate system. As a result, the traditional electrowinning from the sulphate solution can be carried out. The method is also suitable to separate copper(II) from zinc(II) that can be achieved at the stage of extraction, scrubbing or stripping. The use of ALAMINE 336 and LIX 54 is proposed when iron(III) is absent or ACORGA CLX 50 and LIX 54 when Fe(III) is present in the aqueous feed. KELEX 100 and LIX 26 can be considered as bi-functional extractants (a basic and chelating extractant) and can be used in place of mixed extractants to recover both copper(II) and zinc(II) from chloride acidic solutions in the absence of iron(III) and to separate these metal ions at the stage of extraction, scrubbing or stripping.

## IMPURITY REMOVAL FROM COPPER TANKHOUSE LIQUORS BY SOLVENT EXTRACTION

M. Cox, D. S. Flett, T. Velea\* and C. Vasiliu\*

Department of Physical Sciences, University of Hertfordshire, UK  
\*IMNR SA, Bucharest, Romania

A possible flowsheet for the removal of As, Sb and Bi from copper electrorefinery electrolytes has been developed for the Allied Deals Phoenix SA plant at Baia Mare in Romania where the feed to the smelter is a complex ore containing quite high levels of As, Sb and Bi. From a literature survey three commercial solvent extraction reagents, namely LIX 1104®, CYANEX 923® and Acorga SBX 50® were selected for screening. From this preliminary work, CYANEX 923 was selected as the preferred reagent. This paper describes the results of the screening tests and the further work undertaken to develop a workable process for the removal of As, Sb and Bi from the copper tankhouse electrolyte at Baia Mare with CYANEX 923.

### INTRODUCTION

In copper refineries, the total monthly volume of bleed electrolyte from the tankhouse is quite high and the flowrate of the bleed stream is determined by impurity levels of which the most important is As, with lesser importance put on Sb and Bi. At the Allied Deals Phoenix plant at Baia Mare in Romania, quite high amounts of As, Sb and Bi arise from the complex ore feed. According to the company, the maximum impurity concentration at which the electrolyte is removed is 4 g/l As; 1.2 g/l Sb and 0.008 g/l Bi. Solvent extraction has been shown by several authors to be a promising technique for As, Sb and Bi removal from copper tankhouse electrolytes [1-3], and was chosen in this study for application to the problem of impurity control at Baia Mare.

Impurity control by solvent extraction in copper electrorefining has been demonstrated in numerous studies and also in plant practice. Thus tributylphosphate (TBP) is employed to extract arsenic at several copper electrorefineries around the world [1]. This extractant only extracts As(V). Dreisinger *et al.* [2, 3] investigated a large number of extractants and found that, among the solvating extractants, dibutylbutylphosphonate (DBBP) and dipentylpentylphosphonate (DPPP) were stronger extractants for arsenic than TBP and that Sb could be extracted by a mixed reagent (2EHAPo<sub>4</sub>, Albright and Wilson). The extraction of As, Sb and Bi with a commercial hydroxamic acid (LIX 1104®, Cognis) has been described by Schwab and Kroke [4] and others [2, 3]. Stripping of arsenic was difficult and H<sub>2</sub>S or anhydrous sodium sulphide were proposed as strippers. Iron is also co-extracted but can be stripped with HCl. The trialkylphosphine oxide reagent CYANEX 923® (Cytec Inc.) has been studied by Wisniewski and co-workers as an extractant for both As(III) and As(V) [5-8]. These authors have compared this reagent with ENIM 100®, TBP, 2-methylhexanol [7] and neodecanohydroxyamic acid [8]. Extraction equilibrium was established in 5 minutes with CYANEX 923 compared to 15 minutes for the hydroxamic acids; arsenic extraction increased with increasing H<sub>2</sub>SO<sub>4</sub> concentration and H<sub>2</sub>SO<sub>4</sub> was co-extracted. Choice of diluent was important for CYANEX 923 with toluene being a better diluent than Exxsol D 220/230® [8].

Arsenic could be stripped with water, and four extraction and three stripping stages were concluded to be sufficient to effectively extract and strip As [8] although the reported results for water stripping do not bear this out. Removal of arsenic from a copper speiss leach liquor using CYANEX 923 has been reported by Newell [9] who obtained results similar to Wisniewski's but did not address arsenic stripping. Using an actual speiss leach liquor containing 28.5 g/l As; 44.9 g/l Cu; 0.06 g/l Fe; 1.25 g/l Sb and 8.6 g/l Ni, it was also shown that Fe but not Cu and Sb was co-extracted. Zeneca (now Avercia) developed a new alkylphosphonic acid (Acorga SBX 50<sup>®</sup>) for the extraction of Sb and Bi, but not As from copper tankhouse electrolytes [10].

Based on the above literature survey it was decided to screen LIX 1104, CYANEX 923 and SBX 50 for the removal of As, Sb and Bi from the Baia Mare copper refinery electrolyte. TBP was not selected as it only extracts As(V) and not As(III).

## EXPERIMENTAL

The extractants LIX 1104 SM<sup>®</sup>, CYANEX 923 and SBX 50 were kindly supplied by Cognis Mining Chemicals, Cytec Industries B.V. and Avercia, respectively. These were used as received. The diluents used were Orform SX 7<sup>®</sup> from Philips Petroleum and kerosene from Combinatul Petrochimic Pitesti, Romania. Synthetic solutions of As, Sb and Bi were prepared from analytical grade arsenic acid, bismuth chloride and antimony oxide by dissolution in H<sub>2</sub>SO<sub>4</sub>. An actual liquor from Baia Mare assaying 1.3 g/l As; 0.16 g/l Sb; 0.063 g/l Bi, 0.073 g/l Cl<sup>-</sup>, 0.33 g/l Fe, 38.5 g/l Cu and 172 g/l H<sub>2</sub>SO<sub>4</sub> was also used in the testwork.

For the work carried out in the UK, metal ion analyses were carried out using a Perkin Elmer ICP spectrophotometer. For the analyses at IMNR an OES-DCP Beckman (SUA) Spectaspan V was used. As appropriate, H<sup>+</sup> and Cu<sup>2+</sup> were analysed electrochemically and SO<sub>4</sub><sup>2-</sup> was determined gravimetrically.

## ALLIED DEALS PHOENIX (BAIA MARE) OPERATIONS

Currently the flash furnace at Baia Mare is undergoing refurbishment. However on start-up the maximum levels of impurities anticipated by the company in the tankhouse bleed will be 5-6 g/l As; 1.2 g/l Sb and 0.01 g/l Bi. An operating level of 2 g/l As; 0.8 - 1 g/l Sb and 0.005 g/l Bi has been chosen as the goal for this study.

## RESULTS AND DISCUSSION

### Screening Tests

Screening tests with the three selected extractants were carried out on individual synthetic solutions of 100 ppm As, Sb and Bi in 2 M H<sub>2</sub>SO<sub>4</sub> using 50 v/o CYANEX 923 and 10 v/o LIX 1104.

As and Sb extraction with CYANEX 923 was fast (< 2 minutes), decreased with increasing temperature but increased with increasing H<sub>2</sub>SO<sub>4</sub> concentration as reported by Wisniewski for As [8]. Bi was not extracted from the 100 ppm solution of the element. Sb could be stripped readily with water but As was less easily stripped requiring elevated temperature (60 °C).

With LIX 1104, As extraction was very slow, 90 minutes at 60 °C for >90% extraction. Extraction increased with increasing temperature in agreement with literature data [4]. LIX 1104 also extracted Sb and Bi well and faster than As. Increasing temperature decreased the degree of extraction of Sb and Bi. Because of the poor As extraction kinetics; the need to use H<sub>2</sub>S or CuSO<sub>4</sub> for As stripping and a chloride solution for Sb and Bi stripping, which then required a water wash to remove organic phase chloride to avoid transfer to the refinery electrolyte, no further work was carried out with LIX 1104.

With 10 v/o SBX 50 good extraction of Sb and Bi was obtained at ambient temperature (18 °C). Sb and Bi extraction decreased with increasing temperature. From the literature [10], stripping of Sb and Bi can only be sensibly carried out with acid chloride liquors. Stripping tests in this work confirmed this.

With real electrolyte solutions however, CYANEX 923 extracted all three impurities well. The extraction of Bi is probably due to the presence of chloride in this liquor compared with the synthetic liquor. For Sb, where addition of chloride was required to prevent hydrolysis in the synthetic solution, it appeared that Sb extraction from this liquor was probably as an antimony chloro-complex. Co-extraction of sulphuric acid [2, 5] and water [8], as expected, also occurred.

Tests were also carried out on real solutions with SBX 50. It was found that Sb extraction was better than from the synthetic solutions. This may be due to the higher concentration of chloride in the synthetic solutions. Stripping tests with 2.5 M CaCl<sub>2</sub> and 1 M HCl showed excellent recovery of Sb, but Bi was not totally stripped. According to Cupertino *et al.* [10] Bi removal requires 0.5 M HCl and 6 M Cl<sup>-</sup> to strip 195 ppm from the organic phase so better Bi stripping should be possible with higher chloride concentrations.

From these results it was concluded that the best extractant for all three impurities was CYANEX 923, and so further work was carried out with this reagent.

### Extraction Isotherms

Extraction isotherms (Figures 1 to 3) have been obtained for As, Sb and Bi at different temperatures (20, 40 and 60 °C) for the refinery electrolyte enriched in arsenic by addition of As(V) to 17.2 g/l. The As isotherms in Figure 1 show that As(V) extraction decreases with increasing temperature. From McCabe-Thiele construction it can be seen that two stages at 60 °C at an O/A ratio of 10:1 are required to remove arsenic to the required level of 2 g/l or below.

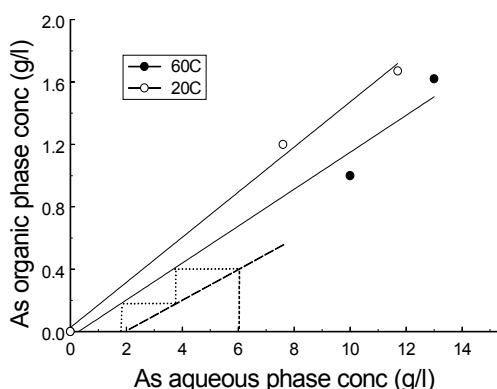

Figure 1. As extraction isotherm with 50% CYANEX 923 in kerosene.

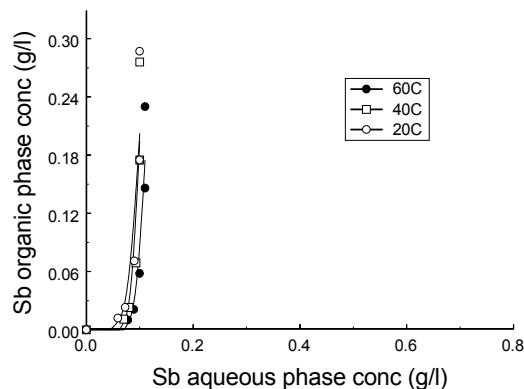

Figure 2. Sb extraction isotherm with 50% CYANEX 923 in kerosene.

Figure 2 shows that Sb extraction decreases slightly with increasing temperature. From the shape of the curves it is obvious that the conditions for As extraction would be more than sufficient to remove Sb to the required level of 0.8 - 1 g/l.

Figure 3 also shows that Bi extraction decreases slightly with increasing temperature. From the diagram it seems that it might be difficult to remove Bi to < 0.005 g/l but, at these levels, analysis of Bi is at the limit of determination.

Co-extraction of sulphate from the same feed as for Figures 1, 2 and 3 is also shown in Figure 4. This shows that significant amounts of sulphate are co-extracted. As sulphate ion is not believed to be involved to any significant degree with the extraction of As, Sb and Bi, this verifies the large co-extraction of sulphuric acid reported by other authors [2, 3, 5]. From Figures 1 and 2 the value of the separation factor for As over  $\text{SO}_4^{2-}$  is 0.75. This may be compared with the value of 6.25 obtained by Wisniewski [5] for 50% CYANEX 923 from 150 g/l  $\text{H}_2\text{SO}_4$  but at 50 °C. While the  $D$  values for  $\text{SO}_4^{2-}$  obtained in this work and that for  $\text{H}_2\text{SO}_4$  in Wisniewski's study are similar, i.e., 0.2 and 0.18, respectively, thus corroborating the conclusion that sulphate extraction is identical with  $\text{H}_2\text{SO}_4$  extraction, the  $D$  values for As (V) are very different, i.e., 0.15 in this work at 60 °C compared with 1.125 at 50 °C by Wisniewski [5]. For comparison, Dreisinger *et al.* [2] obtained a separation factor of 3.7 for neat CYANEX 923 also at 50 °C but from 200 g/l  $\text{H}_2\text{SO}_4$  in the presence of 30 g/l Cu. The respective  $D$  values for As (V) and  $\text{H}_2\text{SO}_4$  were 1.74 and 0.47. The reason for the apparently anomalously low distribution of arsenic found in the current study is unknown.

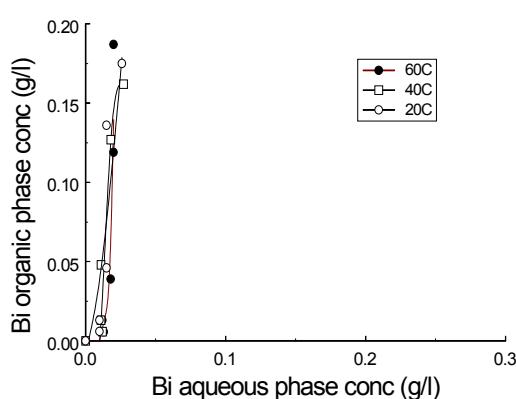

Figure 3. Bi extraction isotherms with 50% CYANEX 923 in kerosene.

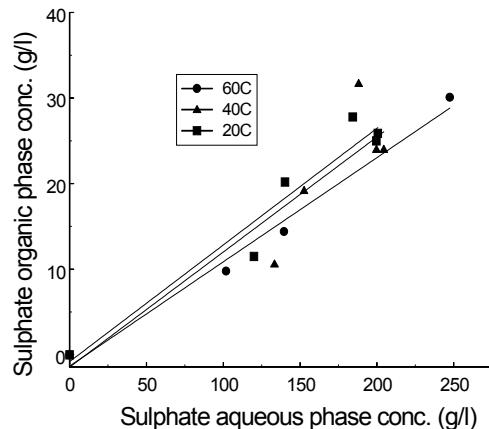

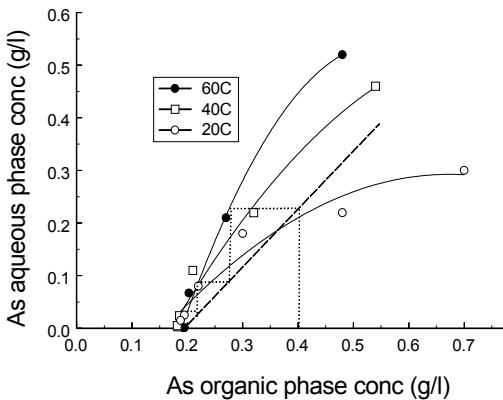

Figure 4. Sulphate extraction isotherms with 50% CYANEX 923 in kerosene.

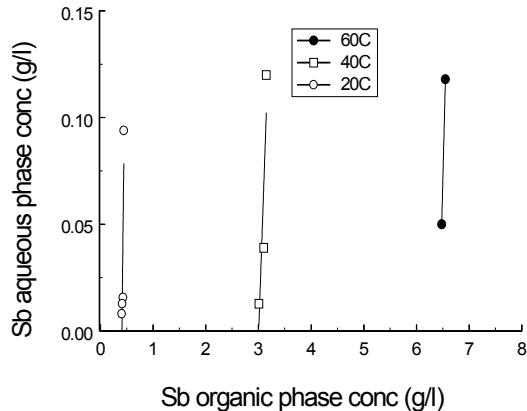

### Stripping Isotherms

Stripping isotherms for As and Sb are shown in Figures 5 and 6, respectively. The residual concentrations of As and Sb in the organic phases were calculated by difference from aqueous solution analyses. Figure 5 shows that it is not possible to fully strip As from the loaded organic phase with water and a residual concentration of ~0.2 g/l is the limit at 60 °C. This contradicts the results of Wisniewski [8] who showed that As at a concentration of ~1.4 g/l could be stripped to a residual organic phase concentration of ~0 g/l with water. It has not yet been possible to reconcile these differences.

Figure 6 shows that Sb stripping varies considerably with temperature and satisfactory stripping is only achieved at 20 °C. Even at that temperature, a residual concentration of 0.4-0.5 g/l can be expected. It is anticipated that stripping with a chloride solution will improve this performance but no results are available yet.

*Figure 5. As stripping isotherms with water.*

*Figure 6. Sb stripping isotherms with water.*

Although not shown here, Bi strips well with water and can be expected to be stripped with As.

## FLOWSCHEET DEVELOPMENT

Based on the above results the best extraction and stripping conditions for the removal of As, Sb and Bi from the Baia Mare copper refinery electrolyte are:

- a) extraction: two stages at 60 °C at an O/A ratio of 10:1;
- b) stripping: As and Bi: three stages at 60 °C with water at an A/O ratio of 2:1, Sb: stripping with a chloride solution, results awaited.

## CONCLUSIONS

Of all the extractants tested for the removal of As, Sb and Bi from the copper refinery electrolyte at Baia Mare, CYANEX 923 was shown to provide most promise for the development of a single extractant-based process. Tests on real electrolytes and electrolytes with an enhanced As content showed that, using 50 v/o CYANEX 923 in Romanian kerosene, the required operating levels of As, Sb and Bi could be achieved by extraction of the tankhouse bleed in two counter-current stages at 60 °C at an O/A ratio of 10:1. However anomalies remain with regard to the As extraction results obtained in this study and earlier published data in the literature and further work is required to resolve these. Stripping of the impurities can be achieved with water, although with the following reservations:

- a) it appears impossible to strip As below ~0.2 g/l although the indications are that Bi strips easily;
- b) Sb stripping with water is very temperature dependent with the best stripping performance being achieved at 20 °C, albeit with a residual concentration of 0.4-0.5 g/l Sb in the organic phase;
- c) two strip circuits may have to be contemplated, one at 60 °C for As and Bi and the second at 20 °C for Sb;
- d) improved Sb stripping at temperature is anticipated using a chloride solution.

## ACKNOWLEDGEMENTS

The authors would like to thank Cytec Inc, Cognis and A vecia for the supply of reagents and Philips Petroleum and Combinatul Petrochimic Pitesti for diluents. The management of Allied Deals Phoenix, Baia Mare, are also thanked for their help and the supply of electrolyte solution. Ms Auta Guta is thanked for valuable technical assistance.

This work was supported by the EU under the INCO-Copernicus Programme contract number ERB IC15 CT 98 0146.

# STUDIES OF COPPER EXTRACTION USING THE SYSTEM SCO / ISOAMYL ALCOHOL / KEROSENE / COPPER SULFATE SOLUTION

E.L. de Barros Neto, A.A. Dantas Neto, T.N. Castro Dantas,  
L. J. N. Duarte and A.C.M. de Araújo\*

\*Universidade Federal do Rio Grande do Norte, Campus Universitário, Natal, Brazil

The purpose of this work is to carry out studies on the equilibrium curves and handling of a microemulsified system containing saponified coconut oil (SCO), isoamyl alcohol, kerosene and copper sulfate solution, so as to feasibly develop a process in a countercurrent extraction column. The equilibrium data were analyzed with the aid of Langmuir and Freundlich isotherms. Better fitting was obtained with the Freundlich isotherm and as this model deals with the multilayer adsorption of the substance on the adsorbent, it can be assumed that the adsorption of copper by the surfactant within the microemulsion phase occurs on multilayers. The minimum solvent rate and the number of transfer units were determined for a column operating at a level of 30% higher than the minimum solvent rate.

## INTRODUCTION

The process of heavy metal recovery with the use of microemulsions has been studied in the laboratories of Surfactant Technology and Separation Processes at Federal University of Rio Grande do Norte (UFRN) [1-5]. Such works have proven the great efficiency of microemulsions in extracting heavy metals, close to 100 %. The representation of microemulsion extraction equilibrium through pseudophases [6-9] is based upon the fact that a microemulsion formed of micelles, water in oil or oil in water, is microscopically structured according to three domains: polar domain, formed of water and some surfactant; interfacial amphiphilic domain, formed of surfactant and co-surfactant molecules; and an non-polar domain, formed of oil, cosurfactant and a small amount of water. They are called aqueous, membrane and oil pseudophases, respectively.

In adsorption, Langmuir and Freundlich isotherms can be used to represent equilibrium data. Langmuir model [10] can be written in the following way:

$$\frac{C_e}{q} = \frac{1}{bq_m} + \frac{C_e}{q_m} \quad (1)$$

where:

$$q = \frac{V(C_0 - C_e)}{W} \quad (2)$$

For Freundlich model [10], the theoretical representation for the experimental data is done through equation (3).

$$q = K C_e^{1/n} \quad (n > 1,0) \quad (3)$$

where K and n are equilibrium constants inherent to the system under study. The value of ln K is a measure of the capacity of the adsorbent, whilst the term 1/n gives an indication about the intensity of adsorption.

Studies on adsorption of metals onto surfaces coated with surfactants [11,12] show that the interaction among them can be represented by adsorption isotherms. Since the extraction process with microemulsions occurs from interactions between the surfactant polar head group and the copper ion, one can consider that the interaction between metal (solute) and surfactant (adsorbent) behaves like an adsorption process. Moreover, in the pseudophases model, the surfactant layer that coats the microemulsion droplets can be considered as a phase. These concepts were employed to apply Langmuir and Freundlich isotherms in the representation of the equilibrium curve of the microemulsified system.

## METHODOLOGY

Firstly, equilibrium data that relate the concentrations on copper in the microemulsion phases (extract) to those in the aqueous solution (raffinate) were determined. The system studied in this part was constituted of a solvent (a microemulsion formed of isoamyl alcohol, SCO, kerosene and water) and the copper sulfate aqueous solution with concentrations ranging between 1 720 and 8 600 ppm in Cu<sup>+2</sup>, regarded as the feed materials to be treated.

The equilibrium between the phases was determined from the analyses of evolution of the concentration on copper in the phases, and takes about 1 minute to be reached. Nevertheless, the samples were allowed to stir for 10 minutes, so as to assure that the equilibrium was attained. The mixture points were kept under a controlled temperature of 30°C. After phase separation, samplings of each phase were performed, after which the samples were analyzed in a SPECTRA-10A atomic absorption spectrophotometer, thus quantifying the amount of copper present in the microemulsion and aqueous phases.

The microemulsion diagram was obtained through successive titration of the samples among its several points. This allowed for the determination of the best regions and extraction conditions, and also the point S.

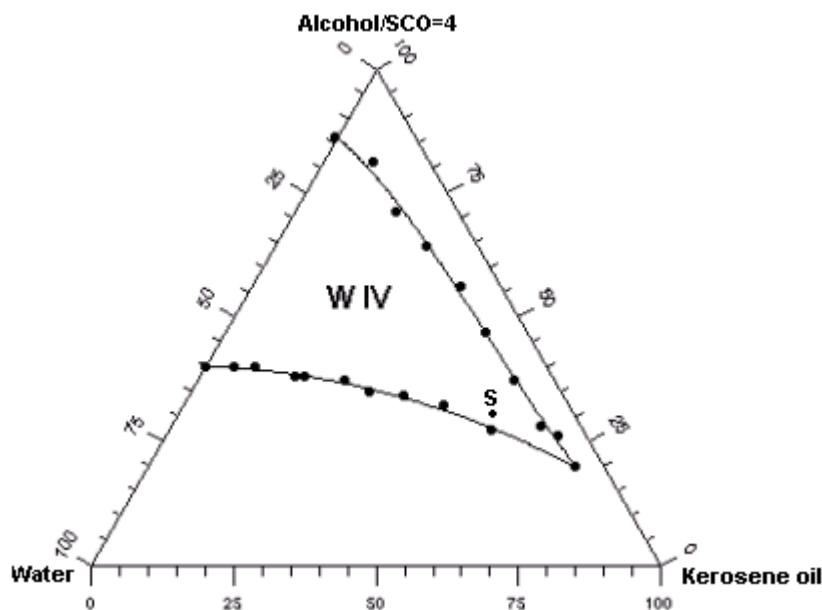

After obtaining the equilibrium curve, operational conditions were simulated for a countercurrent extraction column. Since the microemulsion density is lower than the aqueous solution density, it is inserted at the bottom of the column, whilst the feed aqueous solution is inserted at the top of the column.

## RESULTS AND DISCUSSION

### Microemulsion Diagram

The microemulsion diagram is composed of three pseudoconstituents: isoamyl alcohol / SCO at a ratio of 4.0, water and kerosene. Such pseudoconstituents were selected from previous studies [2,4] that report excellent copper recovery percentages in microemulsion extraction. Figure 1 shows the diagram and the microemulsion region (Winsor IV), evidencing the point S, which is the mixture considered as the solvent for the study of the equilibrium curve.

The choice of point S was based on the fact that, at such point, one has a water-in-oil microemulsion, which provides a good phase separation after interacting with a copper solution [1-5]. Thus, such microemulsion is considered to allow only the mass transfer of solute (copper), previously contained in the aqueous phase, towards the microemulsified phase.

*Figure 1. Pseudoternary diagram showing the Winsor IV region for the system water-kerosene-isoamyl alcohol and saponified coconut oil (SCO).*

### Equilibrium Curve

The equilibrium curve was built from mixtures of the solvent (microemulsion solution with the composition shown in Table 1) with copper sulfate aqueous solutions at various concentrations. Table 2 presents the concentrations of copper in the feed line, in the microemulsion and in the treated solution. The volumes of the microemulsion and aqueous phases are equal to 1 mL and 50 mL, respectively.

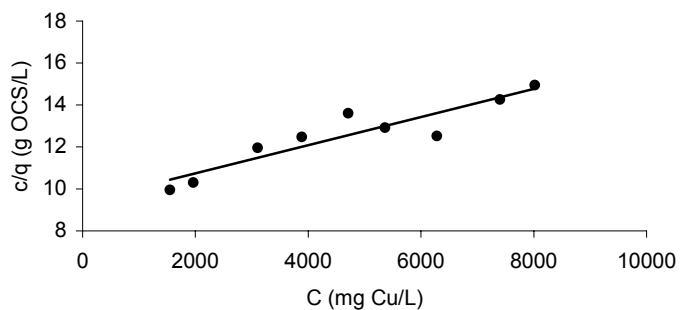

*Table 1. Composition of the microemulsion used.*

Component Composition (%)	SCO	Alcohol	Kerosene	Water
	6.0	24.0	55.0	15.0

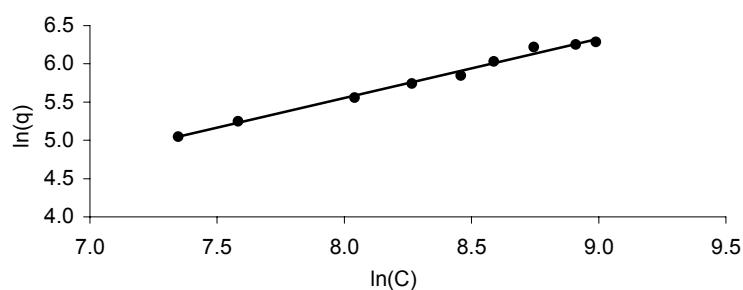

*Table 2. Concentrations of the phases.*

Cu feed (mg/L)	Cu micro (mg/L)	Cu water (mg/L)
1720.0	9347.7	1551.7
2168.7	11425.0	1963.0
3383.9	15579.5	3103.4
4225.2	18695.4	3888.7
5085.2	20772.7	4711.2
5814.3	24927.2	5365.6
6823.8	30120.4	6281.7
7964.3	31159.1	7403.4
8599.9	32197.7	8020.3

The equilibrium data in Table 2 were used to carry out a study of copper adsorption to the surfactant once both are present in the microemulsion. This study regards the surfactant as a coating that directly interacts with the copper ions. The presence of the surfactant itself is a condition to make possible the extraction by microemulsions. Equations (1) and (3) were used with this purpose, and they describe the Langmuir and Freundlich adsorption models. Figures 2 and 3 show the adjustment of such isotherms.

*Figure 2. Langmuir isotherm for the system SCO / Cu<sup>+2</sup> solution.*

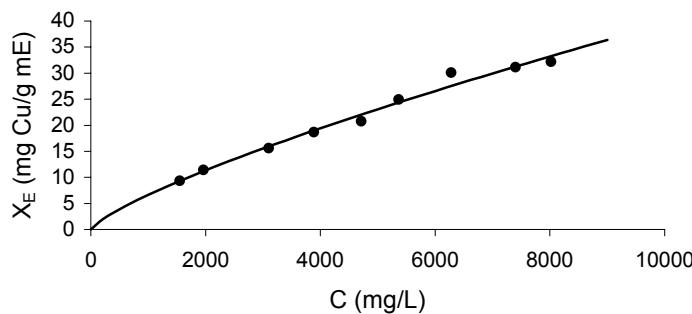

*Figure 3. Freundlich isotherm for the system SCO / Cu<sup>+2</sup> solution.*

Table 3 presents the parameters and the correlation coefficients provided by Langmuir and Freundlich models.

*Table 3. Parameters and correlation coefficients for the adsorption models.*

T(°C)	Langmuir			Freundlich		
	R <sup>2</sup>	q <sub>m</sub> (mg Cu/g OCS)	b	R <sup>2</sup>	n	ln K
30	0.854	1492	7.1·10 <sup>-5</sup>	0.991	0.7749	-0.648

From Table 3, it is noted that the Freundlich model better represents the extraction phenomenon, since it provides a correlation coefficient closer to 1.0. Figure 4 shows the adjustment for this model, applied for the microemulsion system.

*Figure 4. Adjustment of Freundlich model for the system SCO / Cu<sup>+2</sup> solution in the microemulsified system.*

From equation (3), it was possible to develop a model that represents the equilibrium between the microemulsion phases and the copper sulfate aqueous solution for the studied system, thus originated equation (4).

$$X_E = 0.0314 \cdot C^{0.7749} \quad (4)$$

#### Simulation of the Process in a Countercurrent Column

From the equilibrium relationship (equation (3)), the behavior of a countercurrent-operated column was simulated. The copper-containing aqueous solution enters the column from its top at a concentration  $C$  and in a flow rate  $D_T$ , and leaves from its bottom at a concentration  $C_B$  and flow rate  $D_B$ . The microemulsion enters the column from its bottom at a concentration  $X_0 = 0$  and flow rate  $S_B$ , leaving the column at a concentration  $X$  and flow rate  $S_T$ . Since the amount of solute transferred between the phases is negligible when compared to the flow rates, the latter can be considered as unaltered. Therefore, one can say that  $D_B = D_T = D$  e  $S_B = S_T = S$ , and the mass balance can be expressed in the following way:

$$C_o D_T + X_o S_B = C_B D_B + X S_T \quad (5)$$

$$X = \frac{D}{S} (C - C_B) \quad (6)$$

Thus:

$$\left( \frac{S}{D} \right)_{min} = \frac{(C - C_B)}{X} \quad (7)$$

For an aqueous solution with a concentration equal to 8 000 mg/L in Cu<sup>+2</sup>, to be treated in a way as to reach the final concentration of 500 mg/L, a minimum solvent rate of 225.9 g μE/L of aqueous solution is required. The number of transfer units (NTU) [13] is given by equation (8):

$$NTU = \int_{33.22}^{0.0} \frac{dX}{X - X_E} = \int_{33.22}^{0.0} \frac{dX}{X - 0.0314 \cdot \left[ \left( \frac{S}{D} \right) X + C_B \right]^{0.7749}} \quad (8)$$

If a solvent rate 1.3 times higher than the minimal rate is employed, equation (8) can be used with a number of transfer units equal to 4.76.

## CONCLUSIONS

The results obtained in this work show that it is possible to represent the equilibrium data of extraction processes by microemulsions through the Freundlich equation. This model deals with the multilayer adsorption of the substance on the adsorbent; it can be assumed that the adsorption of copper by the surfactant within the microemulsion phase occurs on multilayers. When the behavior of a countercurrent-operated extraction column is simulated, a minimum solvent rate is obtained and the number of transfer units (NTU) can be calculated through an equation determined as a function of the equilibrium and operation equations.

## NOMENCLATURE

b – Langmuir equilibrium constant

C – concentration of copper in aqueous solution (mg of Cu/L)

$C_e$  – equilibrium concentration

$C_o$  – initial concentration

D – aqueous phase flow rate

k – Freundlich constant, provides the capacity of the adsorbent

n – dimensionless equilibrium constant inherent to the system

q – adsorbed amount

$q_m$  – maximal adsorbed amount

$R^2$  – correlation coefficient

S – microemulsion phase flow rate

V – phase volume

W – amount of adsorbent (SCO)

$X_E$  – composition of copper in the microemulsion phase (mg Cu/g  $\mu$ E)

# COPPER HYDROMETALLURGY PROCESS EVOLUTION: CHANGING OPERATING PARAMETERS AND PHILOSOPHIES THROUGHOUT THE LIFE OF GIRILAMBONE COPPER COMPANY'S SOLVENT EXTRACTION CIRCUIT

Kym A. Dudley, David J. Readett, Phillip A. Crane\* and J. Murdoch W. Mackenzie\*

Straits Resources Ltd, West Perth, Australia

\*Cognis Australia Pty Ltd, Broadmeadows, Australia

Ore mineralogy has a major influence on the quality of the leach solution that is presented to a solvent extraction plant, and many operations see a change in the pregnant leach solution quality as the ore mineralogy changes over the project life.

This paper uses as an example the course of the solvent extraction circuit developments at Girilambone Copper Company in illustrating how changes in pregnant leach solution quality can be managed through appropriate selection of solvent extraction circuit operating conditions.

## INTRODUCTION

The Girilambone Copper Company (GCC) has utilised solvent extraction (SX) to process copper-bearing liquors produced from heap leaching since 1993. During this time the initial low-grade oxide leach has progressed, with the changing ore types from the open-cut mine, to a predominately bacterial assisted chalcocite leach operation resulting in leach liquor composition changes throughout the life of the operation. This has required continual SX investigation, test work and plant optimisation to consistently produce an electrolyte suitable for copper electrowinning (EW); and much of this work has been presented in detail elsewhere [1-6].

This paper serves as a collective summary and update of these events to illustrate the importance of understanding the various parameters that affect the copper SX and EW process and to demonstrate the degree of versatility that copper SX offers under changing conditions.

### Ore Mineralogy

From 1993 to 2000, almost 10M tonnes of ore containing approximately 138,000 tonnes of contained copper was mined and placed on the leach heaps at GCC, with the approximate composition shown in Table 1.

### Leach Solution Quality

Changing ore mineralogy and subsequent heap leach performance through the life of the mine resulted in changes in the composition of the pregnant leach solution (PLS) treated through the solvent extraction circuit. Figure 1 shows PLS composition throughout the mine life.

Table 1. Typical composition of GCC ore.

Ore type	Grade (% Cu)	Cu metal (tonnes)	Principal copper minerals (order of abundance)
Oxide	0.75	25,900	Malachite / Azurite
Transition	1.38	13,350	Malachite / Cuprite / Native Copper
Sulphide	2.05	98,800	Chalcocite / Chalcopyrite/(Pyrite)

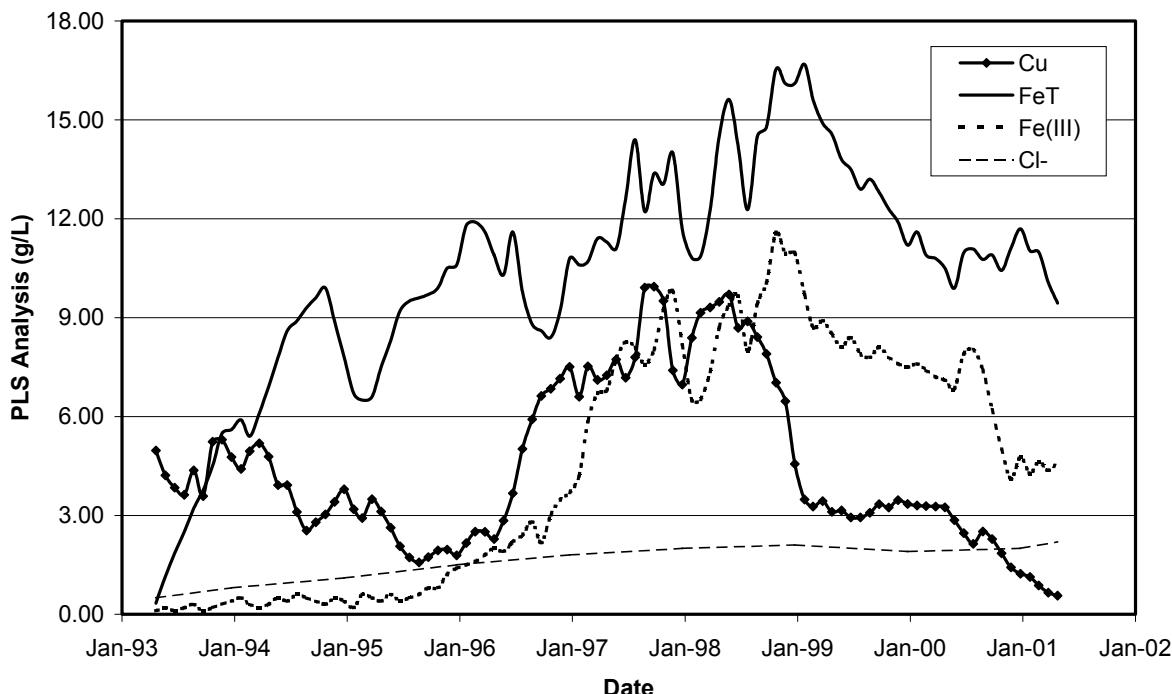

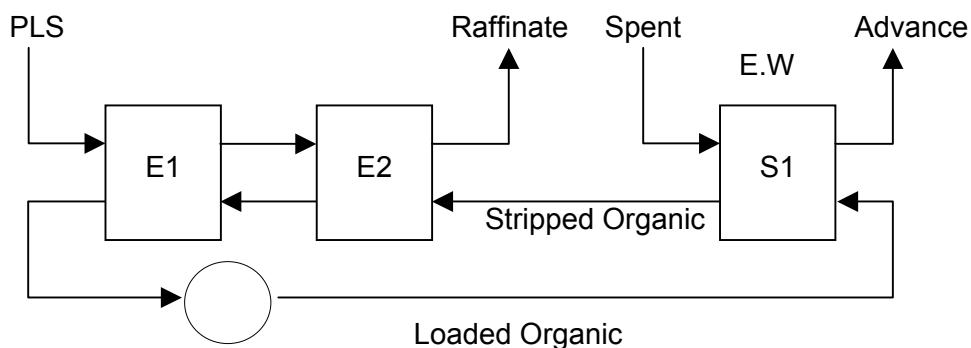

Figure 1. Historic GCC PLS composition trend.

Figure 1 displays the interesting chemical changes that occurred during the transition of GCC from a predominantly oxide leach since 1993 to the predominantly sulphide bioleach operation commencing in 1995. Most notable is that the PLS copper tenor increased shortly after PLS ferric iron generation was initiated primarily through the implementation of heap aeration methods to promote bacterial activity. Also interesting to note is that the levels of both the total iron and iron(III) remain reasonably high despite the decline in copper tenor towards the latter stages of the operational life. PLS chloride concentration, a major EW impurity element requiring control shows a gradual increase throughout the project life.

### Solvent Extraction Plant Design

The initial SX plant at Girilambone was designed as a conventional two extract and one strip circuit (2E x 1S) capable of producing 14,500 tonnes of copper cathode per annum. SX circuit configuration is shown in Figure 2 and typical design parameters in Table 2.

Initially, LIX 984 was selected as the copper extractant for Girilambone, an equimolar mixture of dodecyladoxime (LIX 860-I) and ketoxime (LIX 84-I). This reagent was chosen for its compatibility with the expected PLS solutions to be produced from the oxide heap leach. During 1995, the dodecylaldoxime was replaced with salicylaldoxime (LIX 860N-I), a C9 aldoxime, as it was believed that this offered slightly improved copper extraction kinetics with cooler leach solutions. The resultant extractant mixture is commonly called LIX 984N.

*Figure 2. Configuration of 2E x 1S SX circuit.*

*Table 2. Design parameters of 2E x 1S SX circuit.*

Parameter		Value
PLS	Cu tenor (g/L)	4.8
	Flow (m <sup>3</sup> /h)	400
	Recovery (%)	93
	pH	1.8-2.0
	Fe <sup>2+</sup> / Fe <sup>3+</sup>	2.8 / 0.2
Loaded Organic	LIX 984 conc. (%/v/v)	14.0
	Flow (m <sup>3</sup> /h)	400
	Transfer (kg Cu/h)	1,730
	Cu:Fe selectivity	>2,000:1

## OXIDE ORE TREATMENT PHASE

Throughout the first year of operation, the designed SX plant performed well at design volumetric flow rates. However, the PLS copper tenors were not as high as anticipated, so the PLS and organic flows were increased to maintain design copper transfer to electrowinning. The SX parameters obtained during the initial year of operation are shown in Table 3.

*Table 3. Operational parameters of 2E x 1S SX circuit.*

Parameter		Value
PLS	Cu tenor (g/L)	4.5
	Flow (m <sup>3</sup> /h)	420
	Recovery (%)	85
Loaded Organic	LIX 984N conc. (%/v/v)	14.7
	Flow (m <sup>3</sup> /h)	420
	Transfer (kg Cu/h)	1,730

During this first year of operation, several important lessons were learnt relating to the performance and control of the SX plant.

Shortly after commissioning of the SX circuit, extensive entrainment of PLS in the loaded organic occurred, transferring considerable quantities of manganese and chloride into the EW cells [4]. The initial effect of this created significant cathode stripping problems. A secondary effect was that, in the absence of sufficient ferrous iron, the manganese oxidised at the anode and increased the electrochemical potential of the electrolyte. This, in turn, oxidised the organic in the loaded organic stripping stage, producing by-products, which retarded phase separation rates and extraction kinetics. A vicious circle was established with increasing entrainments accelerating the degradation process [7].

Henkel (now Cognis) and GCC examined extractant performance and implemented clay treatment (developed by Henkel) to rectify the problem [8]. CMPS&F (now Egis) and GCC developed an understanding of coalescing media in the SX circuit to assist with phase disengagement. Both a loaded organic coalescer tank and in-settler coalescing media were commissioned [9]. Problems associated with high soluble silica levels in the PLS were also predominant during this period, and the importance of mixer phase continuity was also established [2].

### TRANSITION ORE TREATMENT PHASE

As leaching of ore progressed into the secondary sulphides (predominately chalcocite, Cu<sub>2</sub>S), leach kinetics remained low, resulting in PLS copper tenors well below design. The immediate action was to increase the PLS flow until the SX plant became hydraulically limited to maintain production. At this point, specific settler flow throughputs were being achieved at 7 m<sup>3</sup>/m<sup>3</sup>/h, whereas the design was around 4.5 m<sup>3</sup>/m<sup>3</sup>/h. Despite the reduced mixer residence time under the high flow conditions, the organic phase maintained high extraction kinetics.

The continued effect of slow leach kinetics during 1994 was such that the solvent extraction circuit required upgrading in December 1994 to accommodate a fourth mixer settler [1], shown in Figure 4.

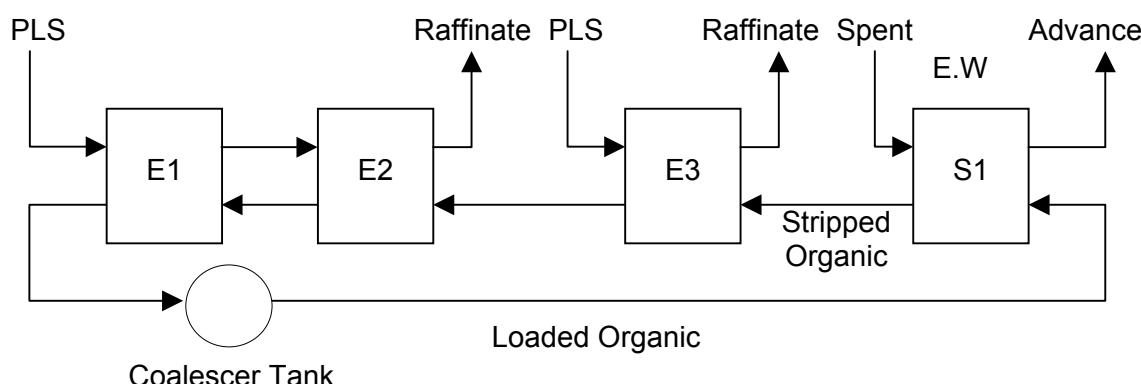

Figure 4. Series-parallel circuit.

The additional settler enabled the operation of a series parallel circuit, consisting of two extract stages in series, one parallel extract stage and one strip stage (2E x 1E(P) x 1S). PLS flowrates could now be pushed to 850 m<sup>3</sup>/h total flow, split equally into E3 and E1 extraction mixer-settlers. Typical operating parameters encountered during this period are outlined in Table 4.

*Table 4. Operational parameters of 2E x 1P x 1S SX circuit.*

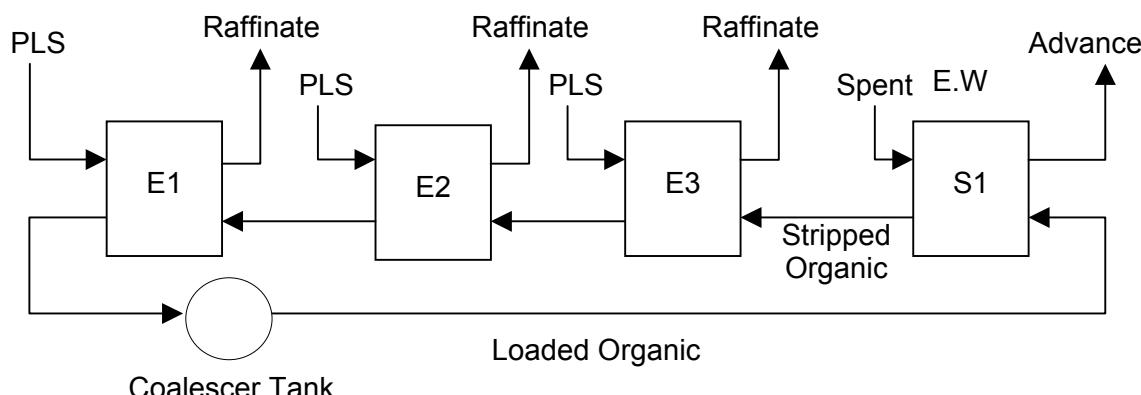

Parameter		Value
PLS	Cu tenor (g/L) Flow (m <sup>3</sup> /hr) Recovery (%) Fe <sup>2+</sup> / Fe <sup>3+</sup>	1.95 - 3.20 580 - 860 90 8.3 / 0.6
Loaded Organic	LIX 984N conc. (%/v/v) Flow (m <sup>3</sup> /h) Transfer (kg Cu/h) Cu:Fe selectivity	18.0 - 14.0 320 - 460 1,730 >1,500:1

## SULPHIDE ORE TREATMENT PHASE

### Pre-Aeration

A PLS grade below 2 g/L continued during the second half of 1995, as most of the ore under leach at this point was chalcocite and the leach rates were slower than expected.

In early 1996, in order to counter the effects of the low PLS grade, another modification was made to the SX circuit, shown in Figure 5 below. Conversion to a 3 - Parallel circuit (3P x 1S, or 1P x 1P x 1P x 1S) allowed the SX plant input to be increased to 1200m<sup>3</sup>/h total PLS flow, offsetting the low PLS grades and lifting productivity. Typical operating parameters encountered during this period are outlined in Table 5.

*Figure 5. The 3-parallel SX circuit.*

### Post-Aeration

With the advent of heap forced-aeration, and the subsequent improvement in bioleaching and chalcocite leach kinetics, the PLS copper grade rose dramatically during 1996, from 1.71 g/L in January to over 8.5 g/L in December that year. The increase in the copper content of the PLS allowed the circuit to be returned to series-parallel operation, as depicted in Figure 4. A simultaneous increase was obtained in the PLS iron content due to accelerated iron mineral leach kinetics and a change in the ratio of iron(II) to iron(III). This resulted in an increase in the transfer rate of iron to the electrolyte, (decreased organic Cu:Fe selectivity) adversely affecting the EW current efficiency [5, 6, 10].

*Table 5. Operational parameters of 3P x 1S SX circuit.*

Parameter		Value
PLS	Cu tenor (g/L)	1.75 - 2.84
	Flow (m <sup>3</sup> /h)	810 - 1140
	Recovery (%)	80
	Fe <sup>2+</sup> / Fe <sup>3+</sup>	9.2 / 1.7
Loaded Organic	LIX 984N conc. (%/v/v)	14.0 - 17.0
	Flow (m <sup>3</sup> /h)	390 - 450
	Transfer (kg Cu/h)	2,500
	Cu:Fe selectivity	>1,800:1

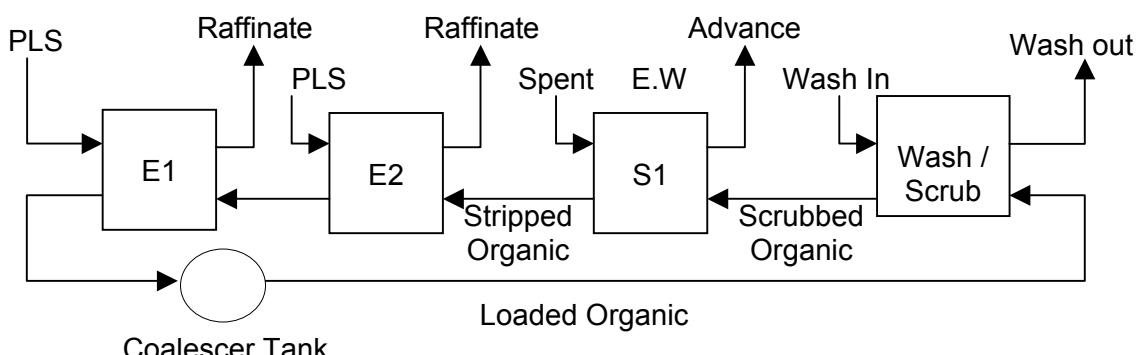

*Table 6. Operational parameters of 2E x 1P x 1S SX circuit (post aeration).*

Parameter		Value
PLS	Cu tenor (g/L)	3.65 - 9.70
	Flow (m <sup>3</sup> /h)	510 - 720
	Recovery (%)	40 - 80
	Fe <sup>2+</sup> / Fe <sup>3+</sup>	5.0 / 11.6
Loaded Organic	LIX 984N conc. (%/v/v)	14.0 - 17.0
	Flow (m <sup>3</sup> /h)	240 - 400
	Transfer (kg Cu/h)	2,500
	Cu:Fe selectivity	< 500:1

### ADVENT OF THE WASH / SCRUB STAGE

In June 2000, the production of ore from the Girilambone pits ceased. Thereafter, the PLS copper content commenced a controlled decline, which impacted upon copper output, and also EW impurity transfer, particularly chloride and iron.

In pilot plant tests conducted on site, a number of extractant and circuit combinations were evaluated with the aim of minimising impurity transfer. The most effective solution was found to be a conversion of one of the extract stages to an organic wash/scrub stage [11]. This was implemented in February 2001. Figure 6 shows the circuit layout and Table 7 shows the operating parameters before and after the conversion.

*Figure 6. 2P x 1W x 1S SX circuit.*

*Table 7. Operational parameters of 2P x 1W x 1S SX circuit (post aeration).*

Parameter		Value	
		Before	After
PLS	Cu tenor (g/L)	< 2	< 2
	Flow (m <sup>3</sup> /h)	700 - 850	700 - 850
	Recovery (%)	>95	>95
	Fe <sup>2+</sup> / Fe <sup>3+</sup>	5.0 / 11.6	5.0 / 11.6
Loaded Organic	LIX 984N conc. (%/v/v)	>11.0	<11.0
	Flow (m <sup>3</sup> /h)	350 - 400	350 - 400
	Transfer (kg Cu/h)	500	500
	Cu:Fe selectivity	< 100:1	> 500:1

## CONCLUSIONS

It is expected that many projects that employ Leach/SX/EW to recover copper from an orebody comprising both oxide and sulphide mineralisation will see variations in PLS composition as ore mineralogy changes over time. The SX process is shown to possess a significant degree of flexibility as PLS compositions change and the experiences gained here and elsewhere may assist existing and new SX projects with managing these changes to maximise productivity.

## APPLICATION OF TWO TYPES OF COMMERCIAL EXTRACTANTS FOR COPPER IN CHINA

Yang Jiaoyong

Beijing Extractive Metallurgy and Technology Development Co., Ltd., Beijing, China

The applications of two types of commonly used solvent extraction reagents, *i.e.*, aldoximes with modifier (Acorga M5640) and the mixture (LIX 984) of modifier-free aldoximes and ketoximes (LIX 84), in China's copper SX plants are discussed in this paper. The paper details the effects of modifier on the extraction performance. Operational data and results from some plants are given. Laboratory experiments with the two types of reagents are also discussed. Data such as loading capacity, sensitivity to pH value, phase disengagement, entrainment, as well as the formation of crud were obtained and are illustrated. Results from both the experiments and the plants operation show that the over-all performances of aldoximes with modifier (Acorga M5640) are preferable.

### INTRODUCTION

Aldoxime reagents, as well known, are the new generation strong copper extractants. However, since their copper complex is difficult to strip with conventional spent sulphate electrolyte, the aldoxime extractants must be blended with modifiers to improve the stripping performance. Acorga M5640, a product of Avera Inc. (formerly Zeneca Specialties), is ester modified with a branched chain ester, whereas LIX 984, a product of Cognis Co. (formerly Henkel), is a blend of aldoxime and ketoxime. Conventionally, the former is called modified aldoxime extractant, and the latter is regarded as extractant without modifier. In some articles the authors [1] hold that the modified extractants are not as good as the unmodified ones because the modifier will cause the formation of excess crud. This is debatable. In fact, it is the emergence of the aldoxime extractants that resulted in the change of the global solvent extraction technology of copper. The much stronger aldoxime reagent makes it possible to reduce the number of stages in the SX circuit, hence reducing the capital investment of the SX plant and lowering the operating costs. Moreover, the reagent can be adopted for feed solutions with a much higher copper content and/or at lower pH. As regards the mechanism of crud formation during extraction and the performance comparison between M5640 and LIX 984, there have already been detailed reports [2,3]. The application of these two types of extractants in China's SX plants is discussed in this paper, and the performance comparison is presented as well. The results produced over a period of 10 years show that Acorga M5640 is much more adaptable compared with LIX 984.

## APPLICATION OF THE TWO TYPES OF EXTRACTANTS IN CHINA

The two types of commonly used extractants in the world, LIX 984 and M5640 have been supporting China's copper SX industry since the early 1990s. At present, cathode copper produced by SX process in China exceeds 20000 t/a. The market share of each reagent in China is about 50 %. Because the identified copper resources are scattered, it is difficult to find copper mines that have adequate reserves and are suitable for SX technology. There are dozens of SX plants with capacities ranging from 200 t/a to 300 t/a cathode copper, among them the largest one so far is only 4000 t/a capacity. The reserves are distributed throughout China including Tibet, that is on the roof of the world, Heilongjiang Province, in the high-latitude cold area (the lowest temperature is 50 °C below zero), and the southern part of Xinjiang Uygur Autonomous Region, at the edge of the arid Taklamakan Desert. Yunnan has smaller SX plants than other provinces. Some typical plants are listed in Table 1. In most plants the real production is lower than the designed capacity due to the shortage of ore supply.

*Table 1. Typical SX plants in China.*

Name of plants	Designed capacity (t/a)	Ore type and grade (Cu)	Leaching method	Extractant	Location of plant	Remarks
Guangtong Copper Plant	1000	Oxide, 1%	Heap	M5640	Lufeng, Yunnan	**
Makuang Fuli Plant	500	Oxide, 2%	Agitating	M5640	Gejiu, Yunnan	
Baoping Copper Co.	1000	Oxide, 0.6-1%	Heap	M5640	Yongsheng, Yunnan	
Chuxiong Copper Mine	2500	Sulphide concentrate, 25%	Roasting-agitating	M5640	Chuxiong, Yunnan	Closed down
Fute Copper Co.	1000	Earthy oxide, 1%	Agitating/heap	M5640	Yuanjiang, Yunnan	Temporarily closed
Yuanjiang Copper Mine	600	Oxide, 1%	Heap	LIX 984	Yuanjiang, Yunnan	
Limin Copper Mine	600	Oxide, 1.2%	Heap	M5640	Jinggu, Yunnan

Mill Copper Mine	500	Oxide, 1.2%	Heap	M5640	Yongsheng, Yunnan	
Pingchuan Copper Mine	1000	Oxide, 1.1%	Heap/agitating	M5640	Yanyuan, Sichuan	
Yaxi Copper Co.	600	Oxide, 1%	Heap/agitating	M5640	Yanyuan, Sichuan	
Dexing Copper Mine	2000	Waste dump, 0.1%	Dump	LIX 984	Dexing, Jiangxi	Actual Production 600 t/a
Tongkuangyu Copper Mine	500	Oxide, 0.3-1%	In situ	LIX 984	Yuanqu, Shanxi	
Duobaoshan Copper Mine	1500	Oxide, 0.7%	Heap	M5640	Nenjiang, Heilongjiang Province	
Neymu Copper Mine	1000	Oxide, 1.1%	Heap	M5640	Neymu, Tibet	
Kunlun Copper Co.	1000	Oxide, 1.5-2%	Agitating/heap	M5640	Jiashi, Xinjiang	Under reform
Zhongyuan Gold Smelter	2500	Gold concentrate 1-3%	Roasting/agitating	LIX 984/M5640	Sanmenxia, Henan Province	
Lingbao Gold Smelter	4000	Gold concentrate 1-3%	Roasting/agitating	LIX 984	Lingbao, Henan Province	
Guoda Gold Smelter	3500	Gold concentrate 1-3%	Roasting/agitating	LIX 984/M5640	Zhaoyuan, Shandong	
Dongfang Gold Smelter	1000	Gold concentrate 1-3%	Roasting/agitating	LIX 984	Mouping, Shandong Province	
Chaoyang Gold Smelter	1000	Gold concentrate 1-3%	Roasting/agitating	LIX 984/M5640	Chaoyang, Liaoning Province	

\*\* It was the first plant with capacity of 1000 t/a in China. It was put into operation in 1992 and was shut down in 2000 due to the depletion of copper resource.

It can be seen from Table 1 that M5640 is widely used especially in areas with tough environmental conditions. In Duobaoshan Copper Mine, Heilongjiang Province, the SX circuit with M5640 can run normally in winter time despite the fact that the temperature of feed solution (PLS) is only 3.0 °C. LIX 984 has been more widely used in gold recovery plants in recent years. However, it has gradually been replaced by M5640 due to such disadvantages as lower loading capacity and the vulnerability to pH of PLS. This will be demonstrated by the comparative results of the operational data with these two types of extractants in Guoda Gold Smelter in Zhanyuan, Shandong province.

## TEST RESULTS AND DISCUSSION

Performance tests comparing between M5640 and LIX 984 were conducted at plants and mines, respectively. Tests were carried out using Averia Inc.'s special apparatus for determining extraction equilibrium and kinetics. The results of the tests are described below.

### Extraction Equilibrium and Stripping Kinetics

Extraction equilibrium and stripping kinetics of the two extractants are shown in Figure 1 and Figure 2. The data indicates that in the case of M5640 the 90% maximum loading capacity can be achieved after 20 seconds of mixing, whereas for LIX 984, 30 seconds are needed. Regarding the stripping kinetics, LIX 984 also shows correspondingly a 10~20 seconds delay. This phenomenon is not only because LIX 984 contains some LIX 84, which is a weaker ketoxime-based extractant, but also due to the fact that the aldoxime of LIX 984 is based on a C<sub>12</sub> alkyl, a long carbon chain compound that may bring about steric hindrance, depressing the extraction equilibrium and stripping kinetics.

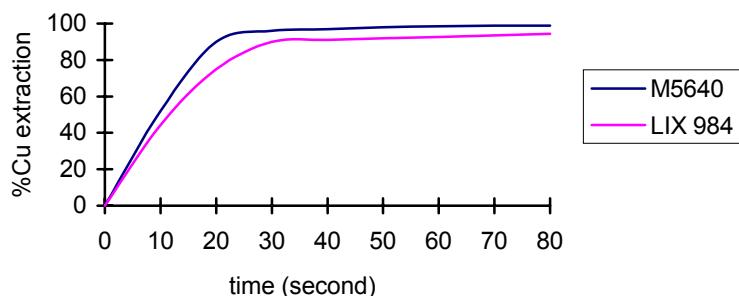

Figure 1. Extraction equilibrium.

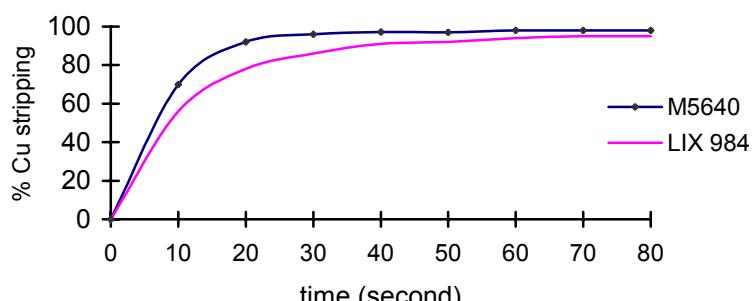

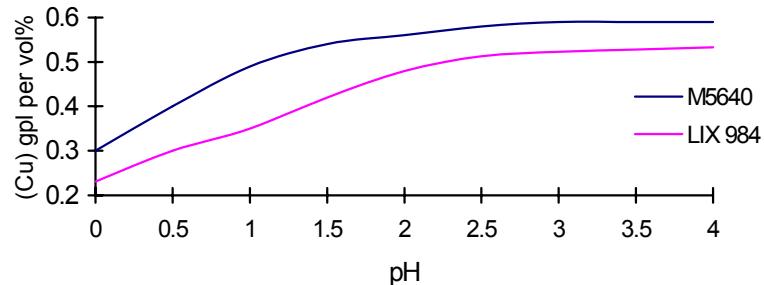

Figure 2. Stripping kinetics.

### **Effect of Feed Solution pH on Copper-loading Capacity**

The variation of copper loading capacity of the two extractants at different pH is shown in Figure 3. It is seen that with regards to copper loading performance, M5640 has higher adaptability to pH variation than LIX 984, especially at pH < 2. This pH-dependent nature is more important in the case of PLS with higher copper content, because acid will be liberated during copper extraction, which will cause the pH to drop further decreasing the extraction recovery of copper. Fortunately, M5640 can reduce this impact to a minimum.

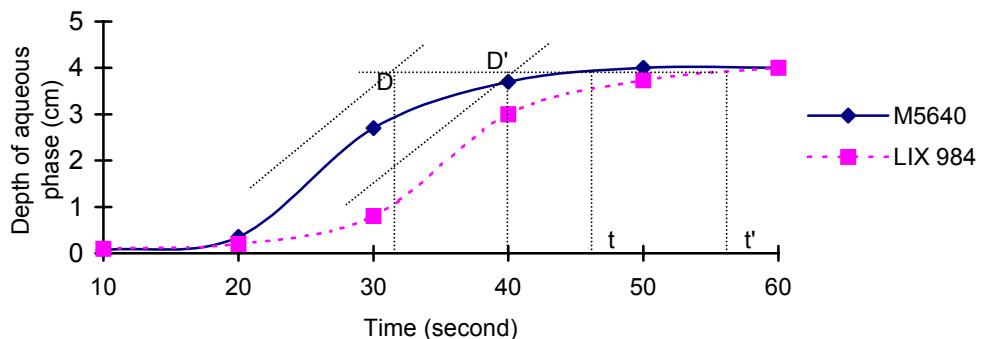

*Figure 3. Effect of pH on copper loading capacity.*

It can also be seen from the curve that both extractants reach their maximum loading capacity at pH 2.5. The maximum loading per volume percent of M5640 is 0.59 g/l Cu, while that of LIX 984 is 0.51 g/l Cu.

### **Phase Disengagement**

The phase disengagement curve is plotted in Figure 4, in which the phase disengagement time is plotted on the horizontal axis and the depth of clear aqueous phase is on the vertical axis. The cross points D and D' represent the depth of aqueous phase at complete phase disengagement for M5640 and LIX 984, respectively, while t and t' represent the final time at which phase disengagement completed. The complete phase disengagement time for M5640 is 48 seconds, and for LIX 984 is 60 seconds.

*Figure 4. Phase disengagement.*

### **Copper/Iron Selectivity**

The plant PLS contains 1.3 g/l Cu and 24.1 g/l Fe at pH 2. The organic phase is 5 % v/v M5640 and 5 % v/v LIX 984, respectively. Test results are given in Table 2.

*Table 2. Copper / iron selectivity.*

M5640			LIX 984		
Cu <sub>org</sub> (g/l)	Fe <sub>org</sub> (g/l)	Cu / Fe	Cu <sub>org</sub> (g/l)	Fe <sub>org</sub> (g/l)	Cu / Fe
1.196	0.001	1196	1.091	0.02	546
1.274	0.001	1274	1.039	0.02	320
1.143	0.001	1143	1.139	0.02	520

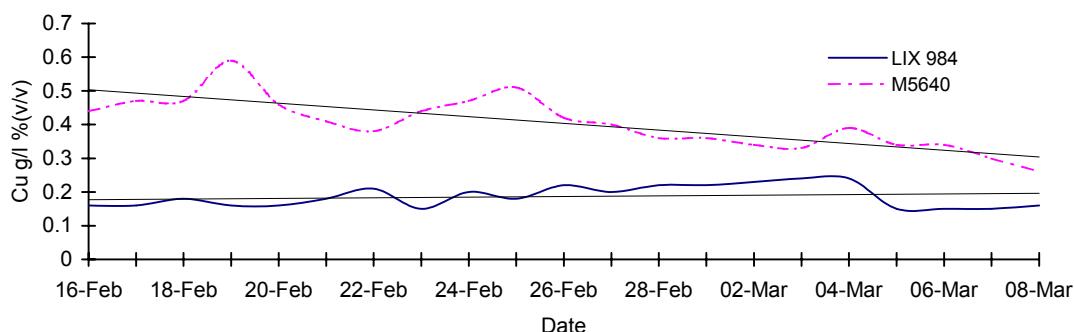

It can be seen that the Cu / Fe selectivity of M5640 is much higher than that of LIX 984 when extracting copper from PLS with high iron content (Cu / Fe = 18.5). The Cu/Fe selectivity (or, rejection ratio) of M5640 is about twice as high as that of LIX 984.

### COMPARISONS OF ACTUAL PRODUCTION DATA BETWEEN TWO EXTRACTANTS

Copper-bearing solution derived from the roasting-leaching process of gold concentrate is treated at the copper SX plant of Guoda Gold Smelter in Shandong Province. There are two SX circuits: one employs M5640 and the other, LIX 984. The operational data of the two SX circuits from 16 February to 8 March are listed in Table 3. Based on these data, the actual copper uptake per volume percent of extractant is calculated and is shown in Figure 5. Table 3 and Figure 5 indicate that with a PLS containing about 7 g/l Cu, a copper recovery of 96 % and actual copper net transition of 0.4 g/l can be achieved for 1 % (v) M5640. Whereas 92 % and 0.2 g/l are achieved with 1 % (v) LIX 984, though the organic concentration of LIX 984 is 9.1 percentage points higher than that of M5640. Moreover, the pH of PLS in M5640 circuit and LIX 984 circuit is 1.7 and 2.7, respectively. That means that M5640 not only has stronger copper loading capacity and higher copper net transition, but also is more suitable to higher acidity of the PLS than LIX 984.

### CRUD

Like in other countries, all SX plants in China, using either M5640 or LIX 984, have had problems with crud. However, most of the plants can run normally by removing the crud regularly, except in certain cases where production had to be temporarily suspended for specific treatment due to heavy crud.

*Figure 5. Copper net transition comparison of the two operation circuits.*

*Table 3. Plant comparison data from 16 February to 8 March.*

### **Plant 1**

Excessive humic acid contained in the feed solution formed grumos that could hardly decompose. The feed solution was mine wastewater containing 0.5-1.2 g/l Cu and 9-24 g/l Fe, at pH 1.5-2. 5 %(v/v) LIX 984 was used as extractant. In the previous semi-industrial tests the SX circuit ran normally and no problems with crud were observed. However, several days after putting into commercial operation grumos formed heavily. As the whole organic layer of the settler turned into emulsion, clear organic phase could not be obtained. Later, it was found that the feed solution was seriously contaminated by humus. Organic carbon content in the feed was as high as 40 ppm, while that in the uncontaminated copper-bearing mine water was less than 5 ppm. It was also found that two years earlier there was a house refuse heap on the mine waste dump. The humic acid produced by the decayed garbage flowed into the feed solution pond, contaminating the copper bearing mine water. After the contaminated waste dump water was bypassed, the SX plant has been operating normally.

### **Plant 2**

Entrained manganese ions caused degradation of the organic reagent, producing large quantity of floating crud. This plant employed mixer-settlers designed by in-house technical personnel. The inappropriate selection of parameters resulted in excessive entrainment of PLS in the loaded organic phase, which went into the stripping system. The Mn<sup>2+</sup> in the PLS was later oxidized to higher valence manganese ions during electrolysis. When the spent electrolyte recycled to the stripping stage, it contacted with organic phase and caused the degradation of the organic reagent. Thus, huge amounts of floating crud were produced and the plant had to be shut down for clean up. The PLS treated in this plant contained 1.2 g/l Cu, 1.5 g/l Fe and 1.6 g/l Mn<sup>2+</sup>, at pH 2. The organic phase was 7%(v) LIX 984 in kerosene. After two months of operation the LIX 984 content was decreased to 2 %(v). This resulted in the sharp decrease of copper extraction recovery. Later, the mixer settlers were modified and the pipelines for loaded organic were changed. The loaded organic phase flowed to the organic holding tank, and was then pumped to the stripping stage, so that the entrainment of PLS in organic phase could be reduced. After modifications, M5640 has been employed as the extractant. The plant has been operating normally since then.

### **Plant 3**

Excessive solid suspensions in the PLS resulted in serious crud. The plant adopted agitated leaching process. Due to lack of effective clarifying and filtering equipment, the PLS entering the SX circuit contained suspended solids as high as 2000 mg/L. Heavy crud resulting from the suspended solids caused the operation shut down. Later, a sand filter pond of large area was added to the leaching section and the suspended solids in the PLS have been reduced to less than 100 mg/L. At the same time, by keeping the organic phase continuous, the solids settle

down at the settler and are discarded together with raffinate, another measure is to draw regularly the aqueous solution containing solids from the bottom of the settler into the raffinate pond.

Nowadays, SX plants in China can easily handle the crud problem. They remove regularly the crud from the oil/water interface in the settler and put it into the crud storage pond for natural phase disengagement. Subsequently, the crud is washed with kerosene. Finally, the concentrated crud is blended with natural sandy bentonite. The exuded organic is further treated with activated clay before recycling to the extraction system. The residue is stockpiled after being solidified. This treatment is fairly effective, though simple. Eighty percent of organic in the crud can be recovered after kerosene washing. As is known to all, the crud is an unstable emulsion composed of organic phase, water and solid particles. Bentonite absorbs water. It can break the stability of the emulsion by soaking in water, hence attaining the goal of separating organic phase from the crud. In order to speed up the separation of the absorbed organic phase from bentonite, sand particles are added, which can lower the viscosity of bentonite and improve the permeability. The years of experience indicate that both type extractants will not generate, or accelerate the formation of crud. Instead, suspended solids, humic acid, silica gel and oxidative metal ions, like  $Mn^{2+}$ , in the PLS, as well as the impurities in kerosene are the real cause of the crud formation.

## CONCLUSIONS

LIX 984 and M5640 have been commercially used in China for about ten years, and have greatly facilitated the development of China's copper SX industry. In most heap (dump) leaching SX-EW plants with PLS containing 1-3 g/l Cu, at pH 2, there is no obvious difference in the performance of both extractants. The nature of both reagents has no special influence on the formation of crud. Nevertheless, when copper extraction is carried out from PLS with higher copper content and lower pH, M5640 shows clear superiority over LIX 984. Loading capacity, copper net transfer and adaptability to acidity variation of PLS of M5640 is better than of LIX 984. Because of that, M5640 is more adaptable to such areas with adverse environment conditions as in the very cold region. This has been proved by long plant runs in Tibet, Xinjiang, Heilongjiang, etc.

## ACKNOWLEDGEMENTS

The author wishes to extend thanks to Guoda Gold Smelter, Shandong, for giving permission to publish their production data, and to Zhongyuan Gold Smelter for assistance in the comparison tests of the two types of extractants.

## PILOT COPPER SOLVENT-EXTRACTION TESTING USING THE BATEMAN PULSED COLUMN

Eliyahu M. Buchalter, Rafi Kleinberger, Baruch Grinbaum\* and Curtis Nielson\*\*

Bateman Projects Ltd, Yokneam, Israel

\*IMI (TAMI) Institute for R&D, Haifa, Israel

\*\*Bateman Engineering Inc., USA

Testwork has been performed using 40 mm and 100 mm diameter pilot Bateman Pulsed Columns as part of an integrated pilot plant investigation at a processing facility of a leading copper producer. Both extraction and stripping were tested.

The target extraction recovery of 90-95% was achieved with 0.1 – 0.15 g/l copper in the raffinate. The required 47-51g/l copper in the advance electrolyte was obtained. Organic-in-aqueous entrainments in the raffinate as low as 1 ppm were obtained without the use of coalescers, flotation columns or other additional separation equipment. No major crud problems were encountered with the operation of the column. The design flux for extraction was found to be  $45 \text{ m}^3/\text{m}^2/\text{h}$  and for stripping  $40 \text{ m}^3/\text{m}^2/\text{h}$ .

### INTRODUCTION

Copper purification by solvent extraction (SX) is one of the largest applications of this technology in the hydrometallurgical industry. The copper SX process consists of extraction, scrubbing (sometimes) and stripping. In general extraction can be achieved in 2 or 3 stages and stripping in one stage. Kinetic requirements often lead to more than one mixer box per stage. Due to phase separation difficulties, settlers are often very large; design fluxes being of the order of  $4 \text{ m}^3/\text{m}^2/\text{h}$ . This results in high solvent evaporative losses. In addition, when crud forms, long down times are required for cleaning the settlers. The fine droplets formed during mixing also result in organic entrainment losses. This often requires the inclusion of expensive additional equipment (such as flotation columns like Jameson cells and after-settlers) into flowsheets. The Bateman Pulsed Column (BPC) has been designed to overcome these and other difficulties experienced with conventional mixer settlers. In addition the floor space occupied by the BPC is relatively small.

Previous work on copper extraction in BPC has been reported by Buchalter [1,2] while comparisons of BPC and mixer settlers has been reported by Fox [3] and Movsowitz [4]. Scale up and application of BPC to uranium, cobalt and nickel has been reported by Movsowitz [5,7], Klienberger [6] and Parkes [8].

To investigate the application of the BPC for copper, SX exploratory tests were conducted using a 40 mm diameter pilot BPC installed at IMI (TAMI) Institute for R&D. Scale-up design parameters were deduced from operating a 100 mm diameter pilot BPC in parallel with a client's mixer-settler pilot plant at the mine site. This paper discusses both sets of tests and the resulting conclusions.

## PILOT BATEMAN PULSED COLUMNS

All BPC units consist of a vertical cylindrical active section containing internals (usually disc and doughnut). Sampling points are situated at regular intervals along the column. Upper and lower settlers are connected to ends of the active section. A mechanical pulsator with adjustable amplitude and frequency is used for pulse generation. Mass transfer takes place in the active section and phase separation in the two settlers. When operating organic continuous, the interface between the two phase will be in the lower settler and in the upper settler for aqueous continuous operation.

### The 40 mm BPC

This all-glass column was tested with two active section heights (2 m & 4 m) and several different configurations of internals (disc/doughnut (d/d), sieve plate (s/p), Polyethylene (PE), polypropylene (PP), stainless steel (SS) and plate spacing: 5, 10 & 23 mm). The column is used to perform go/no-go tests on processes for which limited quantities of solutions are available.

### The 100 mm BPC

The column had a 7 m active section made from 1 m PVDF lengths with sight glasses between them. PVDF disc/doughnut internals were used (plate spacing 23 mm). The column is used to generate data for scale up to industrial-size BPC. Sample points (labeled SP) are equally spaced from the bottom to the top of the active section.

## EXPERIMENTAL

Extraction was tested in the 40 mm BPC while both extraction and stripping were tested in the 100 mm BPC. Actual solutions from an operating plant were used. The pregnant leach solution (PLS) copper concentration varied around 3 g/l. The strip solution was tankhouse spent electrolyte. Two types of tests were conducted: Hydraulic and mass transfer.

### Hydraulic Tests

These tests are done in order to determine the flooding and hold-up characteristics of the system. Flowrates, pulse frequency and amplitude are varied in order to determine the conditions at which flooding occurs. Flooding is defined as the condition in which a phase accumulates at the end of the column at which it enters. Hold-up, determined by sampling, is defined as the percentage of dispersed phase at a specific point in the column.

### Mass Transfer Tests

These tests are performed at selected conditions under which flooding did not occur. After establishing stable operation, the BPC is operated for at least 2 hours before sampling the in and out flows, as well as two-phase samples along the active section.

## RESULTS

### The 40 mm BPC

For this run the organic phase consisted of 16 vol.% LIX 84 in Conoco 170 ES diluent, the A:O ratio was 1.7:1 and the temperature was 21°C. Maximum fluxes achieved for a 2 m active section with various internals are shown in Table 1.

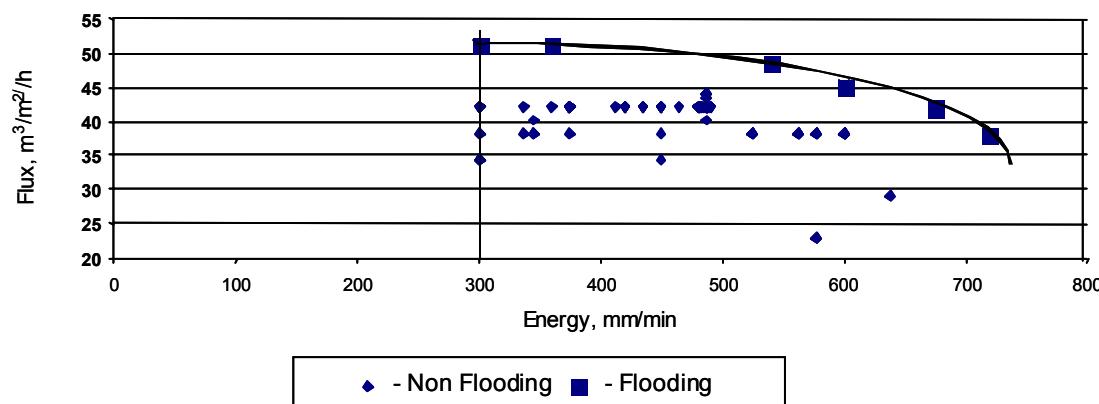

*Table 1. The maximum non-flooding flux achieved with the 2 m active section.*

Internals Type		Flux (m <sup>3</sup> /m <sup>2</sup> /h)	Recovery (%)
PE	d/d with 23mm spacing	55	20
PE	d/d with 5mm spacing	<10	
PE	d/d with 10mm spacing	40	50
SS	d/d with 23mm spacing	55	
SS	s/p with 23mm spacing	40	

With the 4 m active section, using PE disc/doughnut internals with 7.5 mm spacing, the maximum non-flooding flux was 30 m<sup>3</sup>/m<sup>2</sup>/h. At this flux the recovery of copper was 75%. The process is kinetically controlled, therefore the increased height and reduced flux results in an increased recovery. The tests with the 40 mm BPC achieved the objective of proving that the BPC technology was viable for copper extraction. Further in-depth testing was required using the 100 mm BPC.

### The 100 mm BPC

The work using this column was done in two phases. The hydraulic and mass transfer tests were done during the first phase by a combined Bateman and client team. During the second phase, the client ran the column for an extended period for both extraction and stripping. The optimum result for extraction during the first phase was found with an O:A of 1.2:1, at a flux of 45 m<sup>3</sup>/m<sup>2</sup>/h and a temperature of 27°C. Under these conditions, an extraction recovery in excess of 90% was achieved during continuous operation over a 20 hour period. Figure 1 is the flooding curve for extraction.

*Figure 1. Flooding curve for extraction stage.*

The optimum stripping result was found at an O:A Of 3.5:1, using a flux of 40 m<sup>3</sup>/m<sup>2</sup>/h and a temperature of 32°C. This produced an advance electrolyte of 47-51 g/l copper. Both these results met the client's operational criteria. The entrainment of solvent in the raffinate and in the advance electrolyte varied between 1 and 12 ppm. The recommended dispersion for both batteries is organic continuous. It was found that the bottom portion of the column was always organic continuous, while, the top was aqueous continuous. These dispersions are stable and co-exist in the column over long periods. This has the benefit of improving mass transfer while minimizing organic entrainment in the aqueous outlet. In industrial BPC both these interface levels are measured and the distance between them controlled by adjusting the energy input. The purpose of the second phase of testing was to confirm the above design parameters and for the client to become familiar with the operating ease of the BPC for his application.

Comparison of the extraction recovery for the pilot BPC and the client's mixer-settler pilot plant, operated at the same time, is shown in Figure 2. In the first period high PLS concentrations resulted in low (and comparable) recoveries for both plants. In the second period reduced PLS concentrations resulted in both plants meeting the operating criteria. In the third period reduced pulsation intensity (energy) resulted in lower recoveries from the BPC. Comparison of organic entrainment in the raffinate is shown in Figures 3 and 4.

The entrainment from the BPC was consistently and significantly lower than for the mixer settlers. This translates into significant savings in OPEX (of the order of \$110,000 pa). Flooding the column in order to drain crud caused the entrainments to temporarily increase. The column nevertheless remained on-line and recoveries were not affected.

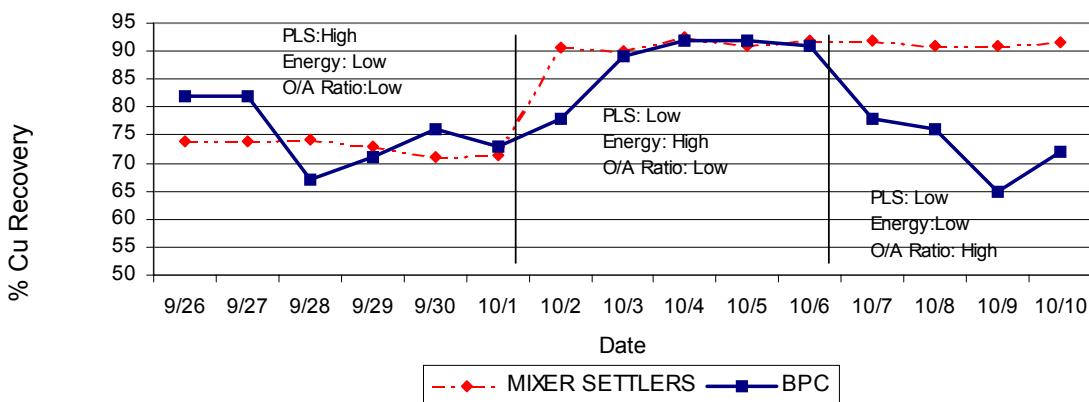

Figure 2. Comparison of Cu extraction in BPC and mixer-settler pilot plants.

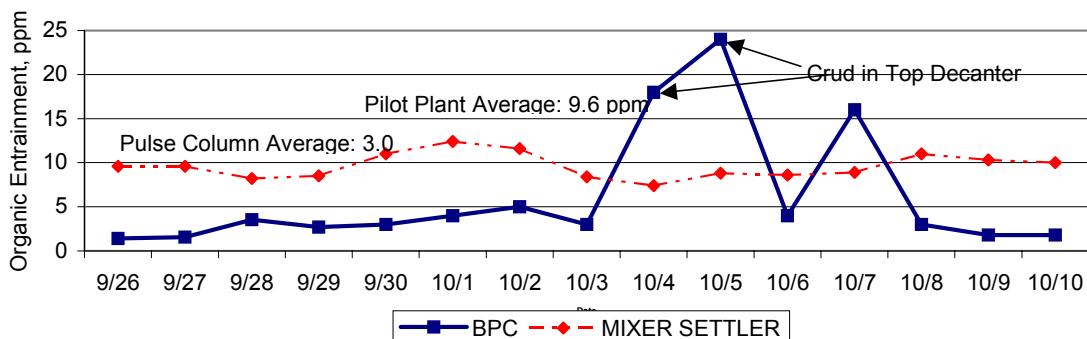

Figure 3. Organic entrainment in raffinate for BPC and mixer-settler pilot plants.

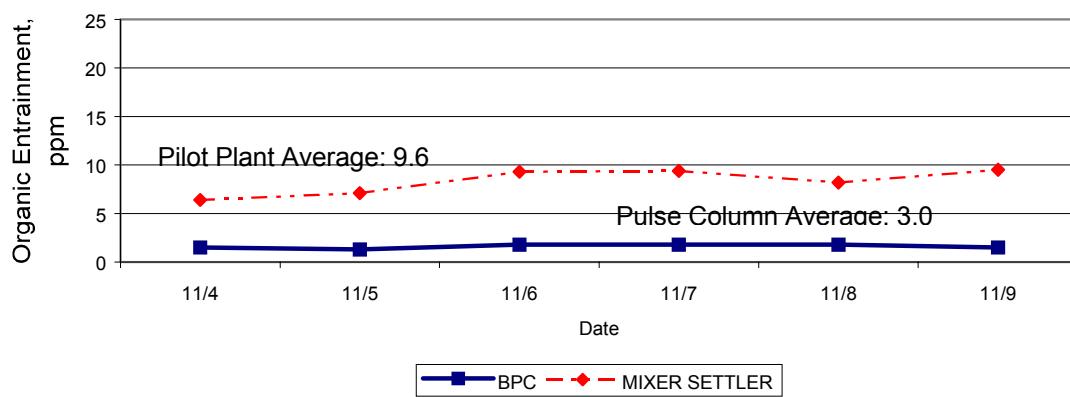

Figure 4. Organic entrainment in raffinate for BPC and mixer-settler pilot plants.

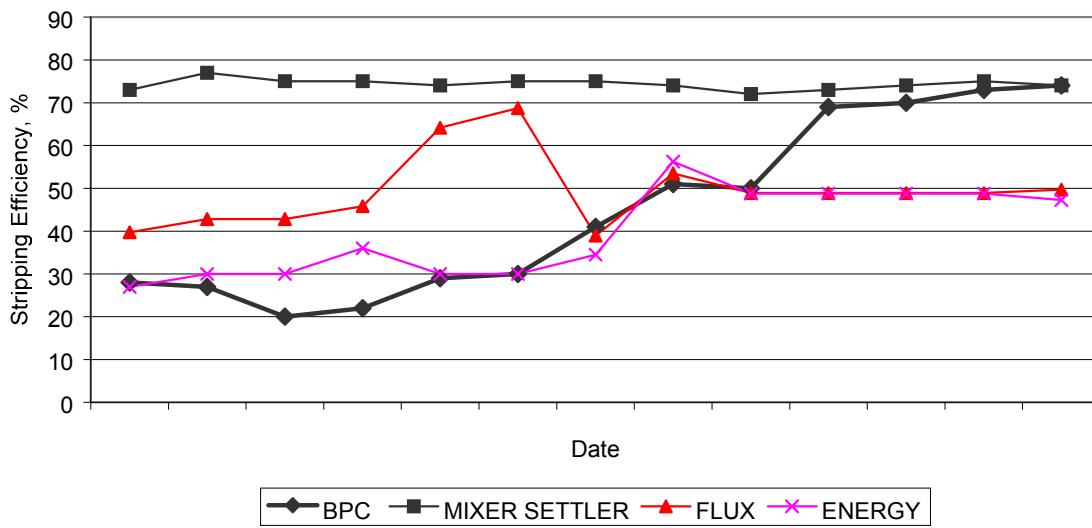

Figure 5. Stripping efficiency for BPC and mixer-settler pilot plants.

The results obtained for the pilot BPC and mixer-settler plants are shown in Figure 5. During the first period, the operation of the column was optimized by testing various fluxes and pulsation parameters. It is clear that at reasonable flux and increased energy, the operation of the two plants was similar.

It was consistently found (both in extraction and stripping) that increased temperature improved the hydraulics in the column and permitted operation at increased flux. A stripping flux of  $40 \text{ m}^3/\text{m}^2/\text{h}$  was achieved at  $21^\circ\text{C}$  and  $60 \text{ m}^3/\text{m}^2/\text{h}$  at  $40^\circ\text{C}$  (above  $40^\circ\text{C}$ , fluxes up to  $75 \text{ m}^2/\text{m}^3/\text{h}$  were achieved). This results from the decrease in viscosity with increasing temperature. It was not always possible to maintain temperature during the testwork. This was the main cause of operational problems during the second phase of stripping.

## CONCLUSIONS

### Extraction

- A copper recovery of 90% was achieved and maintainable.
- The BPC was easy to operate and required minimal operator attention.
- The organic entrainment in the raffinate was 55 to 80% lower than the mixer-settler pilot plant. This translates into savings of about \$110 000 pa.
- The optimal flux was  $42\text{-}45 \text{ m}^3/\text{m}^2/\text{h}$ .
- Crud was removable without shutting down.

### Stripping

- A rich electrolyte of 50 g/l was obtained with a copper increase of 15 g/l.
- The flux was  $40 \text{ m}^3/\text{m}^2/\text{h}$  at  $21^\circ\text{C}$  and  $60 \text{ m}^3/\text{m}^2/\text{h}$  at  $40^\circ\text{C}$ .

These design results were used to design an industrial plant. Comparative Capex with a mixer-settler plant showed a 15% saving (including first fill).

### Operator comments

- “Easy to operate”.
- “Just leave it alone and it works”.
- “Set it and forget it, except when it gets cold”.

## AMMONIA LEACH-SOLVENT EXTRACTION-ELECTROWINNING PROCESS FOR TREATMENT OF HIGH ALKALINE GANGUE-CONTAINING COPPER ORES

Daxing Liu, Kaixi Jiang, Chunyun Wang\* and Peiwen Zhang\*

Beijing General Research Institute of Mining & Metallurgy, Beijing, P. R. China  
\*Dongchuan Bureau of Mine, Dongchuan, Yunnan, P. R. China

Tangdan copper mine, which is located in Yunnan Province, China, has a deposit of 1.16 million metric tons of copper. The copper mineral is a high alkaline gangue containing oxide and sulfide copper with CaO and MgO accounting for 40% weight in the ore. The copper concentrate produced from the mixed ore has a relatively low content of 14~16% copper and 3~4% S while CaO and MgO contents are higher than 20%, respectively. The concentrates are not suitable for direct treatment by a smelter, and are therefore used as supplementary concentrates. A process combining roasting, ammonia leaching, solvent extraction and electrowinning has been developed for treatment of the concentrates. The laboratory tests, process development and pilot operation results are discussed in this paper. A pilot plant with a capacity of 500 t copper cathode per annum was built in 1997 and it has been running well since being brought on line. LIX 54-100 is employed to extract copper from ammonia leach liquors. The effects on the extraction and electrowinning, especially the ammonia concentration, are discussed in this paper. The operational measures for the pilot plant are also given. The economical feasibility of this pilot plant is reviewed.

### INTRODUCTION

Tangdan Copper Mine is located near Dongchuan City, Yunnan Province. The copper deposit is 1.16 million t with an average grade of 0.64% Cu. About 50% of the copper is oxide (malachite and chrysocolla) with the remainder being secondary copper sulphides such as chalcocite and bornite. However, the copper ore contains high alkaline gangue with CaO and MgO up to 40%. Furthermore, the copper minerals are finely divided in the ore body and as a result flotation only achieves a copper recovery of 75~78%. The copper concentrate produced contains 14~16% Cu, 3~4% S, 15% CaO and 15% MgO. This type of concentrate is not readily accepted by smelters and therefore it would have to be sold at a discounted price.

Tangdan also has 300,000 t copper contained as copper oxide in high alkaline gangues. The acid leach of this ore is uneconomical due to the high acid consumption. Previous development work on the Tangdan copper deposit focused on treatment of the whole ore either by ammonia pressure leaching, or by converting copper oxides to sulphides, followed by flotation to produce a copper concentrate. These processes operated at relatively high temperature and pressure (150°C and 1.5 MPa). The unit ammonia consumption was high because of the low copper grade of the ore.

In the early 1990s, Beijing General Research Institute of Mining & Metallurgy (BGRIMM) concentrated on the development of a leach-SX-EW process in order to produce copper cathodes from both the low copper/low sulphide concentrates and the copper oxide ore. Roasting-ammonia pressure leach-SX-EW was adopted for the treatment of the low grade copper concentrates while ammonia leach-SX-EW was adopted for the treatment of the copper oxide ore. A pilot plant with a capacity of 500 t/a copper cathode was built on site in 1996 and put into production in 1997. The plant run well since start-up, thus, providing a technology for the treatment of high alkaline gangue containing copper ores.

## EXPERIMENTAL

### Raw Materials

Two kinds of raw materials were used in the laboratory tests, the low quality copper concentrates and the copper oxide ore mentioned above. The chemical assay of raw materials is shown in Table 1.

*Table 1. Chemical assays of copper concentrates and oxide ores (%).*

	Cu	Fe	S	CaO	MgO
Concentrate	14~16	5~6	3~4	8~10	7~10
Oxide ore	1.5~4	7~8	0.4~0.6	3~5	4~6
	SiO <sub>2</sub>	Al <sub>2</sub> O <sub>3</sub>	As	Au (g/t)	Ag (g/t)
Concentrate	22~25	4~5	0.1~0.15	0.1	100
Oxide ore	60~65	8~10	0.1	0.06	5~6

The copper in the concentrates is present as follows: 30% malachite, 50~60% chalcocite and bornite, and 5% chalcopyrite. The gangue materials are carbonates with the copper minerals finely disseminated in the gangue material. The copper in the copper oxide ore is present as 80% malachite, 10% chalcocite and covellite, and 3~4% chalcopyrite. The gangue materials are also carbonates. Because of the high content of oxide gangue materials in the concentrate and in the oxide ore, direct leaching with sulfuric acid is not economical and for this reason the ammonia leach route was adopted.

### Ammonia Leach

The most important feature of ammonia leaching is that the oxides of Ca, Mg, Al, Si, Mn, and Fe are not leached. This simplifies the downstream treatment of the leach liquor, especially for Fe removal, thus helping ensure a pure copper product is obtained.

Direct ammonia leaching of the low grade copper concentrate without air introduction achieves only 80% copper recovery even at 140~150°C. Roasting under the proper conditions converts copper sulphide to copper sulfate and copper oxide, both of which are easily leached with ammonia under mild conditions. Temperature control is very important in the roasting. Too low a temperature results in low converting efficiency while too high a temperature gives difficult to leach copper silicates or ferric oxides. The preferred roasting temperature is 550~600°C.

The percent copper recovery in leach for the roasted concentrate was studied as a function of the: roasting temperature, particle size, ammonia concentration, NH<sub>3</sub> / CO<sub>2</sub> ratio, leach temperature, pressure and time. The recommended conditions follow: particle size: 80% minus 0.074mm; ammonia concentration 5 molar; NH<sub>3</sub>/CO<sub>2</sub> ratio 2.5:1; liquid / solid ratio in leach is 4; leach temperature is 90~100°C; leach time 1.5 to 2.0 h. Under the proper conditions about 92% copper recovery can be achieved across roast / ammonia leach.

It is critical to control the ammonia concentration in leaching to achieve a proper balance in the total copper recovery process. A high ammonia concentration will improve copper recovery in leach, but it will also increase ammonia losses and negatively impact the solvent extraction process that follows leaching.

### Solvent Extraction

Two reagents were tested for copper extraction from ammonia media, LIX 54-100, a beta-diketone and LIX 84, a ketoxime, both supplied by Cognis Corp. LIX54-100 has a very high copper loading capacity of 100 g/l Cu. Copper can be stripped from LIX 54 with relative ease and 80 to 100 g/l H<sub>2</sub>SO<sub>4</sub> will quantitatively strip the copper from a fully loaded 30 v/v % solution of LIX 54-100. The copper extraction was studied as functions of pH, aqueous ammonia concentration, temperature, and phase ratio.

Equal volumes of 30% v/v LIX 54-100 and liquor containing 20.56 g/l Cu was contacted at 25°C for different aqueous ammonia concentrations. The result is shown in Figure 1. Copper extraction decreased with increasing aqueous ammonia concentration. To ensure a good copper extraction, the aqueous ammonia concentration should be controlled in the ranges of 40 to 60 g/l.

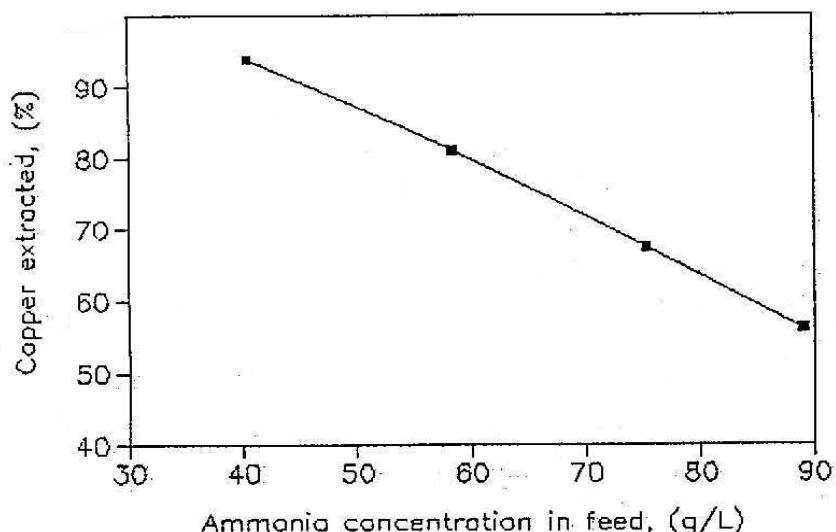

Figure 1. Effect of aqueous ammonia concentration on copper extraction.

The McCabe-Thiele curve is shown in Figure 2. 99% copper extraction can be achieved in 2 stages.

LIX 84 also exhibits a good extraction and stripping performance. However, at a same extractant concentration, LIX 84 extracts less copper than LIX 54-100 does. Considering 20-25 g/l copper in the leach liquor contains, and LIX 54-100 has a higher copper loading capacity and better stripping performance, 30% v/v LIX 54-100 thus was adopted as an extractant for the pilot plant.

### Electrowinning

The quality of the copper cathode as a function of the ammonia concentration in the copper electrolyte was studied at current density of 150 A/m<sup>2</sup>. The results indicate that the cathode quality will not be adversely affected when the ammonia concentration of the electrolyte is less than 2 g/L. To ensure a smooth dense cathode, a portion of Guarfloc 66 is added into the copper electrolyte. The presence of Guarfloc 66 in the electrolyte also reduces the ammonia impact on copper cathode quality.

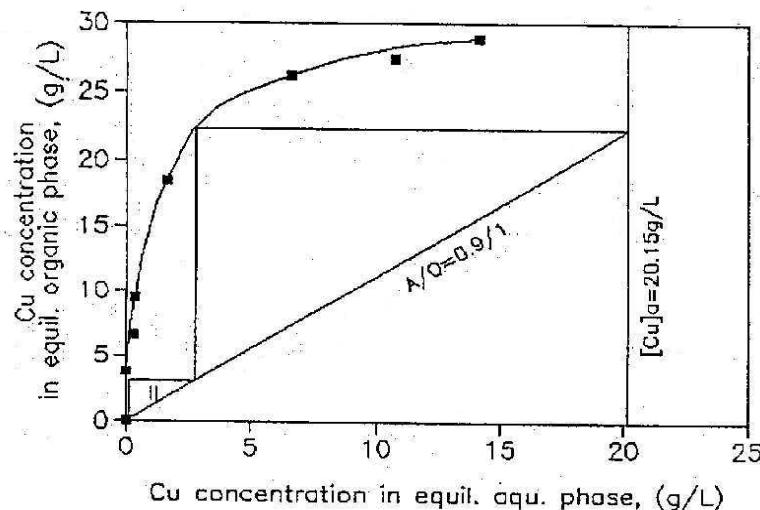

Figure 2. McCabe-Thiele curve of copper extraction.

Aqueous phase: 20.15 g/L Cu and 43.2 g/L ammonia. Organic phase: 30% v/v LIX 54-100.

### Pilot plant

The recommended process flowsheet is shown in Figure 3. Based on this process, a pilot plant with a capacity of 500 t/a copper cathode was built in the end of 1996. The pilot plant has been running for five years and a great deal of operation experience in the running of a roast / ammonia leach / SX / EW plant has been gained.

Two kinds of raw materials are processed at the pilot plant, a low copper / low sulphide / high gangue containing concentrate and a high gangue / high grade copper oxide ore. The copper concentrate is roasted in a rotary kiln 1.2 m in diameter and 16 m in length. The rotary rate is adjustable. The roasting temperature is controlled in the range of 500~600°C. The retention time of concentrates in the kiln is 2 h. Because the low grade sulphide in the concentrate is converted into oxide and sulphate small amounts of sulphur dioxide is given off during the roasting. The sulphur dioxide is absorbed into water so that it is not emitted to the atmosphere. The floatation reagent remained in the copper concentrates will have a bad impact on solvent extraction operation. The problem can be solved effectively via the roasting operation.

After roasting the calcine is mixed with raffinate in a pulping tank at solid to liquid ratio of 1, then flowed into a ammonia concentration adjusting tank, where ammonia is made up to a desired level. The pulp is pumped by a pressure pump into a heat exchanger, then a serial column style autoclave. The autoclave is built by connecting 10 steel pipes of 300 mm in diameter and 5.7 m in length. The ammonia leach is operated at 90~100°C and 0.2 MPa. After leaching the pulp is taken into 3 stages of count-current thickeners. The overflow from the thickeners is pumped to the solvent extraction circuit.

The SX circuit is configured with 2 stages of extraction, 2 stages of scrubbing, and 2 stages of stripping. The residence time in the mixer is 3 min. The flow rates of aqueous and organic phases are 4.5 m<sup>3</sup>/h and 3.5-3.7 m<sup>3</sup>/h, respectively. The specific flow is 3.8 m<sup>3</sup>/m<sup>2</sup>.h. The top of mixer-settler was covered to reduce ammonia evaporation and its impact on operation environment. The scrubbing stages are very important in order to minimize ammonia transfer from the leach solution to the electrolyte. The loaded organic phase is scrubbed with water to remove entrained and co-extracted ammonia. Spent electrolyte can be added to the scrub liquor to adjust the acidity of the scrub stages. The pH of outlet scrub liquor is controlled at 5~6 to ensure that 90% of ammonia in the loaded organic phase is removed. The scrub liquor is recycled to the thickener which follows pressure leaching. Spent electrolyte, containing 30~35 g/l Cu and 80~100 g/l H<sub>2</sub>SO<sub>4</sub>, is used as a stripping agent.

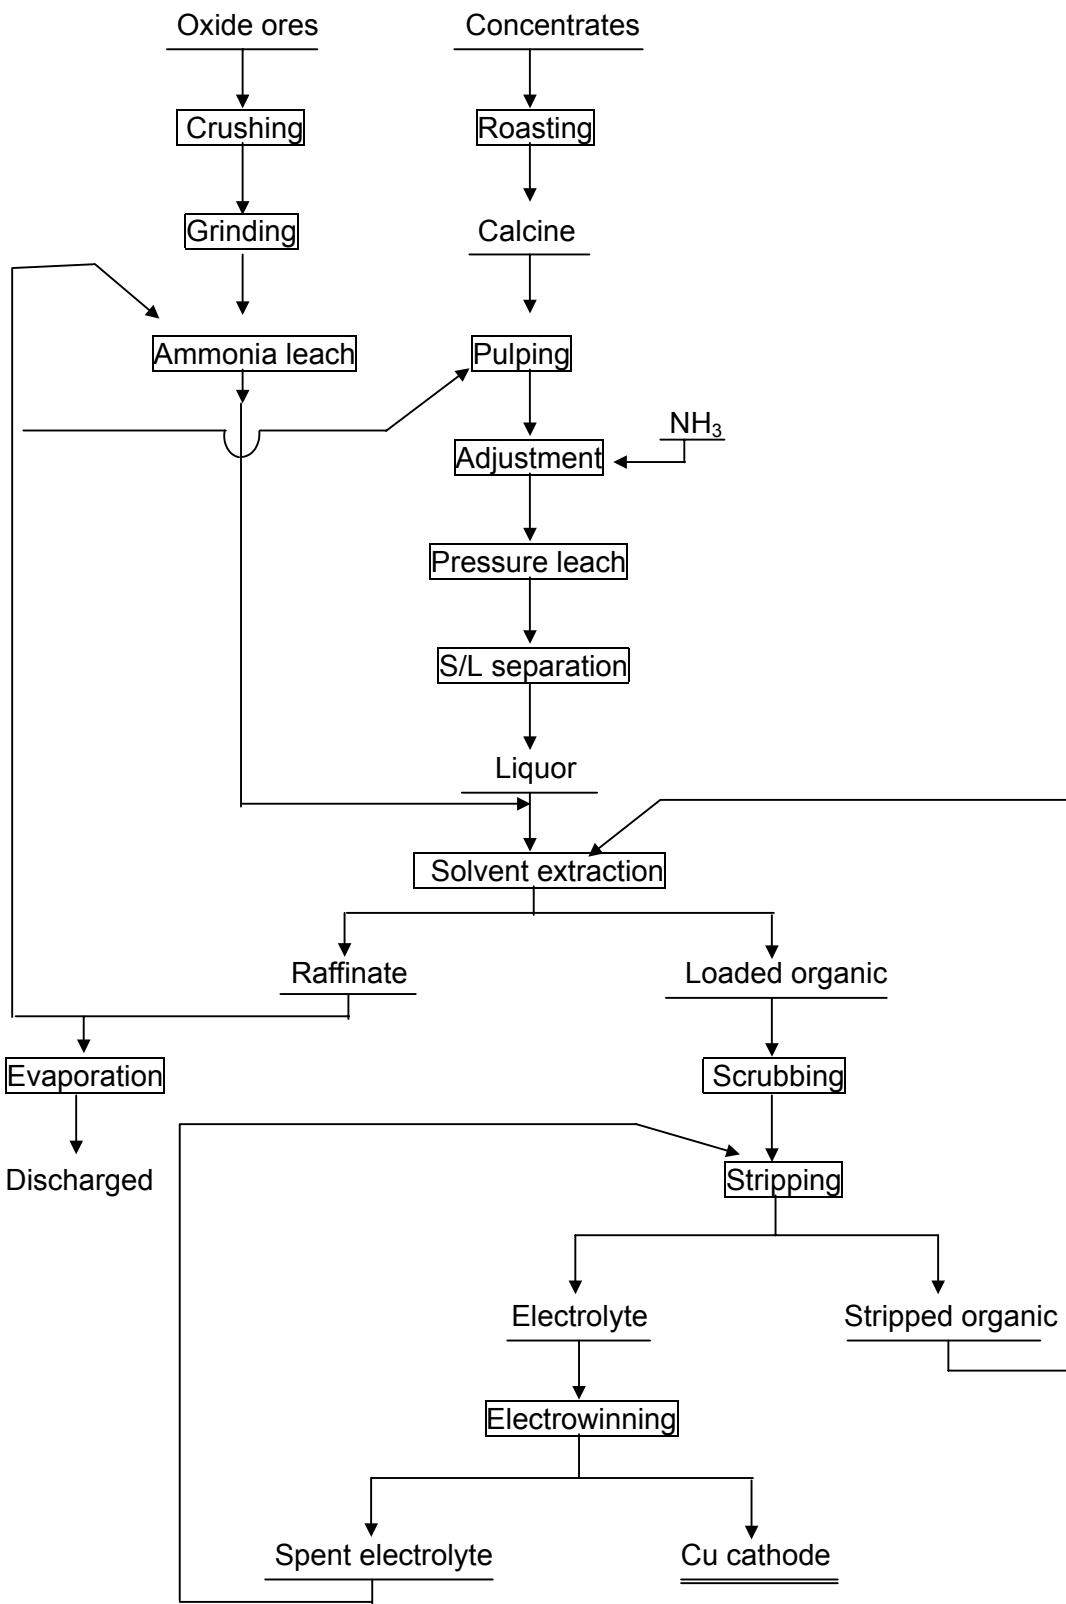

Figure 2. Principle flowsheet of ammonia leach-SX-EW process for treatment of high alkaline gangue containing copper ores.

Organic entrained in the strip liquor is removed by a flotation tank prior to electrowinning. The ammonia build up in the electrolyte is very slow, 6 kg of ammonia is transferred to the tankhouse per 1000 m<sup>3</sup> leach liquor. 0.5 m<sup>3</sup> of copper electrolyte is bleed off per day to control the ammonia in the electrolyte at 2 g/L. There are 30 cells in the tankhouse each containing 17 cathodes and 18 anodes. The dimensions of each cell are 920 by 2300 by 1060 mm. The anode is a Pb-Ag-Ca-Sr alloy and cathodes are grown on copper starting sheets.

The raffinate from extraction, containing less than 0.1 g/l Cu, is taken back to leaching and thickening. To keep water balance of the whole process, 10-12 m<sup>3</sup>/d of raffinate is bleed off to ammonia evaporation, then discharged.

In the pilot operation the ammonia consumption for the processing of copper concentrate is 102 kg/t Cu while for copper oxide ore processing it is 250 kg/t Cu. The operation cost is US\$ 650~700/t Cu.

## CONCLUSIONS

The laboratory tests and pilot plant operation prove that ammonia leach-SX-EW is a practical technology for the treatment of Tangdan's high alkaline gangue containing copper ores.

- 1) Copper concentrates are converted to sulphate or oxide by roasting at 550~600 °C, the calcine is pressure leached using ammonia at relatively low pressure and temperature, e.g., 90~100°C, 0.2M Pa. The pressure leach is conducted in a column style autoclave, a small and cheap equipment with high capacity.
- 2) Ammonia leaching is adopted for the treatment of high alkaline gangue containing copper ores. Impurities such as Ca, Mg, Al, Si, Mn and Fe in the ore are not leached, the leach liquor purification is thus simplified resulting in high quality copper cathodes.
- 3) LIX54-100 has high copper loading capacity, good kinetics and phase disengagement performance. Stripping can be achieved using a low acidic liquor. The SX circuit is configured with 2 stages of scrubbing in order to remove entrained and co-extracted ammonia from the loaded organic phase and ensure copper cathode quality.

## SOLVENT EXTRACTION OF COPPER FROM HIGH CONCENTRATION PRESSURE ACID LEACH LIQUORS

Kathryn C. Sole

Anglo American Research Laboratories (Pty) Ltd, Johannesburg, South Africa

Hydrometallurgical processes for the recovery of copper from sulphide concentrates are under evaluation for the Konkola Deep project in Zambia and for a copper-gold ore deposit. The process flowsheets involve copper dissolution from the concentrate by pressure leaching in sulphuric acid, followed by purification of the leach liquor by solvent extraction, and metal recovery by electrowinning. The autoclave discharge liquors contain 50 to 90 g/l Cu and, under appropriate operating conditions, minimal residual free acid. The choice of extractants and operating conditions for the recovery of copper from such solutions is discussed, and selected results from laboratory and pilot-scale studies are presented.

### INTRODUCTION

Pressure acid leaching (PAL) can offer technical and economic advantages in base metal flowsheets and is now being considered for the treatment of sulphide concentrates [1]. Flowsheets that integrate PAL with solvent extraction (SX) for the downstream processing of autoclave discharge liquors present interesting opportunities for efficient metal recovery.

Significant advances in copper SX have been made over the past thirty years [2], with almost 30% of world copper production today via this route. Most applications involve the relatively dilute liquors (1 to 4 g/l Cu) arising from the dump or heap leaching of low-grade material. In contrast, autoclave discharge liquors from the partial or total oxidation of copper sulphides have tenors ranging from 50 to 90 g/l Cu.

Modern copper extractants (HA) employ the hydroxyoxime functionality for the complexation of copper, the schematic reaction for which can be written:

The reaction stoichiometry shows that 1.54 g H<sub>2</sub>SO<sub>4</sub> is generated per g Cu extracted. The purification of leach liquors with high copper concentrations provides challenges in designing flowsheets to accommodate the substantial quantities of acid produced by the extraction reaction. Limited studies on the processing of such liquors have been documented [3].

This paper examines two case studies (the recovery of copper from a copper-gold deposit and the hydrometallurgical option for the Konkola Deep expansion project in Zambia) in which these challenges are met by innovative process integration. The choice of extractants and operating conditions for the purification of copper from the high-concentration PAL liquors are discussed, and selected results from laboratory and pilot-scale studies presented.

## SELECTION OF EXTRACTANTS

### **Simulation Modelling**

Potential extractant systems for achieving the high copper transfers required ( $\Delta\text{Cu} = 50 \text{ g/l}$ ) for the processing of PAL pregnant leach solutions (PLS) were identified using the *Isocalc* (Cognis) and *MEUM* (Avecia) simulation models. There was excellent agreement between experimental data and the model predictions, confirming the validity of using modelling for the preliminary selection of extractant compositions and operating conditions.

Selected results are presented in Table 1. Various combinations of circuit configurations and organic-to-aqueous (O:A) flowrate ratios will achieve similar objectives; the particular choice of conditions will be governed by capital and operating costs, as well as by site-specific considerations.

*Table 1. Modelling of copper extraction from high-concentration liquors.*

Extractant	Concn. (vol.%)	PLS Cu (g/l)	Circuit configuration	Advance O:A	Raffinate Cu (g/l)	$\Delta\text{Cu}^*$ (g/l)
LIX 984N	32	60	3E, 2S** 2E, 2S	4.2 5.5	8.8 9.88	51.2 50.1
		80	2E, 2S 3E, 1S	6 6	30.0 28.7	50.0 51.3
	32	60	3E, 2S 3E, 2S	6 5	8.47 10.0	51.5 50.0
		60	4E, 2S 3E, 2S	4.5 3.76	9.1 15.0	50.9 45.0

		70	3E, 2S	5 6	15.8 13.3	54.2 56.6
	35	70	3E, 2S	5 6	14.1 12.4	55.9 57.6

\* PLS acid: 5 g/l H<sub>2</sub>SO<sub>4</sub>; SE: 35 g/l Cu, 180 g/l H<sub>2</sub>SO<sub>4</sub>; AE: 45 g/l Cu; Mixer efficiency: 98%

\*\* 3E, 2S = three extraction stages, two stripping stages

### **Extraction Isotherms**

The extractants chosen for the experimental study are described in Table 2. The partially aromatic diluent was Shellsol 2325, supplied by Shell Chemicals.

*Table 2. Copper extractants.*

Supplier	Extractant	Functionality	Modifier
Avecia  Cognis	Acorga M5640	aldoxime	ester
	Acorga M5774	aldoxime	ester
	LIX 664N	aldoxime	ester
	LIX 84-I	ketoimine	none
	LIX 984N	50:50 aldoxime:ketoimine	none
	LIX 973N	70:30 aldoxime:ketoimine	none

Figure 1 shows the extraction of copper from an autoclave discharge liquor containing 70 g/l Cu. Both Acorga extractants, LIX 664N and LIX 984N will produce a raffinate of < 10 g/l Cu under appropriate operating conditions. LIX 84-I and LIX 973N were also tested, but their extraction capability dropped significantly in the presence of too much acid, so they are not suitable for the treatment of autoclave discharge liquors. In general, aldoximes have a higher loading capacity for copper than ketoximes, but, since they form stronger complexes, are typically less readily stripped; hence the need to include a stripping modifier in the formulation of aldoximes.

The effect of extractant concentration is shown in Figure 2. Higher concentrations increase copper transfer due to higher loadings, thereby reducing the equipment size for a given PLS throughput. Higher concentrations usually require higher temperature operation due to viscosity and settling limitations, however even at ambient temperature, the use of 48 vol.% extractant did not pose visible problems, and loadings up to 25 g/l Cu were measured.

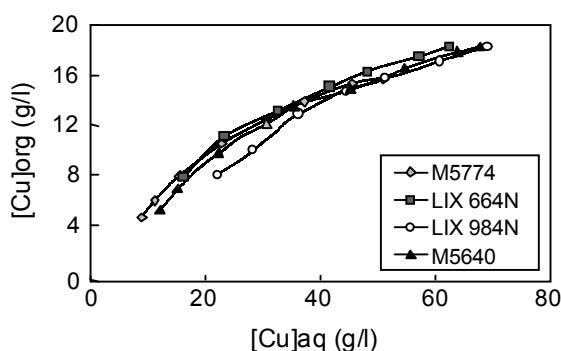

Figure 1. Extraction of copper from PAL liquor (70 g/l Cu, 2.8 g/l Fe, 6 g/l  $H_2SO_4$ ) by 32 vol.% extractant in Shellsol 2325.

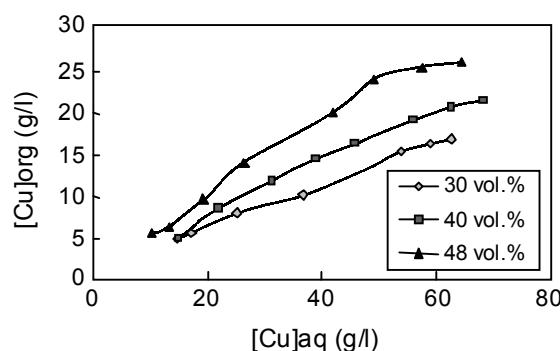

Figure 2. Effect of extractant concentration on copper extraction from PAL liquor by Acorga M5774 in Shellsol 2325.

## RECOVERY OF COPPER FROM A COPPER-GOLD DEPOSIT

A hydrometallurgical process is under development for the recovery of copper from a copper-gold deposit. Copper is liberated from the finely ground concentrate by pressure leaching under conditions that minimise the free acid and iron in solution. The clarified leach solution contains 60 g/l Cu which is treated by SX to maximise copper recovery. The raffinate, containing significant quantities of acid liberated in the extraction reaction, is recycled to the leach. The flowsheet also includes a second conventional SX circuit to recover copper from the filtrate wash water. A single electrowinning (EW) circuit provides a recycle of electrolyte between the two SX strip circuits. Gold is recovered from the leach residue.

Following modelling simulations and initial screening of extractants, LIX 984N and Acorga M5774 were chosen for further evaluation using leach liquor generated from the pressure leaching testwork. The SX performance of the high-tenor circuit (32 vol.% extractant) is summarised in Table 3.

Table 3. Extraction and stripping performance of the high-tenor SX circuit.

Stream	Acorga M5774	LIX 984N
Stripped organic (SO) (g/l Cu)	3.58	3.94
Loaded organic (LO) (g/l Cu)	18.58	16.18

McCabe-Thiele constructions were used to determine the staging requirements and operating conditions for the high-tenor SX circuit (Figure 3). An advance O:A of 5.4 will produce a raffinate of 10 g/l Cu in three extraction stages from a PLS containing 60 g/l Cu at pH 1.4. Using a spent electrolyte (SE) of 35 g/l Cu and 180 g/l H<sub>2</sub>SO<sub>4</sub>, a stripping ratio of O:A = 1.1 will upgrade the advance electrolyte (AE) to 45 g/l Cu in two stages.

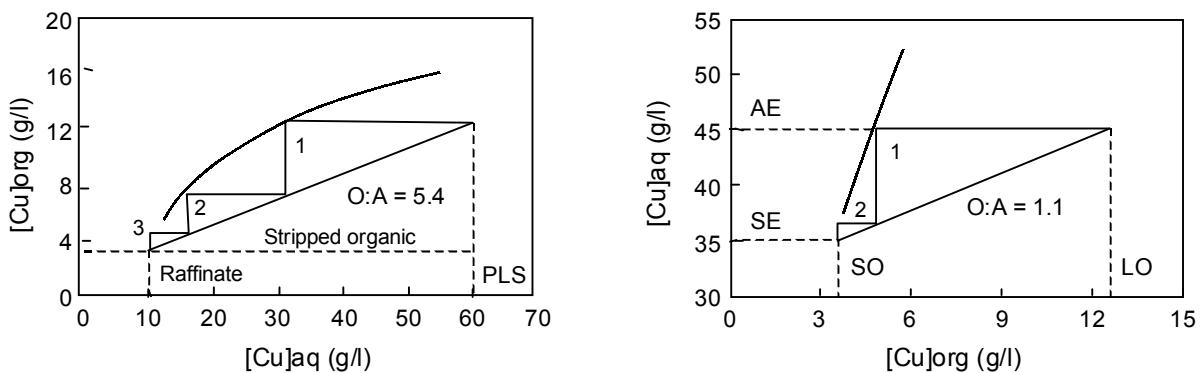

Figure 3. McCabe-Thiele constructions for (a) extraction and (b) stripping of copper in the high-tenor SX circuit (32 vol.% Acorga M5774 in Shellsol 2325).

### KONKOLA DEEPS EXPANSION PROJECT

A hydrometallurgical flowsheet (Figure 4) for the combined treatment of the Konkola Deep sulphide deposit and Chingola refractory ore (CRO) has been proposed. The sulphide concentrate (40-45% Cu) is pressure leached under conditions that maximise recovery of copper and cobalt while rejecting iron as hematite. The autoclave discharge contains 60 g/l Cu and the acid tenor is minimised to 5 g/l, allowing the liquor to be purified directly by SX. The high-tenor SX1 circuit removes the bulk of the copper, the extraction of 50 g/l Cu generating a raffinate containing ~80 g/l H<sub>2</sub>SO<sub>4</sub>. This acid is used to leach copper from the CRO, the aggressive conditions necessitated by the high aluminium, magnesium, and calcium oxides and carbonates in this material. The atmospheric leach liquor is treated for copper recovery in the low-tenor SX2 circuit. Both SX circuits are integrated with EW to produce a high-grade copper cathode product.

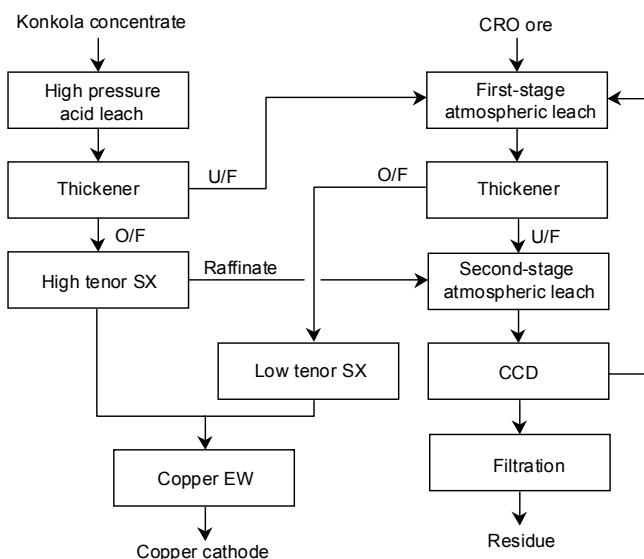

Figure 4. The hydrometallurgical flowsheet for the Konkola project.

This flowsheet capitalises on the synergy between the leaching of the sulphide concentrate (acid producing) and the oxide ore (acid consuming), which provides a convenient way of ‘transferring acid’ from the sulphide to the oxide circuit. Key to the concept is the high copper transfer ( $\Delta\text{Cu} = 50 \text{ g/l}$ ) of the SX1 circuit which generates a raffinate of sufficient acid strength to leach the refractory CRO minerals. SX1 maximises copper extraction using a high extractant concentration and high O:A; SX2 generates a low copper raffinate (< 0.5 g/l).

### Pilot-Plant Evaluation

An eight-week, integrated pilot-plant campaign producing 24 kg/h cathode copper was carried out at AARL [4]. The pilot plant treated 27 tons of CRO and 2.5 tons of Konkola concentrate, and produced 940 kg of LME Grade A copper cathode.

Both SX circuits comprised three extraction and two strip stages, configured for counter-current flow. Two extractants were tested: Acorga M5640 and LIX 984N. The diluent was Shellsol 2325. The operating conditions are shown in Table 4.

*Table 4. Konkola pilot-plant SX operating conditions.*

Parameter	SX1	SX2
Extractant concentration (vol.%)	32	16
PLS	Clarified autoclave discharge	Clarified CRO liquor
PLS composition	60 g/l Cu, 6.5 g/l H <sub>2</sub> SO <sub>4</sub>	5.3 g/l Cu, 2.7 g/l H <sub>2</sub> SO <sub>4</sub>
Extraction advance O:A	4.9	1.0
Target extraction $\Delta\text{Cu}$ (g/l)	50	4.8
Strip advance O:A	0.91	1.76
Strip liquor (SE)	37 g/l Cu, 170 g/l H <sub>2</sub> SO <sub>4</sub>	37 g/l Cu, 170 g/l H <sub>2</sub> SO <sub>4</sub>
Loaded strip liquor (AE)	46.1 g/l Cu, 156 g/l H <sub>2</sub> SO <sub>4</sub>	45.4 g/l Cu, 157 g/l H <sub>2</sub> SO <sub>4</sub>

SX1 consistently achieved copper extractions of 50 g/l. SX2 exceeded the performance specifications, with average raffinates of 0.25 g/l Cu. Typical results are shown in Table 5. Comparison of the plant data with laboratory isotherms generated from the plant solutions showed excellent correlation (Figure 5), indicating optimal operation of both SX circuits. Both extractants performed well and little differentiation of metallurgical performance could be quantified under the pilot-plant operating conditions. LME Grade A copper was produced throughout the campaign, with all cathodes meeting the BSI standard 6017:1981.

*Table 5. Typical performance of SX circuits during the Konkola pilot-plant campaign.*

Element (g/l)	SX1			SX2		
	PLS1	LO1	SO	PLS	LO	SO
Cu	59.29	15.6	6.2	5.81	8.85	3.8
Co	1.23	< 0.001	< 0.001	0.61	< 0.001	< 0.001
Fe	1.22	< 0.001	< 0.001	1.77	< 0.001	< 0.001
Al	1.12	< 0.001	< 0.001	1.31	< 0.001	< 0.001
Mg	7.95	< 0.001	< 0.001	6.83	< 0.001	< 0.001
Ca	0.65	< 0.001	0.001	0.69	< 0.001	< 0.001
Mn	1.31	< 0.001	< 0.001	1.22	< 0.001	< 0.001
Zn	0.10	0.001	< 0.001	0.05	< 0.001	0.001

## CONCLUSIONS

Pressure leaching technologies currently under development for the treatment of copper sulphide concentrates yield leach liquors that contain 50 to 90 g/l Cu. Purifying such liquors by SX requires an integrated flowsheet in which the large quantities of acid produced by the extraction reaction can be accommodated. This work has demonstrated that extractant

concentrations up to 45 vol.% can achieve copper transfers of 50 g/l in three stages. Adequate stripping is achieved in two stages with a conventional SE composition, producing an AE from which LME Grade A copper cathode can be electrowon.

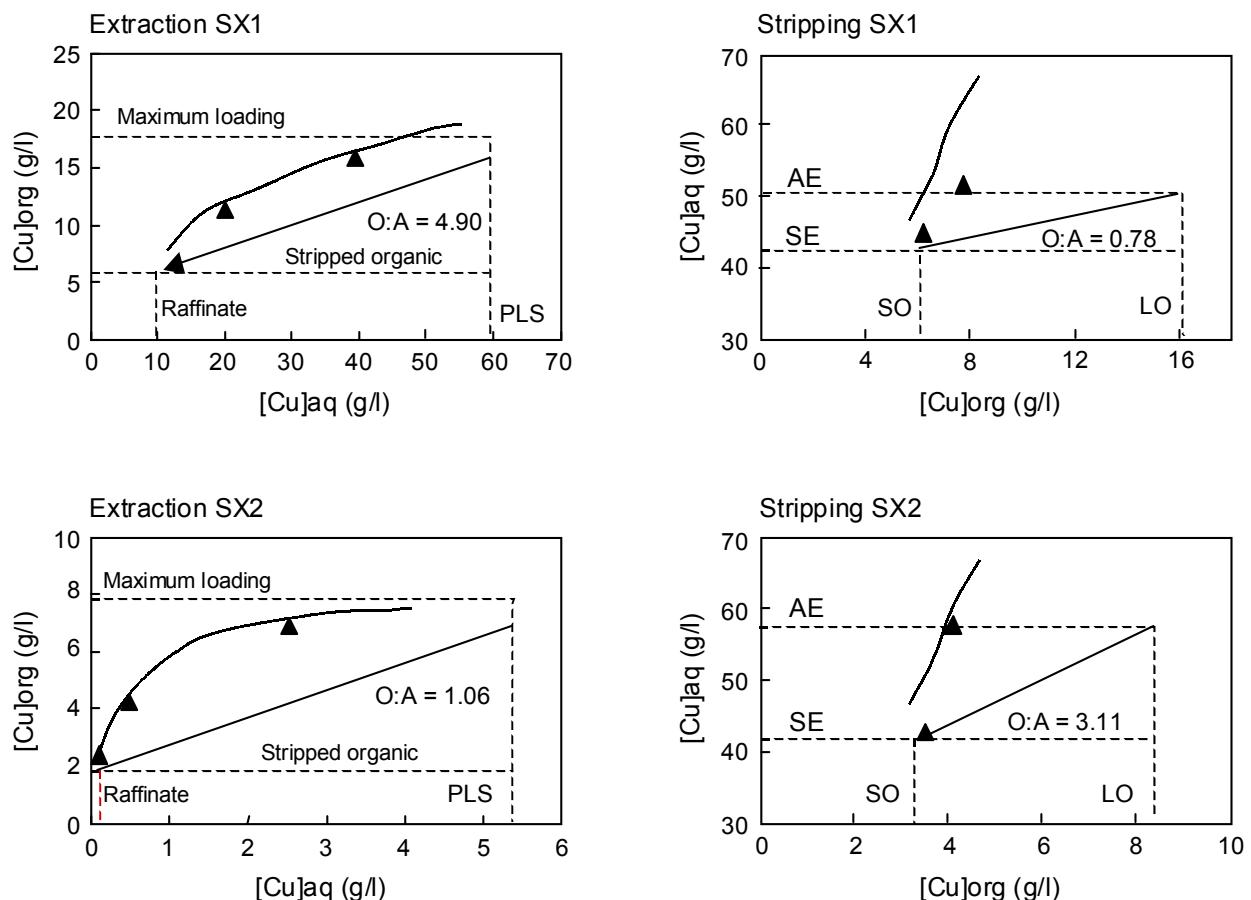

Figure 5. Comparison of laboratory extraction and stripping isotherms (solid lines) with typical pilot-plant operating conditions ( $\blacktriangle$  and dotted lines) for SX1 and SX2.

The performance of conventional extractants and circuit configurations for transferring such high amounts of copper has not been previously documented for continuous trials. The successful completion of the Konkola pilot plant demonstrated that existing extractants can be used in non-traditional applications without problems.

## ACKNOWLEDGEMENTS

The extractants and modelling packages were kindly made available by Avecia and Cognis. Anglo Base are thanked for permission to discuss details of the two development projects. This paper is published by permission of Anglo American Research Laboratories (Pty) Ltd.

## PURIFICATION OF COPPER ELECTROLYTE WITH CYANEX 923

Chun Wang\*, Kaixi Jiang, Daxing Liu and Haibei Wang

Beijing General Research Institute of Mining and Metallurgy, Beijing, P. R. China

Comparative extraction tests on a range of extractants for the removal of impurities from actual copper electrolyte has revealed Cyanex 923 to be the most effective extractant. The extraction of As, Sb and Bi was studied as functions of aqueous acidity, concentrations of chloride ion and Cyanex 923, and contact time. The loading capacities were determined. Organic entrainment and residual antimony in the raffinate were further removed by absorption using activated carbon. A novel process was proposed, which uses Cyanex 923 combined with subsequent absorption using activated carbon to remove As, Sb and Bi from a copper electrolyte. The process can be used as a supplement for producing high quality copper cathode, especially for plants whose Bi and Sb contents in the electrolyte are high.

### INTRODUCTION

In the electrorefining of copper, the impurities in the electrolyte, particularly As, Sb and Bi, will reduce the quality of the cathode copper. Therefore the concentration of Bi and Sb is generally maintained at 0.3-0.5 g/l and As at 0.5-10 g/l [1, 2]. To maintain these impurity levels, a portion of the electrolyte is bled continuously to a purification circuit where both the copper and impurities are co-deposited as a mixed cathode. This conventional process has several disadvantages, such as the potential risk of evolution of toxic arsine gas and recycling of the impurities in the process.

The application of solvent-extraction and ion-exchange techniques for the selective removal of As, Sb and Bi from copper electrolyte has been recently reviewed along with descriptions of plant operations [2, 3]. The solvent extraction of arsenic with tributylphosphate (TBP) is well documented [4] and employed at several refineries for electrolyte purification, such as MHO Hoboken Refinery in Belgium [5 - 7].

Studies on the use of organophosphorus reagents for the extraction of impurities from copper electrolytes have revealed several trends [8]. Arsenic was extracted best by dibutylbutylphosphate (DBBP) followed by DPPP and TBP. Sb and Bi were extracted with an equimolar mixture of mono(2-ethylhexyl)phosphoric acid (M2EHPA) and di(2-ethylhexyl)-phosphoric acid (DEHPA). The use of Cyanex 923 for the extraction of As and the mineral acids has been studied [9, 10]. Another study showed that 1.6 g/l As and 0.15 g/l Sb could be loaded by 50% v/v Cyanex 923, and that Bi was quantitatively extracted [11]. These studies were performed on a synthetic copper electrolyte and in tests by the authors using actual electrolyte, indications were that Bi extraction performance was different from that reported [12].

In the present study, a number of extractants were screened for electrolyte purification. Of those tested, Cyanex 923 was found to be the most promising and a stronger extractant than TBP. The parameters studied in further extraction tests with Cyanex 923, were aqueous acidities, concentrations of chloride ion and extractant, and contact time.

## EXPERIMENTAL

### Reagents

Aqueous solutions used were copper electrolytes obtained from operating Chinese refineries. For tests where acid concentration was varied, either water or concentrated sulphuric acid was added to the electrolyte. Chloride was added where required.

The extractants, Cyanex 923 (mixture of straight chain alkylated phosphine oxides) and Cyanex 925 (mixture of branched chain alkylated phosphine oxides), were supplied by Cytec Industries Co. TBP, DEHPA, mono-alkylphosphoric acid (P538), and a primary amine (N1923) were obtained from domestic chemical plants. N1923 was converted into the sulphate form. Kerosene was used as diluent.

### Extraction and Analytical Procedures

All the batch experiments were conducted by equilibrating measured volumes of the feed and organic solutions in separation funnels and shaking for 1-10 min at room temperature. Aqueous solutions were analyzed by atomic absorption spectrophotometry (AAS) using a Perkin-Elmer model TC5100 instrument or inductively coupled plasma atomic emission spectrometry (ICP-AES) using a Perkin-Elmer model Optima 3000 instrument. The metal contents in the loaded organic phases were determined by mass balance. The absorption with activated carbon was performed by adding a measured portion of activated carbon into the copper electrolyte (2-3 g powder carbon/liter of solution) and stirring for an hour. The total organic content in solution was analyzed as previously described [12].

## RESULTS AND DISCUSSION

### Extraction of As, Sb and Bi with Various Solvents

Neutral organophosphorus reagents (TBP, Cyanex 923 and Cyanex 925); acidic organophosphorus reagents (P538 and DEHPA); primary amine reagent (N1923) and their binary mixtures were compared in extraction tests. The results are summarized in Table 1.

*Table 1. Extraction of As, Sb and Bi with various solvents.*

Aqueous: As 3.50 g/l, Sb 0.21 g/l, Bi 1.20 g/l and H<sub>2</sub>SO<sub>4</sub> 190.1 g/l.  
Phase contact: 5 min at O/A = 1.

Solvent Composition v/v	% Extraction		
	As	Sb	Bi
50% TBP	10.28	0.00	0.00
50% Cyanex 923	70.00	50.48	23.33
50% Cyanex 925	46.28	22.86	7.50
50% P538	0.00	47.62	15.00
10% N1923	0.00	14.28	76.67
40% TBP - 10% DEHPA	32.26	0.40	0.00
37.5 Cyanex 923 - 1.5% DEHPA	58.00	28.57	17.50
25% Cyanex 923 - 3% DEHPA	48.57	19.05	13.33
33% Cyanex 923 - 6.7% P538	46.57	42.86	26.67
16.7% Cyanex 923 - 13.3% P538	13.14	47.62	22.50
37.5% Cyanex 923 - 12.5% TBP	61.43	9.52	11.67
25% Cyanex 923 - 25% TBP	53.42	19.05	8.31
12.5% Cyanex 923 - 37.5% TBP	36.86	4.76	3.33
5% N1923-25% Cyanex 923	56.86	14.28	12.50

For the three neutral organophosphorus reagents, the extraction performance decreases in the order: Cyanex 923 > Cyanex 925 > TBP. Of the other extractants or mixtures tested, no better extraction of As, Sb and Bi was demonstrated.

A more extensive study on the extraction of As, Sb and Bi by Cyanex 923 for different sulphuric acid and chloride concentrations was then undertaken.

### Effect of Sulphuric Acid Concentration

The results of the extraction of impurity elements for different concentrations of sulphuric acid are shown in Figure 1. The extraction of As, Sb and Bi is shown to first increase with increasing sulphuric acid concentration and then to decrease. The observed decrease is due to the competitive extraction of sulphuric acid by Cyanex 923. It has been shown that the extraction of sulphuric acid increases with increasing acid concentration and that 30 g/l sulphuric acid is loaded at an aqueous acidity of 200 g/l  $H_2SO_4$ .

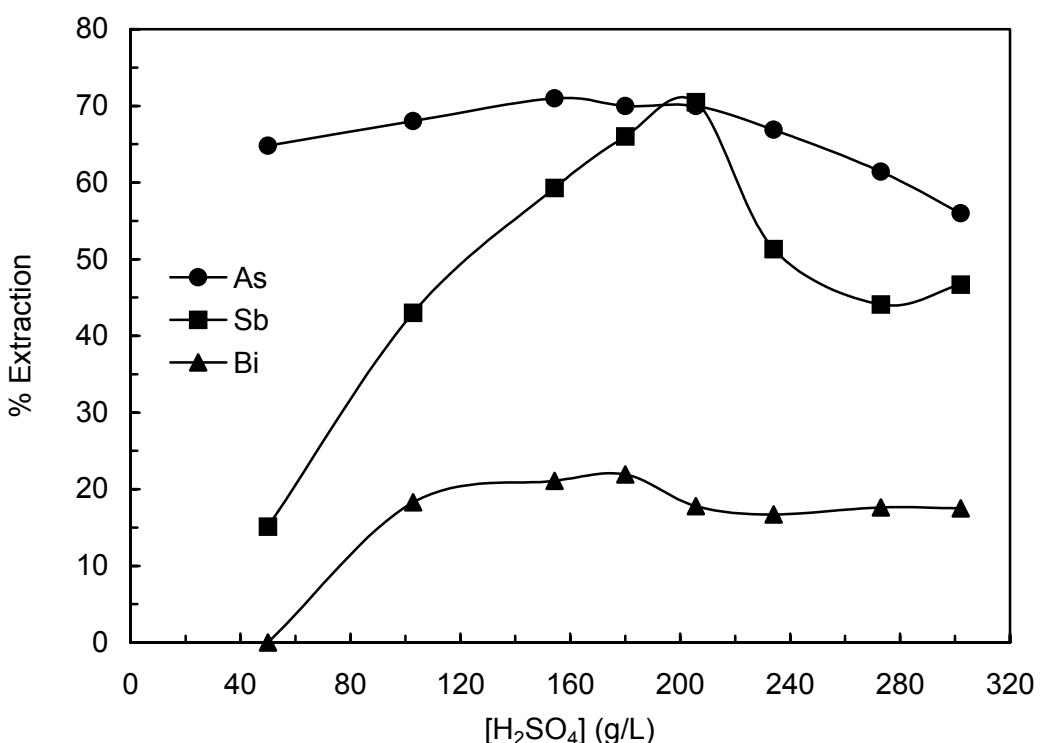

Figure 1. Extraction of As, Sb and Bi at different aqueous acidities.  
Organic phase: 50% v/v Cyanex 923; aqueous phase: As 3.50 g/l, Sb 0.21 g/l, Bi 1.20 g/l.

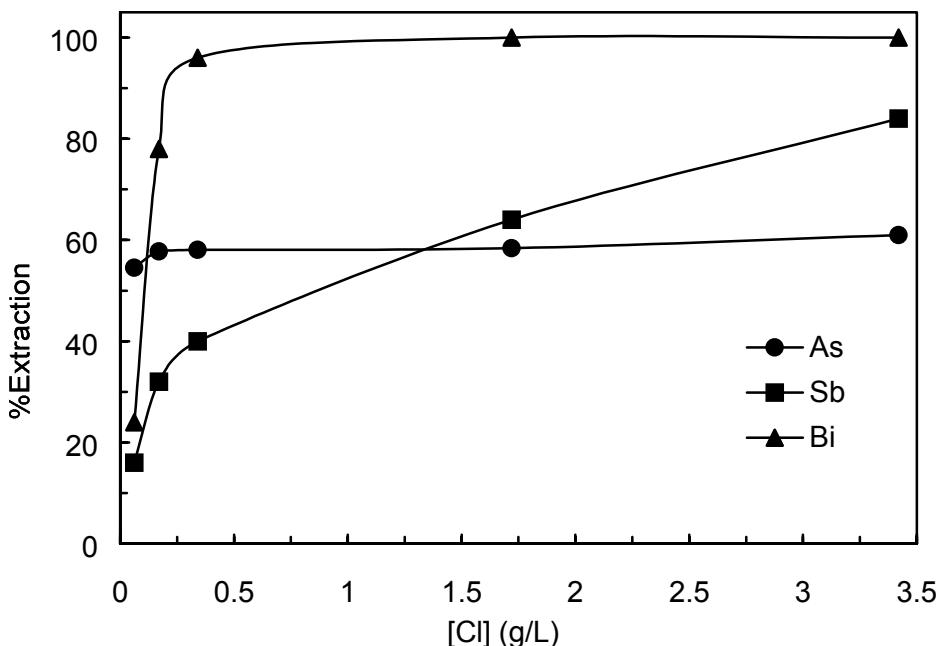

### Effect of Chloride Ion Concentration

As shown in Figure 2, the chloride has a significant impact on the extraction of Bi and Sb. For all the chloride ion concentrations studied Bi was extracted well, while Sb extraction improved at higher concentrations. Arsenic extraction was less affected, ranging from 50 to 60%. The aqueous chloride ion concentrations before and after the extraction were analyzed and are shown in Table 2.

Table 2. Aqueous chloride ion concentrations before and after extraction.

Sample No.	$[Cl^-]_{feed}$ (g/l)	$[Cl^-]_{raffinate}$ (g/l)
1	0.34	0.14
2	0.51	0.18
3	0.89	0.41

After the extraction, 50-60% of chloride ion in the aqueous phase was loaded into the organic phase. This result indicates that Bi and Sb are extracted in the form of chloride complexes.

*Figure 2. Extraction of As, Sb and Bi at different chloride ion concentrations.*

Organic phase: 50% v/v Cyanex 923; aqueous phase: As 3.10 g/l, Sb 0.25 g/l, Bi 0.50 g/l and H<sub>2</sub>SO<sub>4</sub> 190.1 g/l. Phase ratio: O/A=1.

### Effect of Contact Time and Extractant Concentration

For the following tests, the chloride concentration in the copper electrolyte was adjusted to 0.4 g/l, and the extraction of As, Sb and Bi was studied as functions of contact time and extractant concentration.

The variation of contact time between 2-10 minutes had no effect on the extraction of arsenic, antimony and bismuth. 56% As, 21% Sb and 98% Bi can be extracted within 1 min and no further increase is observed with time. Therefore, extraction equilibrium is reached quickly.

Extraction of impurity elements increases with increasing extractant concentration, with 55.8% As, 28.0% Sb and 100% Bi extracted by 50% v/v Cyanex 923.

### Loading of As, Sb, Bi, Cu, H<sub>2</sub>SO<sub>4</sub> and Chloride ion onto Cyanex 923

In these repeated loading tests equal volumes of the organic phase and copper electrolyte were first contacted and after equilibrium had been reached, the loaded organic phase was re-contacted with a further sample of fresh electrolyte for subsequent loading cycles. Extraction results are shown in Figure 3.

In the repeated loading cycles, Bi is very strongly extracted, with 90% of the Bi in the electrolyte being extracted even at the tenth cycle. Cyanex 923, thus, has a very high bismuth loading capacity. As and Sb extraction decrease significantly with increasing cycles and neither are extracted at the end of the tenth cycle. Between 50~70% of the chloride ion can be extracted into the organic phase, which may correspond mainly to the extraction of bismuth. However, copper is not extracted in the test cycles. Nearly 30 g/l of sulphuric acid is extracted in the first cycle and then rapidly decreases to zero. At the end of the test, As, Bi, Sb and chloride in the organic phase amounted to 4.09 g/l, 3.70 g/l, 0.12 g/l and 2.56 g/l, respectively. The co-extracted sulphuric acid could be scrubbed with water.

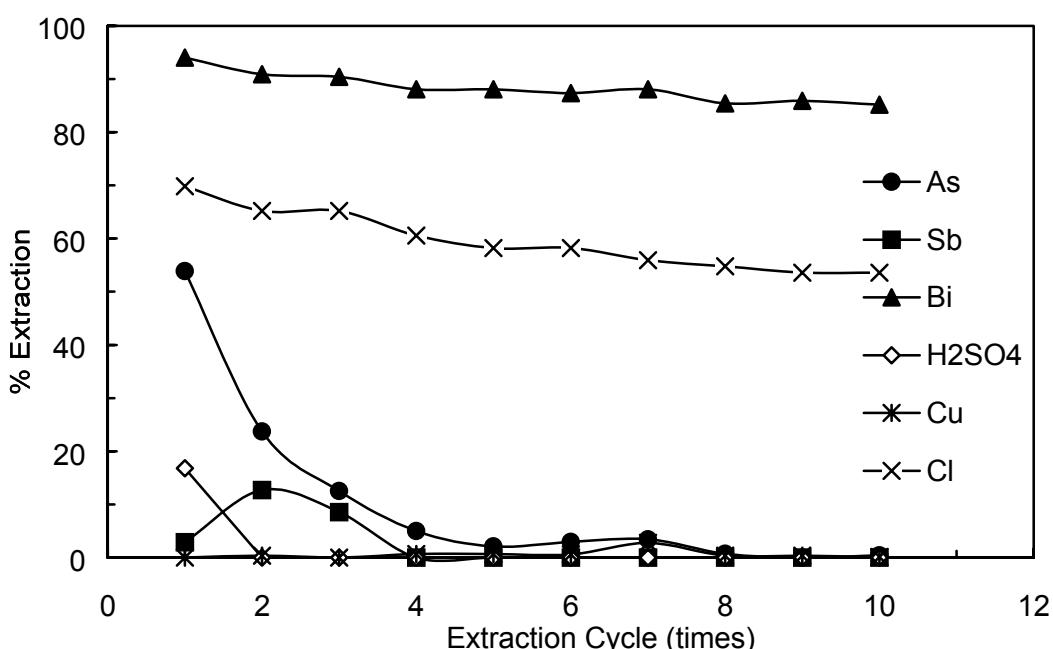

Figure 3. Loading of As, Sb, Bi, Cu, H<sub>2</sub>SO<sub>4</sub> and chloride ion onto Cyanex 923.

Organic phase: 50% v/v Cyanex 923; aqueous phase: As 3.91 g/l, Sb 0.48 g/l, Bi 0.42 g/l, H<sub>2</sub>SO<sub>4</sub> 177.1 g/l and 0.43 g/l Cl.

#### Absorption of Organic, As and Sb in the Raffinate using Activated Carbon

Organic phase from soluble loss or entrainment present in the raffinate after extraction would cause organic burn or cathode surface roughening when returned to the copper electrorefining circuit. The removal of organic from typical raffinate was therefore examined using activated carbon and the results, together with those for As and Sb adsorption, are shown in Table 3.

Table 3. Absorption of organic phase, As and Sb by activated carbon.

Raffinate: As 1.6~2.3 g/l, Sb 0.34~0.48 g/l, total organic phase content 200~410 mg/l.

Test No.	Organic phase content (mg/l)		% Absorption	
	Before absorption	After absorption	As	Sb
R-A-1	411	7.3	13.63	48.87
R-A-2	350	6.5	11.84	48.42
R-A-3	281	2.4	10.05	50.33
R-A-4	220	5.6	13.38	61.24
R-A-5	208	4.0	8.35	55.50

Most of the organic phase can be removed by carbon absorption. The residual solvent level in the treated electrolyte is less than 5 to 7 mg/l, which will not cause deterioration of copper deposit quality [1]. It is also found that arsenic (8 - 13%) and antimony (40 - 60%) could be further removed by absorption on activated carbon. This may be attributed to the absorption of fine slimes (mainly the mixed oxides of arsenic and antimony) from the electrolyte.

#### Stripping of As, Sb and Bi from the Loaded Organic Phase

Water can be used to strip arsenic from the loaded organic phase, with 50% of the As stripped in one stage. However, Sb and Bi are difficult to strip. Reagents including: sodium sulphide, sodium thiosulphate, sulphourea, sodium tartrate, sodium citrate, ethylene diamine tetraacetic acid disodium salt, and sodium oxalate were tested [12]. Sodium tartrate was shown to be the most effective stripping agent, especially for Bi.

Stripping for different sodium tartrate concentrations showed that the stripping of As, Sb and Bi improved with increasing sodium tartrate concentration. Using 80 g/l sodium tartrate solution, 70.9% As, 80.0% Sb and 83.3% Bi can be stripped in one stage.

### Regeneration of Stripping Reagent

The stripping reagent can be regenerated in a two-step process: (1) precipitation of As, Sb and Bi using 30 g/l sodium sulphide, followed by filtration; and (2) pH adjustment of the filtrate using solid sodium hydroxide, pH adjustment to 7-8.

In tests where the regenerated stripping reagent was re-used three times the results indicated that the stripping of As, Sb and Bi using regenerated reagent decreased slightly, but was comparable to that using fresh reagent.

### CONCLUSIONS

Cyanex 923 has been shown to be an effective extractant for removing As, Sb and Bi from actual copper electrolyte. Cyanex 923 has a high bismuth loading capacity when a small portion of hydrochloric acid is added to the electrolyte. The application of this solvent-extraction technology for copper electrolyte purification with Cyanex 923 has resulted in a Chinese patent [13]. The process involves the adjustment of chloride concentration in the copper electrolyte to 0.4-0.6 g/l with 36.5% hydrochloric acid, then three stages of extraction with 50% v/v Cyanex 923; two stages of scrubbing with water; and two stages of stripping with 80 g/l sodium tartrate, followed with absorption of raffinate using activated carbon powder, and regeneration of stripping agent using 30 g/l sodium sulphide.

This process can remove 80% As, 95% Bi and 40%-60% Sb from a copper electrolyte solution and thus can be considered as a supplement to copper plants, especially those whose bismuth and antimony content in the electrolyte is high.

## EXTENDING ZINC PRODUCTION POSSIBILITIES THROUGH SOLVENT EXTRACTION

D. Martín, G. Díaz, M.A. García and F. Sánchez

Técnicas Reunidas. R&D División, Madrid, Spain

The Modified ZINCEX® Process, developed by Técnicas Reunidas, is highly flexible dealing with a wide range of pregnant leach solutions. No matter if those solutions are produced from primary or secondary raw materials, and/or are based on conventional leaching, pressure leaching, heap leaching or bio leaching the result is always high-purity zinc product. The zinc solvent extraction unit within the process is a very effective barrier for impurities and a buffer for the composition of the pregnant liquor. This unit achieves an extremely pure aqueous extract that can be converted into different final products. All of them are characterised by fulfilling the highest purity standards. Also, there is the possibility to adapt the global process to a wide range of pregnant liquor compositions and various production capacities up to a zinc production limit over 150000 t/a with a single solvent extraction plant.

### INTRODUCTION

Traditionally zinc production from zinc sulphide concentrates is based on the roasting, leaching and electrowinning (RLE) process [1]. The concentrates containing around 50% Zn as zinc sulphide and about 30% sulphur are roasted to give zinc oxide calcine. The gaseous SO<sub>2</sub> outlet requires an annexed sulphuric acid plant. Zinc oxide calcines are leached with sulphuric acid solution generating a pregnant leach solution (PLS). In this process there is one single circuit between leaching and electrowinning (EW), therefore a high grade PLS is required and successful EW must carefully control impurities removal stages to avoid impurities passing to the pregnant electrolyte to achieve a high-grade zinc product.

Técnicas Reunidas, S.A. (TR) has developed, at commercial level, the “Modified ZINCEX® Process” (MZP) where the solvent extraction (SX) unit behaves as a very effective barrier for impurities and a buffer for changes in the composition of the PLS. In this way not only zinc concentrates, but different raw materials can be processed to produce special high-grade (SHG) zinc or other zinc compounds.

### THE MODIFIED ZINCEX® PROCESS DESCRIPTION

The former ZINCEX® process [2, 3] was developed by TR in Spain and first introduced in commercial operation at the 8,000 t/a MQN plant in Bilbao (Spain) in 1976. The MQN plant treats secondary zinc materials and after proven success, another ZINCEX® plant with a capacity of 11,500 t/a was built in 1980 for Quimigal at Lisbon (Portugal). This plant treats high-chloride leach liquors from various sources.

The Modified ZINCEX® Process [4-6] is a further developed and simplified version of the ZINCEX® Process, specifically adapted to treat solid oxidised materials or impure sulphate solutions. In 1997 a plant near Barcelona, Spain, was commissioned to recover zinc from 2,800 t/a of spent zinc batteries containing mercury and manganese as the main impurities [9].

ZINCEX® processes have the ability to treat primary and/or secondary zinc materials [10-13] for the recovery of zinc in circumstances where significant amounts of impurities are present. Solvent extraction is the key step used to concentrate and purify the zinc solution, which is then available for a number of products. Whilst the product can be slab zinc, it is equally possible to produce pure zinc sulphate and zinc oxide. In Table 1 flexibility and versatility of the MZP is briefly described.

*Table 1. Flexibility & versatility of the Modified Zincex® Process.*

A conceptual block diagram for the Modified ZINCEX® process SX section, applied to different PLS to generate a zinc solution able to produce the desirable product, is shown in Figure 1. The process steps included in the MZP are extraction, washing, and stripping and organic phase regeneration. A solution of di-2-ethylhexyl phosphoric acid (DEHPA) as extractant reagent in kerosene base is used as the organic phase. This organic phase (RH) has a high affinity to extract the zinc at MZP conditions according to the reaction.

Due to the process conditions applied by TR, impurities such as Co, Ni, Cd, Mg, Mn, Ca, etc. are not allowed to pass to the next process step. Under these conditions, the selectivity of the organic for the zinc is extremely high. Besides, in the washing stage the aqueous entrainment and the last residual co-extracted impurities are physically and chemically removed from the organic extract. Finally, in the stripping stage, an ultra-pure zinc sulphate solution is produced, able to be processed into the appropriate zinc compound (SHG-Zinc,

$\text{ZnSO}_4$ ,  $\text{ZnO}$ ). Additionally a bleed of the organic phase is treated with HCl solution, in the regeneration stage, to avoid the build up of co-extracted impurities (such as Fe) that are not stripped. A comparative diagram for impurities behaviour is presented in Figure 2, as a summary of the MZP ability to deal with any kind of zinc PLS to generate a commercial zinc product.

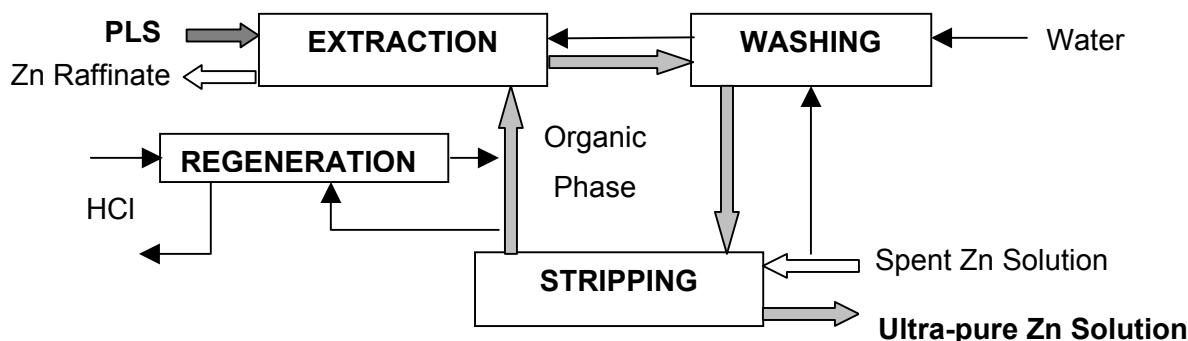

Figure 1. MZP: Conceptual scheme of solvent extraction section.

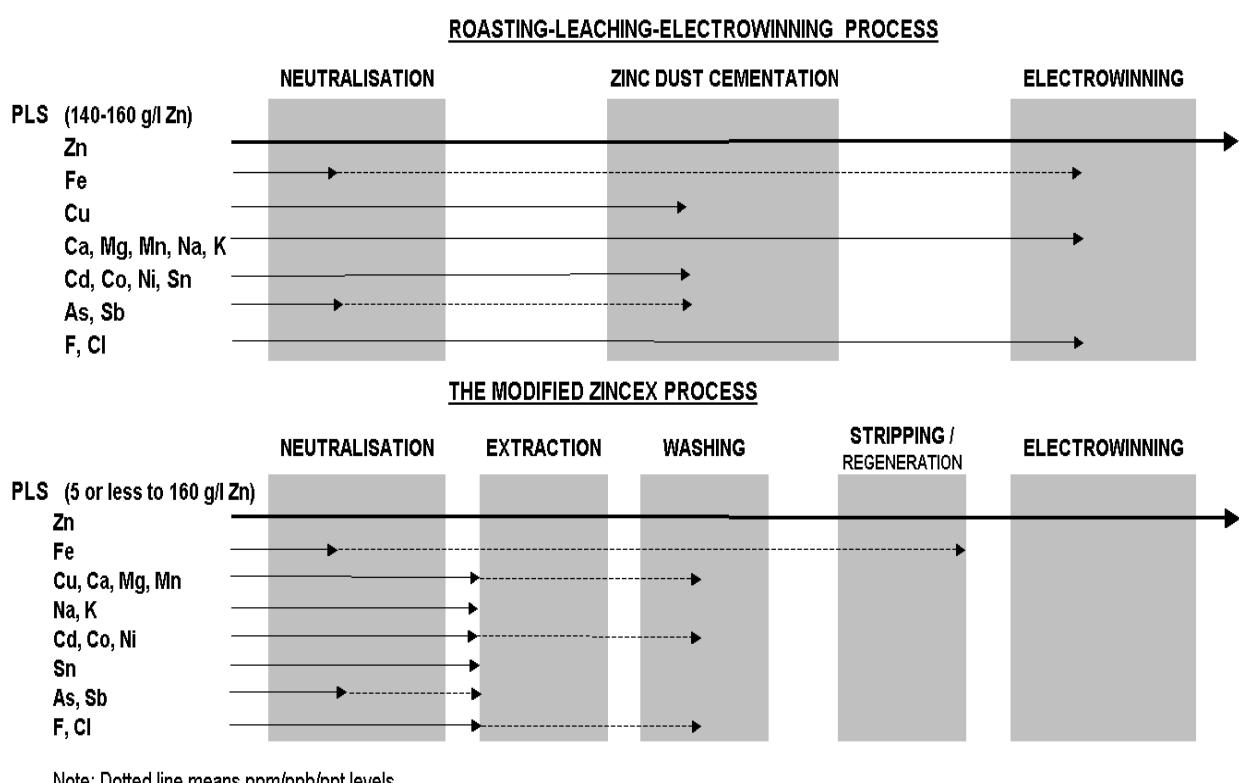

Figure 2. Comparison between RLE and MZP. Concentrations and impurities.

As can be observed Figure 2, and because of the physical and chemical separation between the PLS and the electrolyte, SX is a more effective barrier to impurities than the conventional RLE process. This is true for both steady and disturbed operation.

## RANGE OF APPLICATIONS FOR MODIFIED ZINCEX PROCESS

PLS quality and zinc product could be taken to define the range of application for MZP. Several experimental investigations and industrial plant projects performed during the last 25 years have demonstrated the viability of the MZP to treat any PLS (see Table 2).

### Zinc Concentration in PLS

#### **Low zinc concentration in PLS**

To date many primary zinc ores have not been treated due to their low zinc content that does not allow processing by the traditional RLE process. With the MZP [11-15] it is possible to treat these raw materials because the MZP solvent extraction circuit will produce an electrolyte that can be processed in any EW tankhouse. A general application is shown in Figure 3, where a zinc oxide ore is treated by means of the proper leaching process, producing a PLS zinc concentration between 5-50 g/l Zn and Cu, Cd, Co, Ni, Fe, Ca and Mg as impurities, independent of the source.

Table 2. Typical selected cases of PLS composition (g/l) fed to MZP SX section.

PRIMARY	Zn	Main Impurities	Project Case
Oxidised ores from acid leaching	30	Cd, Cu, Ni, Co, Cl, F, Mg	Skorpion
Sulphides ores from Bio leaching	120	Cd, Cu, Cl, F, Mg	Confidential
Sulphide ores from Bio + Acid leaching	50	Cd, Cu, Ni, Co, Cl, F, Mg	Confidential
Sulphide ores from Indirect bio-leaching	10	Cd, Cu, Ni, Co, Mg	RTM, S.A.
Sulphide ores from Pressure leaching	150	Cd, Cu, Ni, Co, Cl, Mg	Confidential
SECONDARY	Zn	Main Impurities	Project Case
EAFD from acid leaching	25	Cd, Cu, Cl	Elansa
Cu SX PLS Bleed from heap leaching	33	Cu, Ni, Co, Cl, Mg	Sanyati
Spent domestic batteries from acid leaching	20	Cd, Cu, Ni, Cl	Proces
Waelz O./Galv. Ashes from acid leaching	32	Cd, Cu, Ni, Co, Cl, F	Comm. of EU

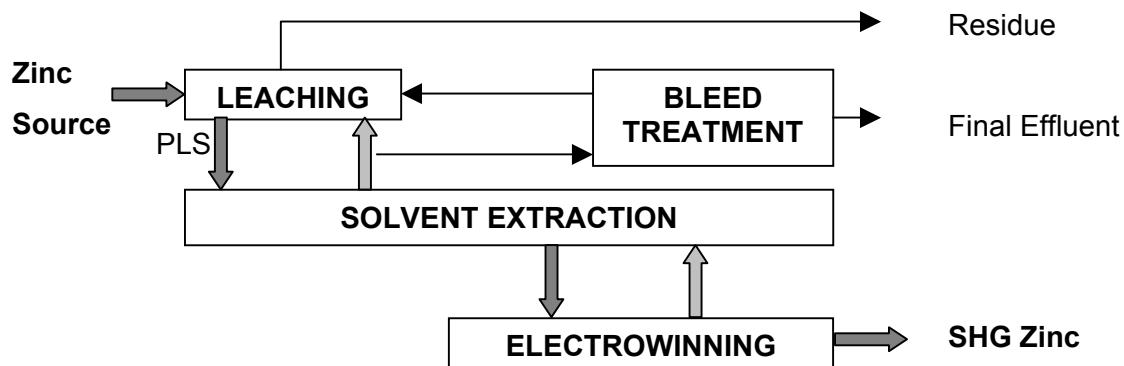

Figure 3. MZP applied on primary & secondary zinc materials.

A bleed of the raffinate is treated in a bleed-treatment unit, in order to avoid impurities building up in the system, and to then allow the EW unit to produce SHG zinc from the electrolyte.

### **High zinc concentration in PLS**

Some zinc ore treatments (pressure, heap and bio leaching) are capable of producing high zinc concentrated PLS. In this way the associated impurity levels are too high and present difficulties for the traditional process route. Thus the benefits due to the reduction in equipment sizes in the leaching unit can be impaired by a major complexity in the purification unit. The use of the MZP for this PLS is technically and economically viable. Figure 4 shows an example of processing by bio leaching. In the bio-leaching unit a PLS with 120 g/l Zn is produced and impurities such as Cu, Fe, Co, Ni, Cd, Ca, Mg are present in high levels. The SX unit, in the MZP conditions, produces an electrolyte without impurities that can be processed by EW to obtain SHG zinc ingots.

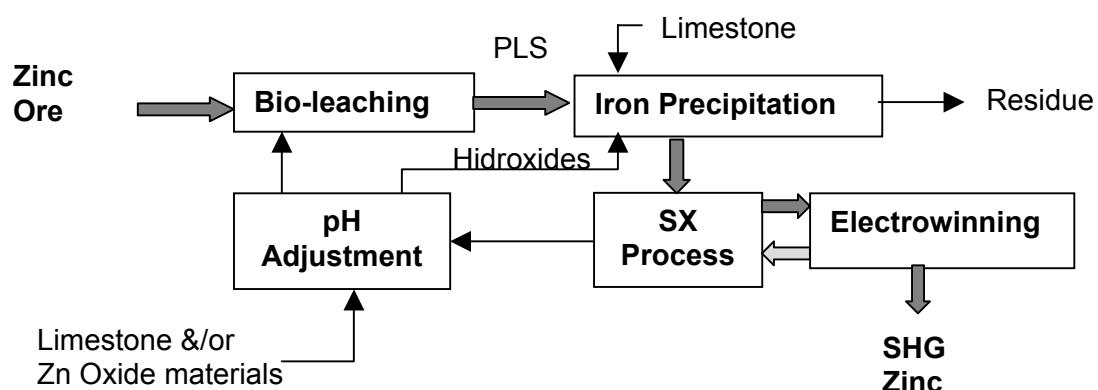

Figure 4. Example of MZP applied to zinc sulphide ores.

### **Impurities in PLS**

Primary and secondary zinc raw materials contain different impurities that produce a negative effect in the traditional RLE zinc processing. These impurities are Sb, As, Cl, Co, Cu, F, Ge, Ni, Fe, Se, Te, Hg, Sn, Mn, Ca, K and Mg and the effect is produced mainly during the EW stage. While some of them are difficult to remove by cementation using RLE conventional process, others cannot be avoided (Cl, F, Mg, etc.) or make operation difficulties (Ca, Mn, etc.). The MZP is not conditioned by this fact, as these impurities are not allowed to pass to the electrolyte. It is possible to find two kinds of contaminated PLS, a lot of impurity compounds in the PLS and a high concentration of impurities of some of them. Typical examples for these types of PLS are described below.

### **Variety of impurities**

Secondary zinc sources such as Electric Arc Furnace Dust (EAFD), Waelz Oxides, Galvanizing A, Tyre Ashes, Spent Batteries, etc. are becoming, nowadays, more a zinc source than a residue. MZP applied on these raw materials [4-10] has been demonstrated to be a viable solution to recover the zinc content. The MZP copes with the negative effect of the impurities being a fully effective barrier.

Electric Arc Furnace Dust (EADF) can be processed by MZP (Figure 3) and this treatment has been successfully tested [6, 7]. Technical, environmental and economical feasibility has always been proven through several studies at all levels. PLS contain 30 g/l Zn, 25 g/l Cl, 0.9 g/l Cu, and produces an electrolyte with 90 g/l Zn suitable to produce SHG Zinc by EW process.

### **High concentration of impurities**

Hydrometallurgical processing of metals, such as Cu, Ni, etc. can require a bleed to avoid build up of impurities such as Zn. This results in losses of the desirable metal as well as the zinc content is not valued anymore. A profitable solution to avoid this is the use of MZP to recover the zinc content in the bleed that is a Zn PLS and at the same time returning a solution able to be recycled to the main process. In this way the value of the zinc is realized and the desirable metal is not lost from the PLS. The high level of impurities (for Zn processing) is not a problem for MZP while other processes to remove zinc from this impure solution means high costs and reagent consumption and without any zinc valorisation.

Application of the process on a Cu PLS in a conventional leaching, SX, and EW circuit is shown in Figure 5. The feasibility of treating PLS containing 1-2 g/l Cu, 16 g/l Mn, 33 g/l Zn, 0.5 g/l Co, 2.4 g/l Mg, 0.1 g/l Ca, etc. has been demonstrated by Técnicas Reunidas.

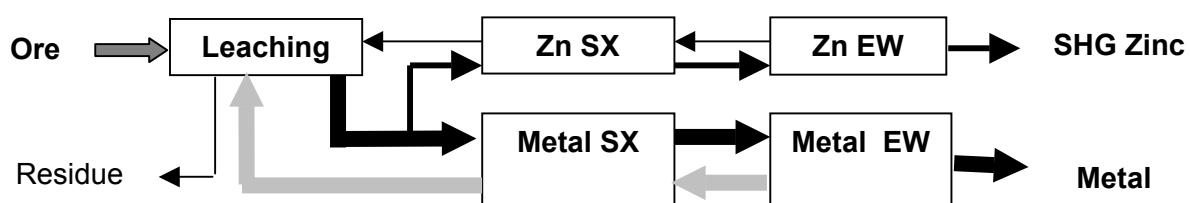

Figure 5. MZP applied on PLS bleeds of other metals production.

### **Zinc Product Alternatives**

MZP has the flexibility to produce zinc solutions able to be converted to any desired zinc product. This is possible due to the SX circuit that can be designed for every operation specifically to reach the desired zinc solution quality. Figure 6 shows a case of zinc sulphate salt production using MZP.

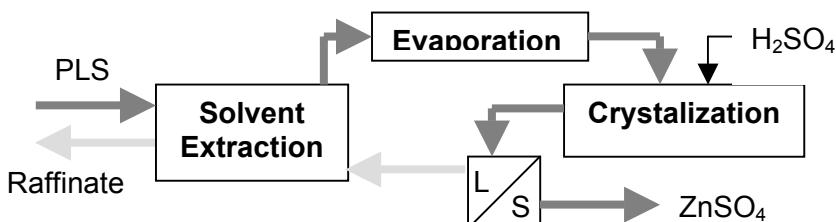

Figure 6. Zinc Sulphate production from MZP.

In Figure 7 we can see different alternatives for MZP applications regarding the zinc product.

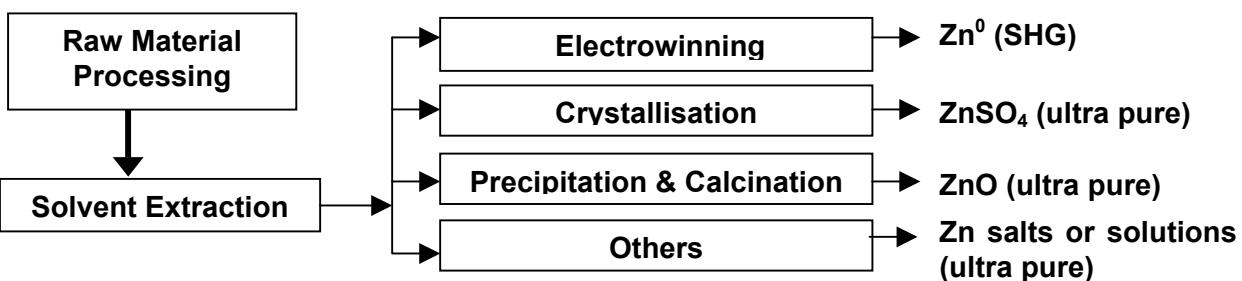

Figure 7. MZP zinc product alternatives.

## CONCLUSIONS

In conclusion the statement can be made that the viability of the Modified Zinced® Process to deal with any kind of PLS and to produce different zinc products has been demonstrated. Irrespective of the raw material source, the zinc content in the PLS and the variety and quantity of impurities present, the MZP is the most suitable, efficient and reliable application. In this process the Solvent Extraction stage, using appropriate operation conditions, is able to produce ultra-pure zinc solutions that can be processed to obtain the desired final zinc product.

## EFFECT OF TBP AS A MODIFIER FOR EXTRACTION OF ZINC AND CADMIUM WITH A MIXTURE OF DEHPA AND MEHPA

E. Keshavarz Alamdari, D. Darvishi, S. K. Sadrnezhaad\*, Z. Mos'hefi Shabestari,  
A. O'hadizadeh and M. Akbari

Dept. Mining and Metallurgical Engineering, Amirkabir University of Technology, Tehran, Iran

\* Dept. Materials Science and Engineering, Sharif University of Technology, Tehran, Iran

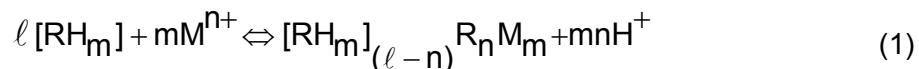

The simultaneous extraction of zinc and cadmium by a mixture of di(2-ethylhexyl)phosphoric acid (DEHPA) and mono-2-ethylhexylphosphoric acid (MEHPA) in the presence of tri-*n*-butylphosphate (TBP) as a modifier was investigated. The effects of temperature, pH and TBP concentration on extraction of zinc and cadmium were determined. It was shown that the extraction reaction for zinc is endothermic, while that for cadmium is exothermic. An increase in the TBP concentration caused greater synergistic shifts than when TBP was not dissolved in the organic phase. Separate formulae were deduced from the experimental data for the distribution factors of both zinc and cadmium.

### INTRODUCTION

Zinc and cadmium usually occur together in the nature. During leaching of low-grade ores, zinc and cadmium dissolve simultaneously into the leach liquor. The level of impurities in the electrolyte is generally high. The purification process is, therefore, very necessary, especially if production of ultra-high purity (UHP) zinc or cadmium is required.

Cadmium is one of the most toxic constituents of industrial wastes and effluents. It should, therefore, be totally removed from wastes and effluents before disposal to the outdoor environment [1]. Approximately half of the world's total consumption of cadmium is utilized in alkaline storage batteries. Cadmium recycling is, therefore, an important subject both economically and environmentally [2].

The method of solvent extraction may be used for selective extraction of impurities from leach liquors. The extractants can be considered as molecules that are chained together with hydrogen bonds [3]. The number of bonds depends on the acidic nature of the extractant. So  $\ell$  extractant molecules, each having  $m$  hydrogen ions, bond together to make a structure that can extract metal ions. The stoichiometric equation describing the solvent extraction process can, therefore, be written as:

where  $[RH_m]$  is an organic extractant molecule,  $[RH_m]_{(\ell-n)}$   $R_nM_m$  is the extracted metallic complex and  $H^+$  is the proton released by the organic extractant in exchange for the cationic metal species,  $M^{n+}$ . The equilibrium constant of the reaction, expressed in terms of the concentration of the reactants, can be defined as:

$$K_C = \frac{[RH_m]_{(\ell-n)} R_n M_m \cdot [H^+]^{m.n}}{[RH_m]^\ell [M^{n+}]^m} \quad (2)$$

where the concentration equilibrium constant  $K_C$  depends on temperature and concentration. Assuming the effect of concentration to be negligible, and taking logarithms of both sides of Equation (2) yields:

$$\log D = \frac{\Delta H_{app.}}{2.3 RT} + \frac{\Delta S_{app.}}{2.3 R} + m.n \text{ pH} + \ell \log [RH_m] + (m - 1) \log [M^{n+}] + \log m \quad (3)$$

in which the distribution coefficient,  $D$ , is defined as  $D = \sum[M_{org.}] / \sum[M_{aq.}]$ .

The thermodynamics of solvent extraction of some metals has recently been investigated by the same authors [4]. We report in this paper the effect of TBP as a modifier for the separation of zinc and cadmium from mixtures of DEHPA and MEHPA serving as suitable organic extractants. Coefficient factors mathematically obtained for quantifying the distribution ratio that prevails in the extraction system are also reported.

## EXPERIMENTAL METHODS AND MATERIALS

Organic phases containing 12% DEHPA and 8% MEHPA as extractant plus 0%, 2.5%, 5% and 10% TBP as modifier were prepared by dissolving the materials into pure kerosene. Initial metals concentrations in the aqueous solution were both 5 g/l. NaOH and sulfuric acid were used for adjusting pH of the system. Around 20 ml of aqueous solution was mechanically stirred with equal volume of organic phase in a jacketed vessel for one hour. The mixture was then allowed to disengage into two separate phases. The metal content of the aqueous phase was determined by titration against a standard solution of EDTA (0.09 M) using Eriochrom Black T as the indicator. These experiments were carried out at three temperatures (25, 40 and 60°C) using a thermostatic reaction bath.

## RESULTS AND DISCUSSION

### Effect of TBP as a Modifier

Experiments were carried out to study the effect of pH on the extent of extraction and determination of the maximum recovery. Extraction curves are presented in Figure 1. It is seen that zinc extraction occurs at  $0.6 < \text{pH} < 1.7$ , while cadmium extraction occurs at  $-0.05 < \text{pH} < 1.1$ . The extraction of cadmium occurs, therefore, under more acidic conditions than that of zinc. Figure 1 also shows that addition of TBP has a small effect on the  $\text{pH}_{0.5}$  (the equilibrium pH value at which 50% extraction of metal occurs) of zinc and cadmium extraction. Other experiments have, however, shown that at higher TBP concentrations, the rate of extraction of cadmium increases more rapidly with pH.

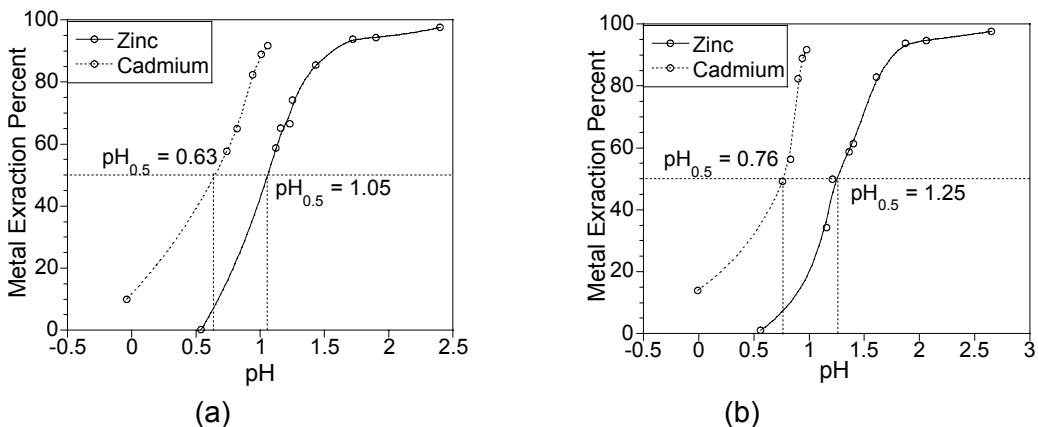

Figure 1. Extraction of zinc and cadmium at 25°C. a) 0% TBP; b) 10% TBP.

The effect of TBP on extraction of zinc and cadmium was investigated at different extractant concentrations. The extraction curves obtained show a synergistic shift to the right by increasing the relative amount of TBP with respect to the extractants (DEHPA and MEHPA). As is seen in Figure 1, the extraction percentage of cadmium and zinc varied from 0% to 90% depending on the pH and the relative amount of the organic modifier. The selectivity of the mixture can be expressed by the difference between the  $pH_{0.5}$  values of the two metals. The data obtained for  $pH_{0.5}$  and  $\Delta pH_{0.5}$  of the metals are illustrated in Table 1.

Table 1.  $pH_{0.5}$  for zinc and cadmium and  $\Delta pH_{0.5}$ .

TBP (%)	$pH_{0.5}$		$\Delta pH_{0.5}$ Zn-Cd
	Zn	Cd	
0	1.05	0.63	0.42
2.5	1.13	0.65	0.48
5	1.02	0.56	0.46
7.5	1.19	0.74	0.47
10	1.25	0.76	0.49

The values given in Table 1 show that the presence of TBP facilitates the separation of zinc from cadmium due to its  $\Delta pH_{0.5}$  enhancing effect. Figure 2 shows that at constant pH,  $\log D$  varies linearly with  $\log [TBP]$  with a slope of  $-1.00$  for zinc and  $-0.35$  for cadmium. A possible reason for this effect is that TBP, DEHPA and MEHPA molecules form hydrogen bonding with each other; hence they reduce the possibility of polymerization of DEHPA and MEHPA molecules to extract metallic ions. This causes diminution of the equivalent extraction potential and decreasing of the distribution ratio for zinc and cadmium extraction reactions. However it increases the gap between the required pH for extraction of Zn and Cd and it can, therefore, improve the selectivity of the extraction process.

As was mentioned before, the reason for synergistic shifts returns to the formation of new bonds in organic media. An equivalent organic value can, thus, be defined and the concentration of extractants can be considered as a function of TBP so that the equivalent concentration of extractant reagents can be estimated from the expressions defined for this purpose at TBP concentrations around  $[TBP]=0$ :

$$\begin{cases} [RH_m] = \sum [RH] + \sum [RH_2] = 0.66 \\ [RH_m]_{eqv} = 0.66 - a[TBP] \end{cases} \quad (4)$$

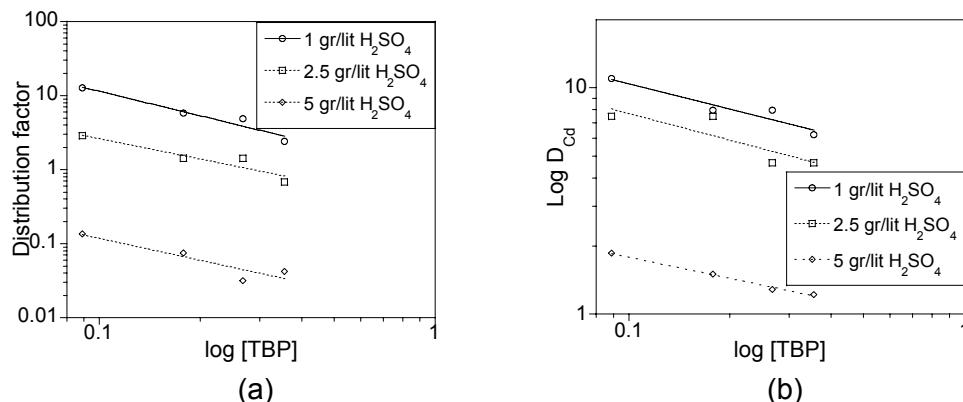

Figure 2. Variation of  $\log D$  vs.  $\log [TBP]$  at constant initial pH for a) zinc; b) cadmium.

So that:

$$\ln [RH_m] = \ln 0.66 - \frac{a[TBP]}{0.66} - \frac{a^2[TBP]^2}{2 \times 0.66^2} - \frac{a^3[TBP]^3}{3 \times 0.66^3} - \frac{a^n[TBP]^n}{n \times 0.66^n} \quad (5)$$

Substituting (6) in (3) and eliminating the terms with the order of 3 and more, one can obtain:

$$\begin{aligned} \log D = & \frac{-\Delta H_{app}}{2.3RT} + \frac{\Delta S_{app}}{2.3R} + m.n \text{pH} + \frac{I \times \ln 0.66}{2.3} - \frac{I \times a[TBP]}{2.3 \times 0.66} \\ & - \frac{I \times a^2[TBP]^2}{2 \times 2.3 \times 0.66^2} - \frac{I \times a^3[TBP]^3}{3 \times 2.3 \times 0.66^3} - \frac{I \times a^n[TBP]^n}{n \times 2.3 \times 0.66^n} \\ & + (M-1) \log [M^{n+}] + \log m \end{aligned} \quad (6)$$

Variation of  $\log D$  versus  $[TBP]$  is shown in Figure 3. As was assumed before, the relationship between  $\log D$  and  $[TBP]$  is of polynomial form. The coefficients used in Equation (6) can thus be evaluated by a curve-fitting method. The coefficient of the ( $\log [RH_m]$ ) term in Equation (3) can also be obtained by substituting the coefficients of the TBP terms into Equation (6).

### Effect of Temperature

The effect of temperature on the distribution coefficients of Zn and Cd was determined at three different temperatures (25, 40 and 60 °C). The results obtained are shown in Figure 4. As shown, by increasing the temperature (decreasing the inverse of temperature) the distribution factor of zinc increases, while that of cadmium decreases. So the extraction of zinc and cadmium are endothermic and exothermic, respectively. The apparent enthalpies of the reactions can be calculated from the slopes of the plots of  $\log D$  against  $1/T$ .

### Devising a Correlation for Estimation of the Distribution Factor

The data obtained at different conditions for both zinc and cadmium were analyzed by SPSS for Windows Ver. 8. The following equations were obtained for prediction of the distribution factors of both zinc and cadmium:

$$\begin{aligned} \log D_{Zn} = & -0.66 - \frac{501.86}{T} + 0.63 \text{pH} + 0.36 [TBP] - 5.00 [TBP]^2 \\ & + 8.94 [TBP]^3 - 1.03 \log [Zn^{2+}] \end{aligned} \quad (7)$$

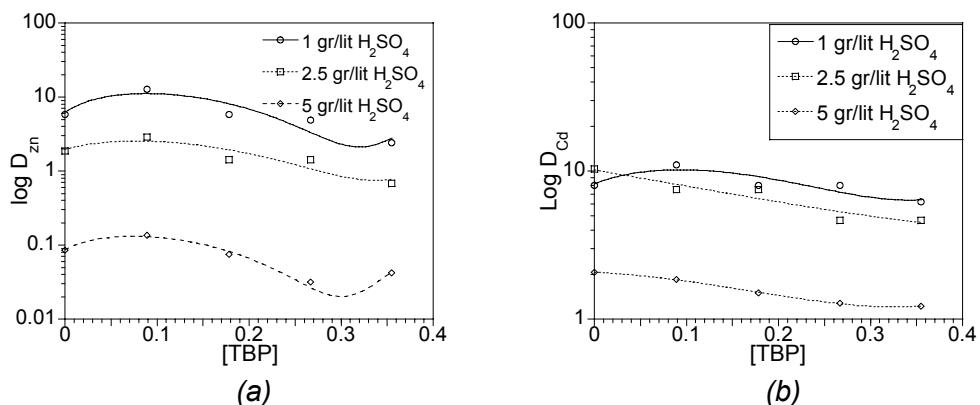

Figure 3. Variation of  $\log D$  vs. [TBP] at constant initial pH for a) zinc; b) cadmium.

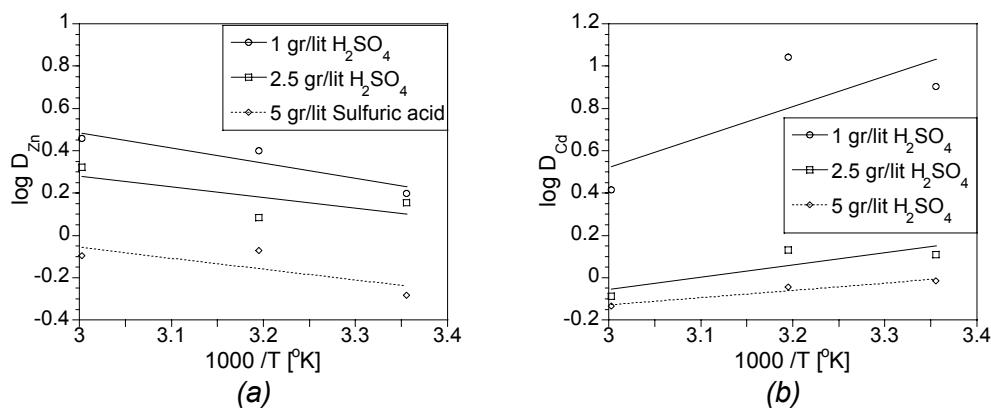

Figure 4. Effect of temperature on  $\log D$ . a) zinc; b) cadmium.

and

$$\begin{aligned} \log D_{Cd} = & -2.34 + \frac{195.98}{T} + 0.55 \text{ pH} - 0.27 [\text{TBP}] + 2.23 [\text{TBP}]^2 \\ & - 5.50 [\text{TBP}]^3 - 0.90 \log [\text{Cd}^{2+}] \end{aligned} \quad (8)$$

The experimental values for the distribution factors are compared with those predicted from formulae in Table 2. The values show that the estimated distribution factors for zinc and cadmium are very close to those obtained from the experiments. The values predicted from Equations (7) and (8) are plotted against the experimental values of Figure 5. The slope of the data equals one with a confidence factor of 95% and 96% for zinc and cadmium extraction, respectively.

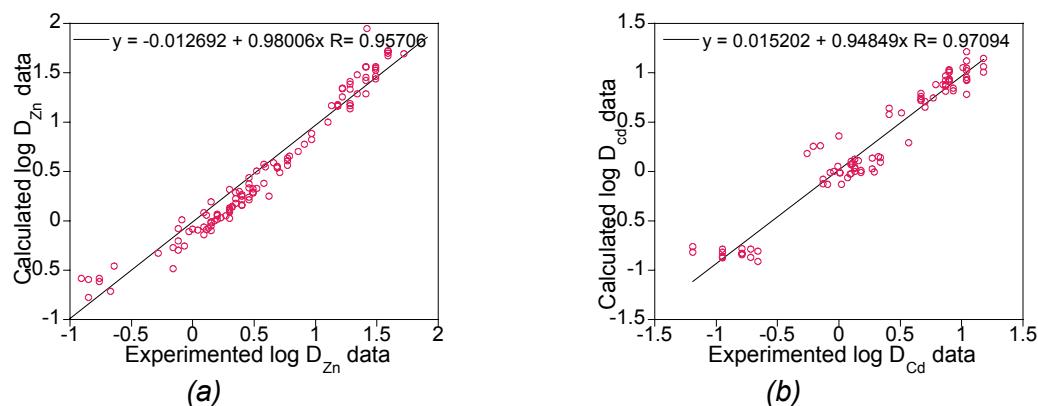

## CONCLUSIONS

The extraction of metal ions by DEHPA and MEHPA in presence of TBP was modelled based on theoretical concepts of polymerization reactions of the extractant reagents and utilization of the experimental data. Equations obtained for zinc and cadmium distribution coefficients were assessed through comparison of their results with the experimental data. These equations can be utilized to estimate the extent of the zinc and cadmium extraction reactions and evaluation of  $\log D$  against  $\log [\text{TBP}]$  as two applicable correlations. The experimental results show that TBP can influence the extraction mechanism and rate of reaction. Proposing the new idea of polymerization of DEHPA and/or MEHPA by TBP helped the modification of Equation (2) and turned out to be useful. TBP caused the

extraction curves to shift to the right of the diagram. However, in the case of cadmium, its shifting effect was not very significant. From the equations given, the apparent enthalpy of extraction of zinc was obtained to be 9.6 kJ and that of cadmium was found to be -3.75 kJ.

*Table 2. Comparison of estimated and experimental values of zinc and cadmium distribution factors.*

TBP (%)	Experiment		Estimated	
	D <sub>Zn</sub>	D <sub>Cd</sub>	D <sub>Zn</sub>	D <sub>Cd</sub>
2.5	3.83	10.99	3.77	8.69
	4.55	7.99	4.03	8.16
	2.23	4.82	1.95	5.18
	1.21	1.36	1.21	1.11

Equilibrium in the Zn/H<sub>2</sub>SO<sub>4</sub>/D2EHPA system has been studied in order to establish how stoichiometry varies as D2EHPA becomes progressively loaded with zinc to its maximum extent. Modelling assuming one- and two-zinc complexes taking into account the non-ideal behaviour of liquid phases has been investigated. The mechanism seems to be complicated by thermodynamic non-idealities in concentrated solutions, whether aqueous or organic, but applications of the models of Pitzer to the aqueous species and van Laar, Wilson, NRTL and UNIQUAC to the organic species were not able to reproduce data for loaded conditions assuming only one-zinc complex. A reasonable model for the extraction and stripping processes with constant mechanism can be proposed assuming two-zinc complexes in equilibrium.

### INTRODUCTION

The European Federation of Chemical Engineering has encouraged the adoption of test systems for liquid-liquid extraction studies and over recent years the reactive system Zn/H<sub>2</sub>SO<sub>4</sub>/D2EHPA has been investigated by many workers. Various diluents have been used but models proposed so far seem to be limited to certain concentration domains due to changes in stoichiometry as conditions change from extraction to stripping. The overall reaction is

For extraction conditions the value of  $n$  is near 1.5 when aliphatic diluents are used but near 1.0 for stripping. The observed dependence of  $n$  with concentration of the reactive species may be a consequence of incorrect modelling and/or non-ideality of the liquid phases. Sainz-Diaz *et al.* [1] modelled Zn/D2EHPA equilibrium using the Hildebrand-Scott theory assuming three species in the organic phase: dimeric-D2EHPA, ZnR<sub>2</sub>RH complex ( $n = 1.5$  from FT-IR analysis) and diluent. The Hildebrand-Scott model is based on symmetric convention (Lewis-Randall rule), *i.e.*,  $\gamma_i \rightarrow 1$  for very concentrated solution to pure; consequently, the zinc-complex is assumed liquid at the same T and P. The model is able to reproduce extraction data within 10% deviation but it has not been evaluated for stripping conditions. Loading of D2EHPA experiments have shown that  $n$  takes a value of 1.5 (for *n*-heptane diluent) and decreases slightly as D2EHPA loading increases towards about 50-60% [2].

In this work, the Zn/D2EHPA equilibrium is investigated assuming the existence of (a) one zinc complex with non-ideal behaviour of liquid phases accounted for by thermodynamic models, and (b) two zinc complexes with all activity coefficients equal 1.0. The kinetics of extraction and stripping have been examined because during extraction of zinc the back reaction becomes increasingly important as the extractant D2EHPA becomes loaded beyond about 20%.

## DESCRIPTION OF THE $\text{ZnSO}_4/\text{D2EHPA}$ SYSTEM EQUILIBRIA

### Single Mechanism with Thermodynamic Models

The equilibrium constant value depends on the convention assumed to describe the non-ideality of the organic phase species; due to the presence of dissolved salts, aqueous phase species are described by asymmetric convention (Henry's law), *i.e.*,  $\gamma_i^* \rightarrow 1$  for very dilute solution. Therefore, writing the equilibrium relation in terms of the asymmetric convention,

$$K_a = \frac{a_C a_H^2}{a_A a_{BD}^n} = \frac{\gamma_C \gamma_H^2}{\gamma_A \gamma_{BD}^n} \frac{C_C C_H^2}{C_A C_{BD}^n} = \frac{\gamma_C^\infty (\gamma_H^\infty)^2}{\gamma_A^\infty (\gamma_{BD}^\infty)^n} \frac{\gamma_C^* (\gamma_H^*)^2}{\gamma_A^* (\gamma_{BD}^*)^n} \frac{C_C C_H^2}{C_A C_{BD}^n} = K_\gamma^\infty K_\gamma^* \frac{C_C C_H^2}{C_A C_{BD}^n} \quad (2)$$

with  $K_\gamma^\infty$  as a function of temperature only. For very dilute systems,  $K_\gamma^* \rightarrow 1$ , so

$$K_a^\infty = \frac{K_a}{K_\gamma^\infty} = \frac{C_C C_H^2}{C_A C_{BD}^n} \quad (3)$$

Much of the equilibrium data found in the literature is commonly adjusted using Equation (3). However, Equation (3) is valid only at infinite dilution conditions; for example, the Pitzer model [3, 4] predicts  $\gamma_A^* \approx 0.75$  for 0.01 mol/m<sup>3</sup>  $\text{ZnSO}_4$  in aqueous solution! As experimental data usually involve higher concentrations,  $K_\gamma^*$  is unlikely to be near unity. The same conclusions are valid if data obtained from experiments with excess of D2EHPA relative to zinc are fitted by Equation (3), except if  $\gamma_B^* \approx 1$  for the whole range of  $C_B$ .

More reliable description is obtained assuming the standard state of all species in the organic phase as the pure component state (Lewis-Randall rule). Thermodynamic models such as van Laar, Wilson, NRTL and UNIQUAC were fitted to extraction and stripping equilibrium data by (1) slope analysis and (2) minimisation of the following objective function  $g(n, K_{eq}$  and model parameters) by Newton's method:

$$\min g = \log(K_{eq}) - \log \left[ \frac{\gamma_C (\gamma_H^*)^2}{\gamma_A^* \gamma_{BD}^n} \right] - \log \left( \frac{C_C C_H^2}{C_A C_{BD}^n} \right) \quad (4)$$

where  $K_{eq}$  is a new equilibrium constant; note that the ratio of activity coefficients is no longer unity at infinite dilution. Activity coefficients for aqueous phase species were estimated by Pitzer [3, 4] considering the formation of aqueous hydrogen sulphate. In contrast to Sainz-Diaz *et al.* [1], the  $n$  coefficient is assumed to be an adjustable parameter. Extraction data from Bart and Rousselle [5] and stripping data from Zimmermann and Robl [6] were fitted using Equation (4). Fitting results for extraction are shown in Table 1. Both slope analysis and optimisation procedures show that the regular solution model of van Laar is able to describe the  $\text{ZnSO}_4/\text{D2EHPA}/\text{isododecane}$  equilibrium. UNIQUAC and van Laar models showed similar results (parameters are listed in Table 2) while the NRTL and Wilson models did not show comparable results. Model equations are available in Sandler [7]. Extraction

data fitting including  $n$  as an optimisation parameter confirms the constant mechanism ( $n = 1.5$ ) obtained by Sainz-Diaz *et al.* [1] using the FTIR spectra technique. Activity coefficients at infinity dilution of extractant and complex shown in Table 3 were obtained by extrapolation of models at null concentration with parameters from Table 2.

*Table 1. Comparative mechanism and equilibrium constant for the extraction of zinc with D2EHPA using different thermodynamic models.*

Model	Optimisation			Slope Analysis		
	$n$	$\log(K_{eq})$	min*	$n$	$\log(K_{eq})$	$R^2$
van Laar	1.50	-2.146	8.95 (56 pt)	1.52	-2.093	0.94
UNIQUAC	1.44	-2.220	12.14 (52 pt)	1.44	-2.213	0.91
Wilson	1.40	-2.060	19.67 (55 pt)	1.75	-1.170	0.86
NRTL	1.28	-2.439	16.41 (55 pt)	1.59	-1.858	0.83

\* Number of valid points used from a total of 72 data points (pt).

*Table 2. Optimised parameters of van Laar and UNIQUAC models for extraction conditions.*

van Laar	UNIQUAC	
$\Lambda_{BC} = 0.2971$	$\tau_{BC} = 1.8740$	$r_B = 25.460$
$\Lambda_{BD} = 0.3292$	$\tau_{BD} = 1.1076$	$r_C = 25.460$
$\Lambda_{CB} = 2.3581$	$\tau_{CB} = 1.9927$	$r_D = 8.546$
$\Lambda_{CD} = 3.2021$	$\tau_{CD} = 1.0568$	$q_B = 22.358$
$\Lambda_{DB} = 1.3180$	$\tau_{DB} = 0.8718$	$q_C = 30.494$
$\Lambda_{DC} = 0.0022$	$\tau_{DC} = 0.7161$	$q_D = 7.096$

*Table 3. Equilibrium parameters at infinite dilution for van Laar and UNIQUAC models.*

	$\gamma_B^\infty$	$\gamma_C^\infty$	$\log(K_a^\infty)$ by optimisation	$\log(K_a^\infty)$ by slope analysis
van Laar	1.388	10.938	-2.971	-2.915
UNIQUAC	0.254	0.800	-2.980	-2.973

Short-cut correlations for the activity coefficients of extractant and complex in the asymmetric convention have been derived for fast calculations (Pitzer for aqueous phase species):

$$\gamma_{BD}^* = 1 \quad \text{for all } C_B \quad (5-a)$$

$$\gamma_C^* = 1 \quad \text{for } C_C < 0.00007 \text{ mol/L} \quad (5-b)$$

$$\gamma_C^* = 0.0312C_C^{-0.3604} \quad \text{for } C_C \geq 0.00007 \text{ mol/L} \quad (24.5\% \text{ relative error}) \quad (5-c)$$

Stripping data were fitted by the van Laar model only and, as shown in Table 4, poor fitting was obtained. It was found that  $1.0 < n < 1.5$  is suitable to reproduce stripping data if one single zinc-complex is assumed. Therefore, it seems that thermodynamic models are not suitable to describe the Zn/D2EHPA equilibrium with constant mechanism for high loading conditions. Unless some change in mechanism occurs, the slightly lower  $n$  value compared to extraction may indicate inadequate modelling.

*Table 4. Estimated equilibrium parameters for stripping (van Laar model).*

Optimisation			Slope Analysis		
$n$	$\log(K_{eq})$	min	$n$	$\log(K_{req})$	$R^2$
1.33	-2.400	1.36 (19 pt)	1.38	-2.305	0.77

### Parallel Mechanism with Activity Coefficients equal 1.0

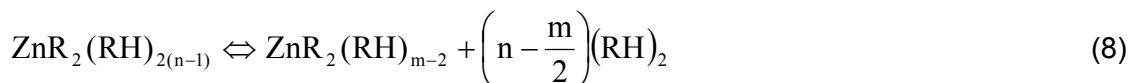

If splitting of the free-D2EHPA molecules from dimeric to monomeric form really occurs as loading of the organic phase increases, so Equation (1) and the following additional reaction with constant mechanism could be assumed to compete for zinc ions at the liquid-liquid interface

and five species are then supposed to exist in the organic phase: free dimeric and monomeric D2EHPA, dimeric and monomeric zinc-D2EHPA complexes and the diluent. Under these conditions, the equilibrium model is a non-linear algebraic equation with five parameters to be estimated by data fitting ( $K_D$ ,  $K_M$ ,  $K_{RH}$ ,  $m$  and  $n$ ). Assuming all activity coefficients equal unity, the following equilibrium relationships

$$K_D = \frac{C_{CD} C_H^2}{C_A C_{BD}^n} \quad K_M = \frac{C_{CM} C_H^2}{C_A C_{BM}^m} \quad K_{RH} = \frac{C_{BM}^2}{C_{BD}} \quad (7)$$

and respective mass balance equations of reactive species were solved by Newton's method with initial concentrations as initial guesses. The parameters were estimated by the direct search method of Hooke and Jeaves in order to minimise the difference between experimental and calculated zinc concentrations in aqueous phase. Extraction [5, 8] and stripping [2, 6] data were fitted to the model and convergence to a singular solution was achieved independently of the initial value of the parameters. Two zinc complexes produced by competitive reactions with  $n = 1.46 \pm 0.10$  and  $m = 1.99 \pm 0.07$  are indicated. Furthermore, statistical analysis of the results revealed strong correlation between  $K_M$  and  $K_{RH}$  parameters indicating that Equation (6) is not representative of the system, i.e., as commonly ascertained in the literature, no partial break-down of the dimer-D2EHPA to monomer-D2EHPA occurs in the investigated range of concentrations. Information concerning the second zinc complex is obtained by elimination of  $K_{RH}$  and  $K_M$  constants resulting in the following homogeneous reaction:

$$K_C = \frac{C_{CM} C_{BD}^{n-m/2}}{C_{CD}} \quad (9)$$

According to this new model, the dimeric zinc complex produced in Equation (1) (heterogeneous reaction) could break down producing free dimer D2EHPA as in Equation (8) (homogeneous reaction) as loading of the organic phase increases. The following mass balance equations were used in further fitting calculations to find  $K_C$ ,  $K_D$ ,  $n$  and  $m$ :

$$C_{CM} + C_{CD} = C_{CM}^o + C_{CD}^o + \left( C_A^o - C_A \right) \frac{V_{aq}}{V_{org}} \quad (10)$$

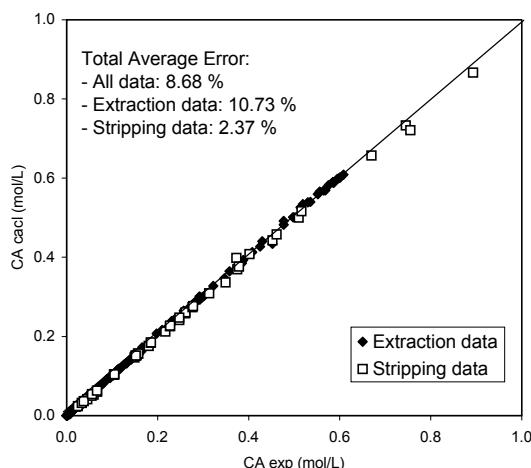

$$C_{BD} = C_{BD}^o - n \left( C_A^o - C_A \right) \frac{V_{aq}}{V_{org}} - \left( n - \frac{m}{2} \right) \left( C_{CM}^o - C_{CM} \right) \quad (11)$$

$$C_H = C_H^o + 2 \left( C_A^o - C_A \right) \quad (12)$$

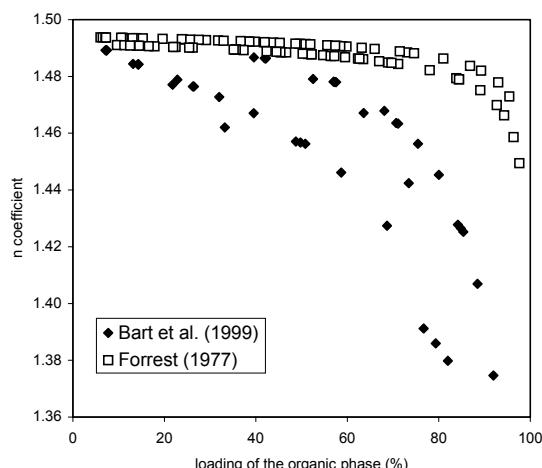

Final fitted parameters including 95% confidence levels are shown in Table 5. No correlation between pairs of parameters was found by statistical analysis. As shown in Figure 1, extraction and stripping data were reproduced within 11% total error. Figure 2 shows the behaviour of the  $n$  coefficient with loading in the absence of monomer zinc-complex ( $m = 2n = 3$ ). Further detailed discussion is presented by Mansur *et al.* [9].

*Table 5. Final fitting results for Zn/D2EHPA equilibrium.*

$K_D \text{ (mol/L)}^{2-n}$	$0.278 \pm 0.001$
$K_C \text{ (mol/L)}^{n-m/2}$	$0.010 \pm 0.003$
$n$	$1.457 \pm 0.003$
$m$	$2.06 \pm 0.08$

## CONCLUSIONS

Much work on the Zn/D2EHPA possible test system has been done in order to find a unifying theory to describe extraction and stripping conditions. Models available in the literature are only accurate for specific concentration domains because a change in mechanism is found as loading of organic phase increases. The use of thermodynamic models was not able to explain data assuming a single-complex mechanism. The origin of the problem may reside in the existence of an additional zinc complex formed according to Equation (8). Thermodynamic models are not necessary to describe equilibrium when competitive zinc complexes are considered; extraction and stripping data are reproduced within 11% average error. Maybe the inclusion of thermodynamic theories to estimate activity coefficients will improve predictions for this new model.

## ACKNOWLEDGMENTS

The experimental work done at the University of Bradford was made possible by financial support received from the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES, Brazilian Government Agency, PICDT/UFMG and PDEE Doctorate Grant nº 0299/99-5), which is gratefully acknowledged. M. B. Mansur would also like to record his appreciation for financial support from Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), Brazil and Fundação de Amparo a Pesquisa do Estado de Minas Gerais (FAPEMIG), Brazil, to attend this Conference.

# THE INTEGRATED RECOVERY OF RARE EARTHS FROM APATITE IN THE ODDA PROCESS OF FERTILIZER PRODUCTION BY SOLVENT EXTRACTION. A PLANT EXPERIENCE

**Abdulla W. Al-Shawi, Svein E. Engdal, Ole B. Jenssen, Tom R. Jørgensen  
and Morten Røsæg**

Norsk Hydro ASA, Porsgrunn, Norway

An integrated method to recover rare earths from apatite within the Odda process of fertilizer production was commissioned by Norsk Hydro, Norway, in 1996. The method involves selective precipitation of a rare earth phosphate concentrate by partial neutralization of a fertilizer solution stream. The phosphate concentrate is re-dissolved in nitric acid, partially neutralized, filtered and fed into a Cyanex 923 extraction circuit, where rare earths were separated from phosphate and calcium ions. Loaded Cyanex 923 was stripped with HNO<sub>3</sub>, and in order to meet a stringent specification levels, further purification by a tributylphosphate extraction circuit ensured rare earths are free from ammonium and other impurity ions. The rare earth nitrate solution leaving the tributylphosphate circuit was evaporated to generate a 470 g/L rare earths oxide trading solution.

## INTRODUCTION

Apatites, also called phosphate rocks, are virtually the sole raw material for phosphate fertilizers. Fluorapatite, with a simplified chemical formula Ca<sub>5</sub>(PO<sub>4</sub>)<sub>3</sub>F, represents the most common form of apatite. Fluorapatites are further divided into sedimentary apatites (phosphate rocks precipitated from seawater and bones), which represent the primary source of apatite, and magmatic (igneous) apatites, which are also considered important. The total worldwide consumption of apatite in 1989 was 160 million tonnes. About 90% of mined apatite is used in fertilizer production, being divided almost equally among superphosphates, ammonium phosphates and compound fertilizers, including those produced by the Odda process [1].

The abundance of rare earths in the earth's crust is 0.015%. Monazite (55% REO), bastnasite (70% REO) and xenotime (42% REO) are considered to be the principal raw materials [2]. Igneous apatites on the other hand often contain much lower but appreciable concentrations of rare earths substituted in the apatite lattice for calcium ions [3,4].

Sulphuric acid attack on apatite for phosphoric acid production is termed the 'wet process', and represents between 85-90% of the world production. In this process, sulphuric acid attacks apatite to produce phosphoric acid and calcium sulphate (phosphogypsum), which separates as an insoluble salt. Unfortunately, up to 70% of the apatite's rare earth content is retained by the phosphogypsum, which complicates their recovery. Attempts on the recovery of rare earths from the phosphogypsum and the phosphoric acid have been reported both in patents and on laboratory scale [5-7].

Table 1. Rare earths content of some apatites.

Apatite (Origin)	Rare earth oxides, % <sub>w/w</sub>
Kola/Russia (Igneous)	0.8-1.0
Phalaborwa/South Africa (Igneous)	0.4-0.9
Florida/USA (Sedimentary)	0.06-0.29
BouCraa/Morocco (Sedimentary)	0.13-0.18

Nitric acid attack on apatite on the other hand is known as the Odda process for fertilizer production; it is also referred to as the nitrophosphate route [8] (Figure 1).

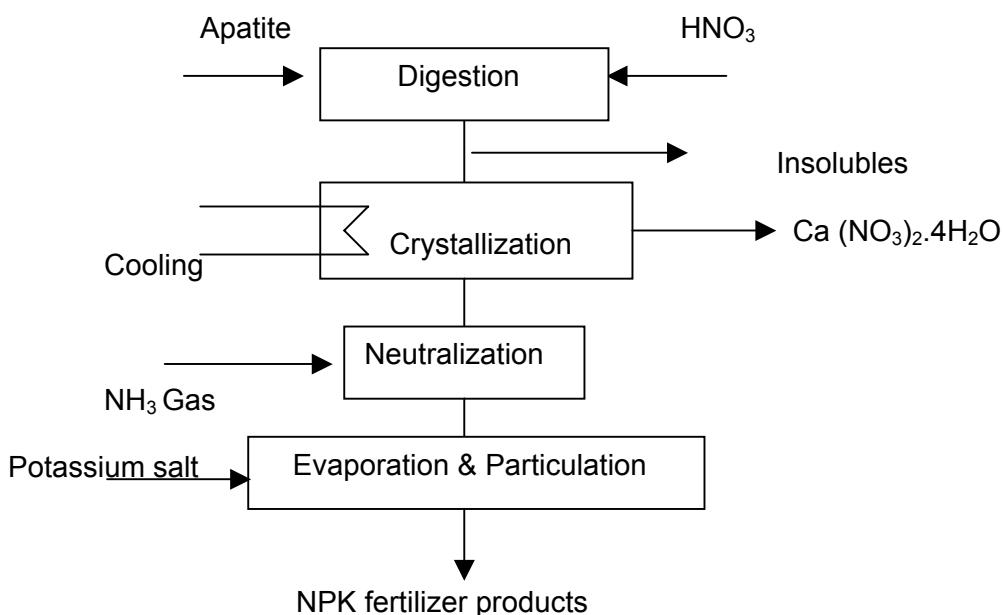

Figure 1. The Odda process for fertilizer production.

In the Odda process all the rare earths are completely solubilized and report to the mother liquor solution after the calcium nitrate crystallisation stage. There is no loss of rare earths with the calcium nitrate crystals. On this basis, their recovery from the Odda process is more suitable than from the wet process [9,10].

Kemira Oy, Finland, has operated a full-scale industrial plant based on solvent extraction technology to recover rare earths from Kola apatite at the Oulu fertilizer plant, Finland between 1965-1972. Tributylphosphate was utilized as the organic solvent for that production plant, which operated on 100 000 tonnes of apatite per year with REO content of 1%, producing a rare earth hydroxide/oxide mixture [11].

## PROCESS DESCRIPTION

Norsk Hydro's rare earths recovery is inserted after the calcium nitrate crystallization in the Odda process of fertilizer production. The recovery process consists of three main separation stages:

1. Selective precipitation of rare earths from post calcium nitrate crystallization solution.
2. Cyanex 923 extraction circuit for rare earths separation from Ca and  $\text{PO}_4$  ions.
3. Tributylphosphate extraction circuit for rare earths separation from ammonium ion and other impurities.

The overall process is illustrated in Figure 2.

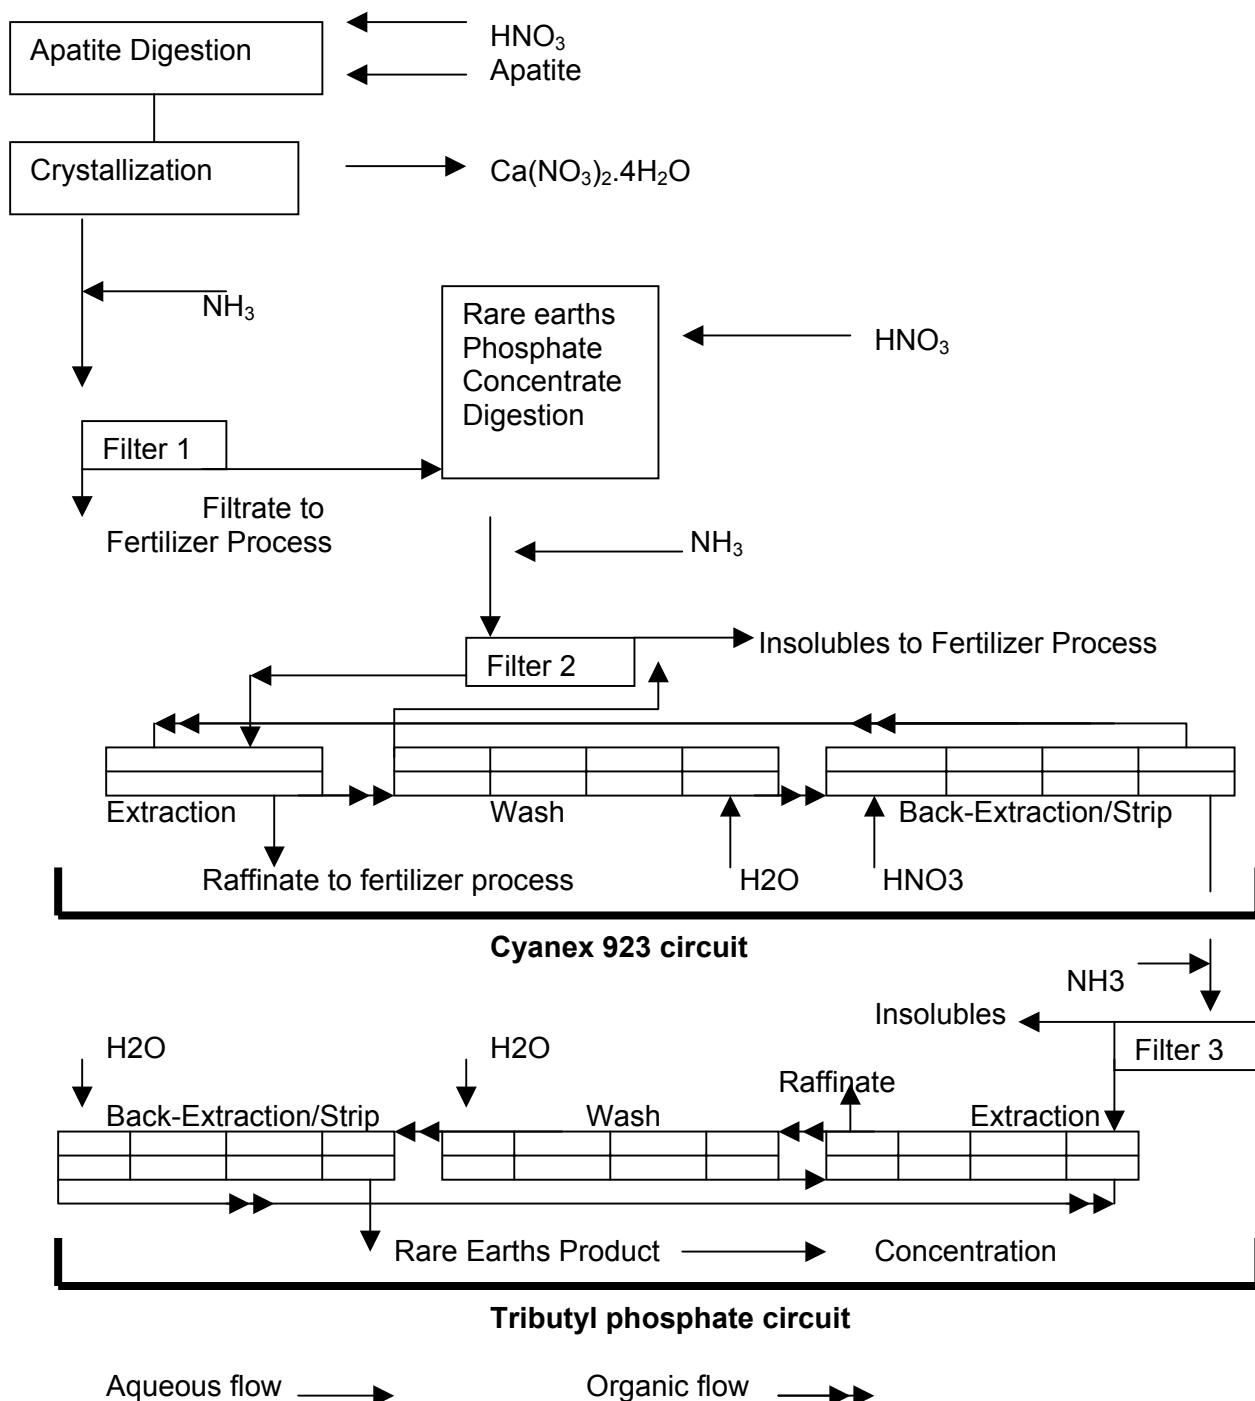

Figure 2. Rare earth extraction circuits.

### Selective Precipitation of Rare Earths from Mother Liquor Solution

The initial stage of the recovery involves a selective precipitation of rare earth phosphate concentrate (cake) from calcium nitrate crystallization mother liquor. This selective precipitation was performed by partial neutralization of the mother liquor with ammonia to a pH of 1.6-1.9 (1+13), where (1+13) denotes the dilution of 1 part of the process solution with 13 parts water prior to pH measurement (Table 2).

At this pH range, rare earths phosphates precipitate out of solution (> 85%) with minimum co-precipitation of dicalcium phosphate (DCP). The rare earths phosphate concentrate is then separated on filter 1.

The rare earth phosphate concentrate was then digested with fresh nitric acid, and the solution was then neutralized to a pH of 1.0 (1+13) with ammonia, filtered on filter 2, and fed into the Cyanex 923 extraction circuit.

*Table 2. Precipitation of rare earths at pH 1.8(1+13) from mother liquor solution.*

Stream	Amount	Density, kg/L	[RE]	[Ca]	[PO <sub>4</sub> ]
Mother liquor pre-filter 1	32 m <sup>3</sup> /h	1.52	5.7 g/L	60-70 g/L	400 g/L
Mother liquor post-filter 1	30 m <sup>3</sup> /h	1.51	0.8 g/L	65 g/L	380 g/L
RE phosphate concentrate	1.31 t/h	2.10	6.2 %	5.3 %	21.6 %
Feed solution post-filter 2	2.20 m <sup>3</sup> /h	1.50	70 g/L	50 g/L	120 g/L

### Cyanex 923 Extraction Circuit

Cyanex 923 is a mixture of four phosphine oxides, that extract rare earth nitrates by a solvating mechanism [12]. The Cyanex 923 circuit (50% with Exxol D80) is intended to separate the rare earths from both calcium and phosphate ions. As Cyanex 923 extracted both nitric acid and rare earth nitrates, the distribution ratios increased with the reduction of the total acidity at equilibrium (Table 3).

*Table 3. Rare earth distribution ratios with 50% Cyanex 923.*

Post extraction pH / Element	La	Ce	Pr	Nd	Y
Raffinate pH 0.90 (1+13)	0.09	0.17	0.25	0.34	2.30
Raffinate pH 1.20 (1+13)	0.74	1.40	2.36	4.25	> 10
Raffinate pH 1.35 (1+13)	1.29	3.89	6.82	7.16	> 10
Raffinate pH 1.80 (1+13)	15.6	12.90	31.2	51.50	> 10

The Cyanex 923 circuit consisted of the streams shown in Table 4.

*Table 4. Cyanex 923 circuit streams.*

Stream	Volume, m <sup>3</sup> /h	pH (1+13)	Total RE, g/L	Ca, g/L	PO <sub>4</sub> , g/L

Strip solution out	4.20	8 M HNO <sub>3</sub>	30-33	0.02	0.01

### **Tributylphosphate (TBP) Extraction Circuit**

The strip solution from the Cyanex 923 circuit is neutralized with ammonia to pH 3.0, filtered on filter 3, and fed into the TBP extraction circuit (Table 5). At this pH other metallic impurities precipitate. Rare earth distribution ratios from nitrate solution with 100% TBP are well documented in the chemical literature [13]. The ammonium ion concentration in the feed solution of this circuit salts-out the rare earths extraction which enables their concentration in the strip solution to be doubled.

*Table 5. Tributylphosphate circuit streams.*

Stream	Volume, m <sup>3</sup> /h	pH	Total RE, g/L	NH <sub>4</sub> , g/L	Ca, g/L	PO <sub>4</sub> , g/L

100% TBP, out extraction	2.1	4.0	70 - 80	5	0	0
Strip solution out	2.0	3.0 - 4.0	70 - 80	0.1	0.007	0.0025

The strip solution from the TBP circuit is then concentrated to produce a rare earth nitrate solution, which is 470 g/L in REO.

### **PLANT EQUIPMENT AND PROCEDURES**

Conventional mixer-settler units were employed in both extraction circuits, and were all operated in a counter-current configuration. Membrane pumps were utilized to pump aqueous and organic solutions into the plant. All neutralizations were performed by ammonia gas, and all pH measurements were taken after dilution of 1 part process solution with 13 parts water.

The Cyanex 923 circuit has 1 extraction stage (0.515 m<sup>3</sup> mixer, 3.6 m<sup>3</sup> settler), 4 washing and 4 back-extraction (strip) stages (0.515 m<sup>3</sup> mixer, 1.2 m<sup>3</sup> settler). The TBP circuit consisted of 4 extraction, 4 washing and 4 back-extraction (strip) stages (0.515 m<sup>3</sup> mixer, 1.2 m<sup>3</sup> settler). Both extraction circuits were maintained at ambient temperature and were operated in parallel.

Cyanex 923, manufactured by Cytec, Canada, diluted with Exxol D80 (aliphatic hydrocarbon), Exxon, USA, to 50% in volume concentration, and 100% TBP, Bayer, Germany were used.

Plant control was installed by ABB Master process-system, Sweden. The control system has many measurement devices like flow amount (46), temperature (13), tank level (28), pH (10), and pressure (4).

### **SPECIFICATION**

Norsk Hydro's rare earths recovery process from apatite is designed to produce a pure rare earths nitrate solution with stringent specification, the process was also fully integrated with the main fertilizer production process. Environmental issues were fully implemented by ensuring that the rare earth process has no waste streams or products. The product specification is shown in Table 6.

*Table 6. Market specifications of the rare earth nitrate solution.*

Total rare earths oxides (TREO)	> = 470 g/L
Ce <sup>3+</sup> /TREO	> 50 %
Total free Acidity (HNO <sub>3</sub> )	< 0.7 mol/L
Phosphorus/TREO	< 0.001 wt.%
Fluoride/TREO	< 0.003 wt %
Calcium/TREO	< 0.007 wt %
Aluminium/TREO	< 0.0025 wt %
Iron/TREO	< 0.005 wt %
Ammonium/TREO	< 0.005 wt %
Vanadium	< 0.0003 wt %
Ce <sup>4+</sup> / total Ce	= 0
Yttrium/TREO	> 2.0 % wt %
Radioactivity	< 10 Bq/Kg

## EXTRACTION OF LANTHANIDES AND YTTRIUM WITH PC-88A FROM AQUEOUS PHOSPHATE MEDIA

Ahmed A. Abdeltawab, Susumu Nii, Fumio Kawaizumi, and Katsuroku Takahashi

Department of Chemical Engineering, Nagoya University, Nagoya, Japan

The extraction of lanthanides (La, Gd, Yb) and yttrium from an aqueous phosphate medium with 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester (PC-88A) was studied. Different concentrations of PC-88A in *n*-dodecane were studied for the separation of lanthanides and yttrium ions from both single and multi-component systems. Heavy lanthanides ions were extracted with low concentrations of PC-88A from phosphoric acid aqueous solutions of low concentration. The extraction distribution ratios of all lanthanides and yttrium ions were found to decrease with increasing H<sub>3</sub>PO<sub>4</sub> concentration. The extraction distribution ratio increased with increasing pH value up to 2. The experimental results supported an extraction mechanism different from that in the case of nitrate medium.

### INTRODUCTION

A great deal of attention has been directed to phosphate deposits as a secondary source for lanthanides and yttrium [1]. This attention arises from the importance of studying the recovery of lanthanides and yttrium from phosphoric acid solutions produced during processing of phosphate ores.

Although solvent extraction techniques have been extensively applied to the practical separation of lanthanides using acidic organophosphorus extractants [2], the separation of lanthanides from phosphoric acid media has not been studied intensively. In most cases, production of lanthanides and yttrium have been carried out by using dialkylphosphonates such as 2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester (PC-88A), particularly from chloride and nitrate media [3].

In this work, the extraction behavior of lanthanides and yttrium with PC-88A from phosphoric acid aqueous solution has been studied.

### EXERIMENTAL

#### Reagents

The commercial extractant, PC-88A, was supplied by Daihachi Chemical Industry Co., Ltd. Japan (Lot No.: N-10102) and used without further purification. Lanthanide nitrates and *n*-dodecane were supplied by Wako Pure Chemical Industries, Ltd. Japan. All inorganic chemicals used were of analytical grade.

### Extraction Equilibrium Procedure

Organic solutions were prepared by diluting PC-88A with *n*-dodecane to the desired concentration. Aqueous solutions were prepared by dissolving lanthanides and yttrium nitrates in phosphoric acid. The concentration of each metal ion was 0.2 mol/m<sup>3</sup>. Solution pH was adjusted with 1000 mol/m<sup>3</sup> sodium hydroxide. The pH values were measured with a Horiba F-22 pH meter (probe no. S8721) with a measuring range: pH 0-14 ± 0.01. Equal volumes of aqueous and organic phases, 10 cm<sup>3</sup>, were equilibrated in 30 cm<sup>3</sup> screwed cap vials by vigorously shaking for 30 min at 25 ± 1°C. After reaching equilibrium, the aqueous phase was separated, and lanthanide and yttrium concentrations were determined by ICP-atomic emission spectroscopy (IRIS Plasma Spectrometer, Thermo Jarrell Ash Corporation).

## RESULTS AND DISCUSSION

### Effect of PC-88A Concentration

The effect of PC-88A concentration, *C*, on the extraction distribution ratios of lanthanides (La, Gd, Yb) and yttrium from phosphoric acid aqueous solutions (500, 1000 mol/m<sup>3</sup>) is shown in Figures 1 and 2. Extraction of Yb and Y was increased considerably by increasing the PC-88A concentration, while the extraction of La and Gd slightly increased, which indicates the possibility of separating the heavy lanthanides and yttrium from the lanthanides mixture with low concentrations of PC-88A.

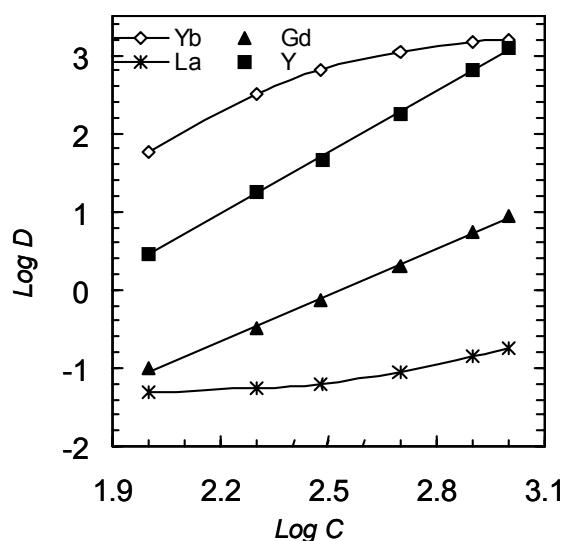

Figure 1. The effect of PC-88A concentration on extraction of lanthanides and Y from 500 mol/m<sup>3</sup> H<sub>3</sub>PO<sub>4</sub>.

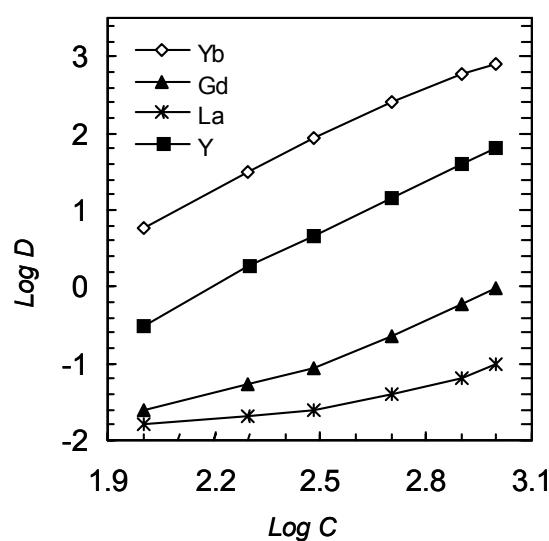

Figure 2. The effect of PC-88A concentration on extraction of lanthanides and Y from 1000 mol/m<sup>3</sup> H<sub>3</sub>PO<sub>4</sub>.

This increase of the extraction distribution ratio with increasing atomic number of the light to heavy lanthanides was also reported by Koopman *et al.* [4] for the extraction of lanthanides with di(2-ethylhexyl)phosphoric acid (D2EHPA) from phosphoric acid solution. This tendency was explained by the order of polarizability sequence POO<sup>-</sup> > H<sub>2</sub>O, the phosphate carrier D2EHPA replaces water ligands from the cations, resulting in an increasing affinity with increasing charge density of the bare cation [4]. On the other hand, as the bare ionic radius decreases with increasing atomic number from 1.061 Å for La to 0.858 Å for Yb and 0.88 Å for Y [5], the affinity also increases. The extraction distribution ratios of La, Gd, Yb and Y decreased considerably when phosphoric acid concentration increased from 500 mol/m<sup>3</sup> (Figure 1) to 1000 mol/m<sup>3</sup> (Figure 2) for the same PC-88A concentration values.

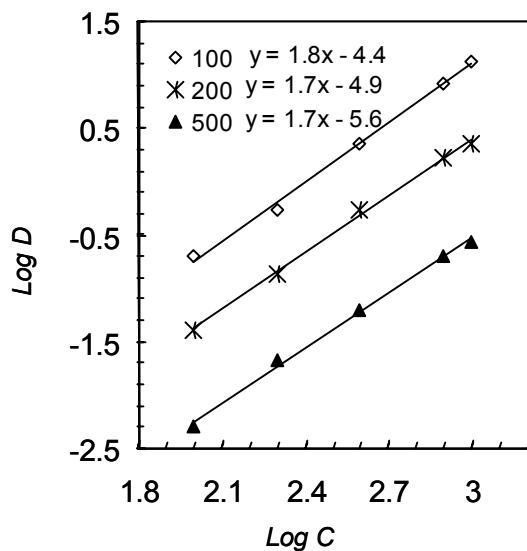

Figure 3. The effect of PC-88A concentration on extraction of La from (100, 200, and 500 mol/m<sup>3</sup>) H<sub>3</sub>PO<sub>4</sub>.

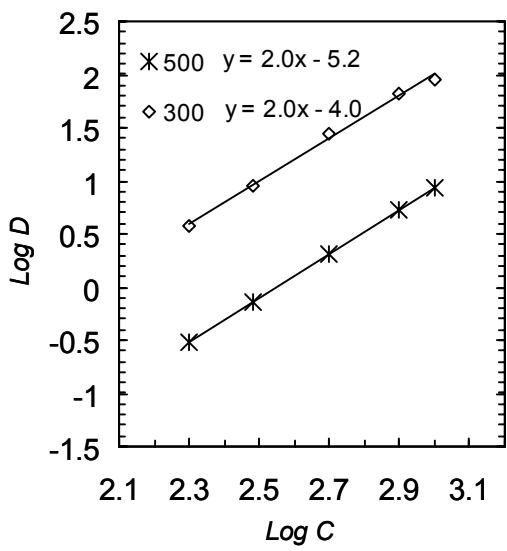

Figure 4. The effect of PC-88A concentration on extraction of Gd from (300, and 500 mol/m<sup>3</sup>) H<sub>3</sub>PO<sub>4</sub>.

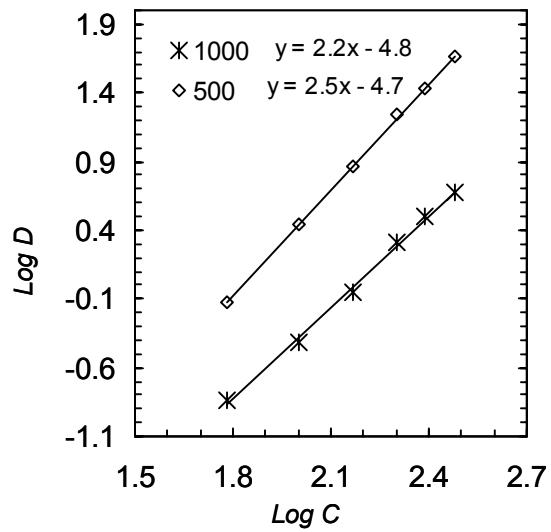

Figure 5. The effect of PC-88A concentration on extraction of Y from (500, and 1000 mol/m<sup>3</sup>) H<sub>3</sub>PO<sub>4</sub>.

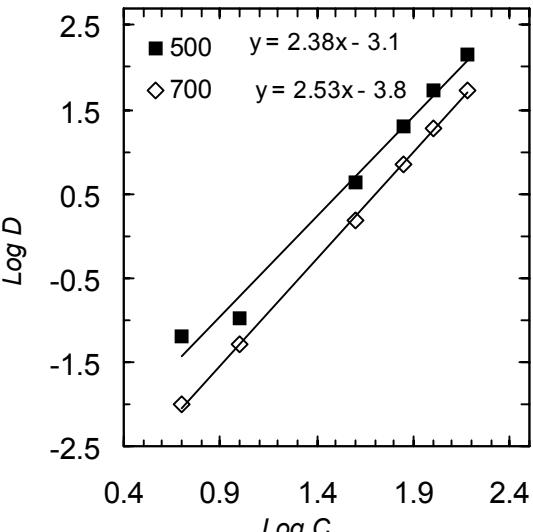

Figure 6. The effect of PC-88A concentration on extraction of Yb from (500, and 700 mol/m<sup>3</sup>) H<sub>3</sub>PO<sub>4</sub>.

The effect of PC-88A concentration on the extraction behavior of individual metal ions in single component systems of different phosphoric acid concentrations are shown in Figures 3 to 6. Figure 3 shows the effect of PC-88A concentration on extraction of La from phosphoric acid solutions of different concentrations (100, 200, 500 mol/m<sup>3</sup>). By increasing the PC-88A concentration, the extraction distribution ratio of La increased considerably at all phosphoric acid concentrations up to 500 mol/m<sup>3</sup>. The slope is approximately 2. At higher phosphoric acid concentrations (1000 to 2000 mol/m<sup>3</sup>) the extraction of La was very low and no valuable increase in the extraction distribution ratio when increasing PC-88A concentration. Figures 4, 5 and 6 show the results of Gd, Y and Yb systems, respectively. In all cases the observed values were close to straight lines with a slope of approximately 2; in contrast with the previously reported results for extraction from nitrate media [3], which suggests that in phosphate media, the charges of the Yb and Y ions (= +3) are not completely neutralized by

the deprotonated anionic species of the extractant but partly by some coexisting anionic species in the aqueous phase such as  $[H_2PO_4^-]$ . Similar extraction behavior was reported by Inoue *et al.* [6], for the extraction of calcium with PC-88A. Consequently the extraction reaction may be expressed as following:

where HR is PC-88A.

### Effect of pH

The effect of aqueous phase pH on the extraction distribution ratio of lanthanides (La, Gd, Yb) and Y from  $1000 \text{ mol/m}^3$  phosphoric acid solution is shown in Figure 7 (100  $\text{mol/m}^3$  PC-88A) and Figure 8 (200  $\text{mol/m}^3$  PC-88A). The extraction distribution ratios of La, Gd, Yb and Y increased considerably with increasing aqueous phase pH. At low pH values (pH 1-1.2) the extraction distribution ratios of La and Gd were very low, which indicates the possible separation of heavy lanthanides and yttrium at those low pH values.

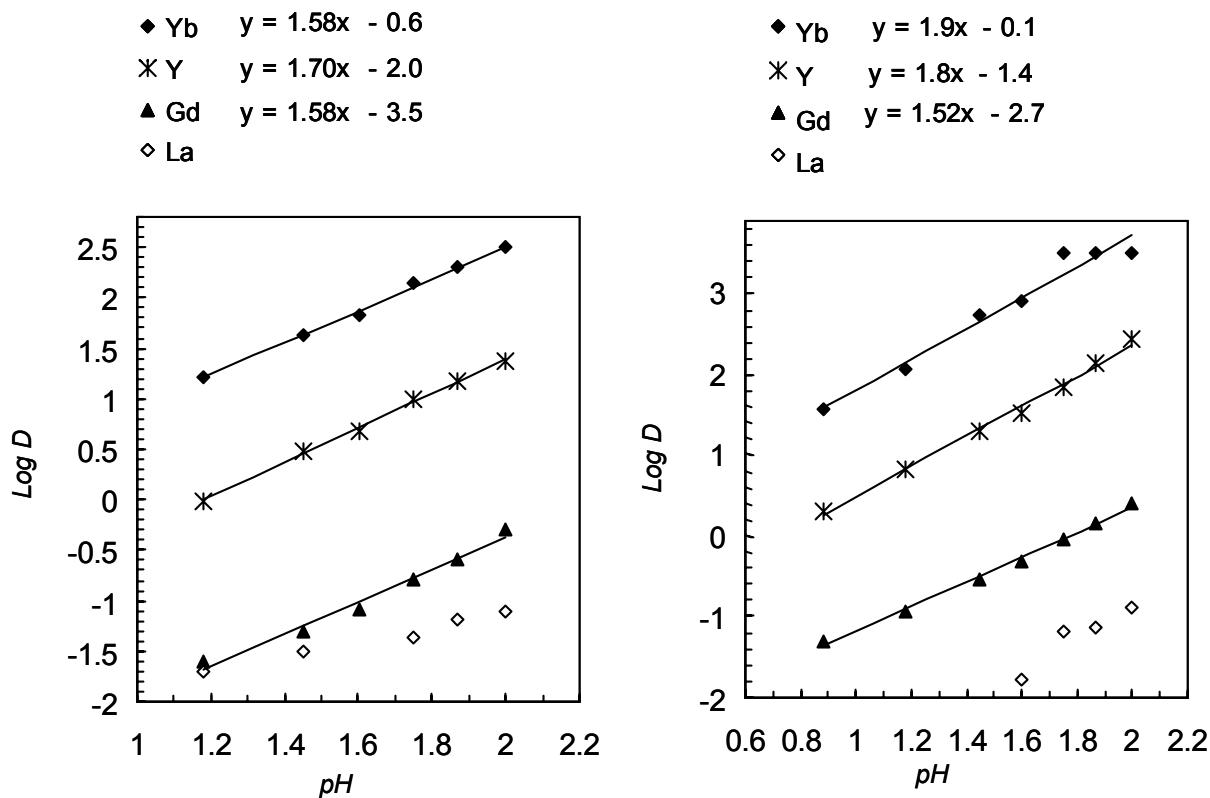

Figure 7. The effect of pH on extraction of lanthanides and Y from  $1000 \text{ mol/m}^3 H_3PO_4$  with  $100 \text{ mol/m}^3$  PC-88A.

Figure 8. The effect of pH on extraction of lanthanides and Y from  $1000 \text{ mol/m}^3 H_3PO_4$  with  $200 \text{ mol/m}^3$  PC-88A.

The effect of aqueous phase pH on the extraction behavior of individual metal ions from 1000 mol/m<sup>3</sup> phosphoric acid in single component systems with different PC-88A concentrations are shown in Figures 9 to 11.

The experimental points lie on straight lines with a slope of approximately 1.5, which confirms that lanthanide(III) ions are not extracted as +3 ions but extracted as lanthanide phosphate ionic species as shown in equation 1.

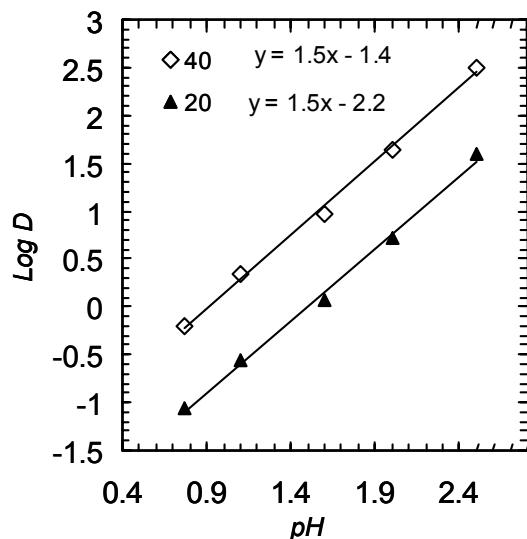

Figure 9. The effect of pH on extraction of Yb from 1000 mol/m<sup>3</sup> H<sub>3</sub>PO<sub>4</sub> with 20 and 40 mol/m<sup>3</sup> PC-88A.

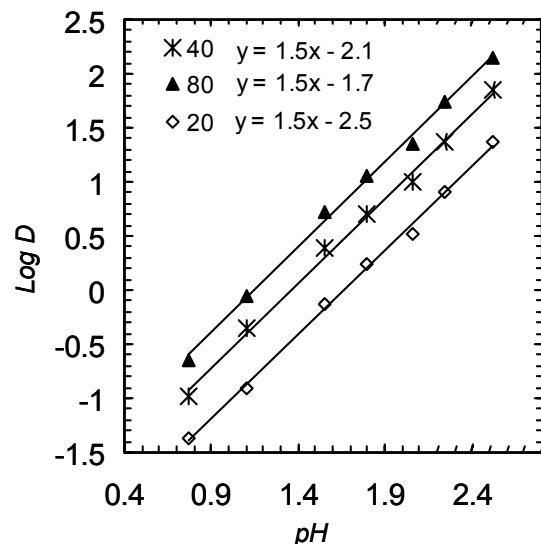

Figure 10. The effect of pH on extraction of Y from 1000 mol/m<sup>3</sup> H<sub>3</sub>PO<sub>4</sub> with 20, 40, 80 mol/m<sup>3</sup> PC-88A.

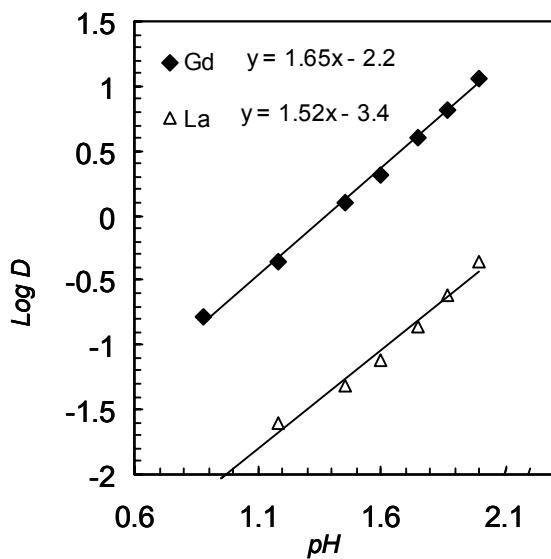

Figure 11. The effect of pH on extraction of Gd and La from 1000 mol/m<sup>3</sup> H<sub>3</sub>PO<sub>4</sub> with 400 mol/m<sup>3</sup> PC-88A.

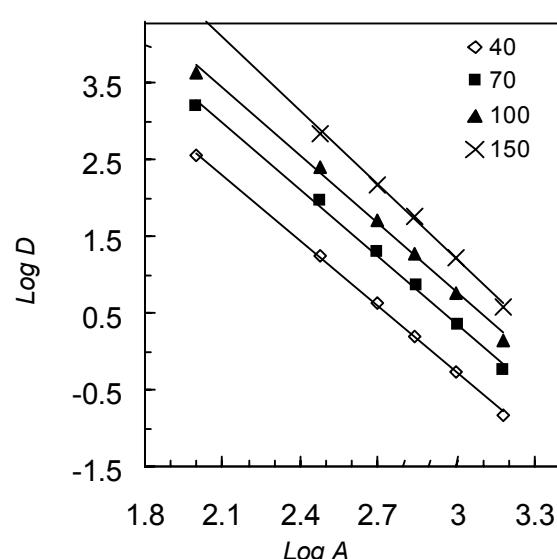

Figure 12. The effect of H<sub>3</sub>PO<sub>4</sub> concentration on extraction of Yb with 40, 70, 100 and 150 mol/m<sup>3</sup> PC-88A.

### **Effect of Phosphoric Acid Concentration**

The effect of phosphoric acid concentration on the extraction of Yb with different concentrations of PC-88A is shown in Figure 12. The extraction distribution ratio of Yb decreased considerably with increasing phosphoric acid concentration. This may be because the formation of the complex: M ( $H_2PO_4$ )<sub>3</sub>, where M is the metal ion, increases in the aqueous phase with increasing  $H_3PO_4$  concentration and this complex is a neutral complex and not extracted. This negative effect of high concentrations of phosphoric acid on the extraction efficiency of lanthanides agrees with the results reported by Krea *et al.* [1].

### **CONCLUSIONS**

The extraction of lanthanides (La, Gd, Yb) and yttrium from an aqueous phosphate medium with PC-88A was studied. Heavy lanthanide ions were extracted with low concentrations of PC-88A from phosphoric acid aqueous solutions of low concentration. The extraction distribution ratios of all lanthanides and yttrium ions were found to decrease with increasing  $H_3PO_4$  concentration. The extraction distribution ratio increased with increasing the pH value up to 2. The experimental results strongly supported the suggested extraction mechanism.

## EXTRACTIVE LEACHING IN THE TECHNOLOGY OF RARE METAL RAW MATERIALS: PROBLEMS AND PERSPECTIVES

Svetlana Chizhevskaya, Alexander Chekmarev and Michael Cox\*

D. Mendeleyev University of Chemical Technology of Russia, Russia

\*University of Hertfordshire, United Kingdom

Industrial processing of comparatively low-grade raw materials results in a considerable increase in the cost of rare metals production. Non-traditional techniques can decrease the negative influence of such raw materials on the overall economic efficiency. In this review the opportunities and limitations of replacement of such common techniques as acid leaching, solvent extraction or extraction-in-pulp to the direct recovery of metal values from the solid phase by organic solvents (extractants), in a process known as extractive leaching, are discussed, with examples of several types of oxide and silicate raw materials containing rare metals. Mechanical activation of the raw materials is shown to be a promising method for improving process efficiency.

### INTRODUCTION

The current situation regarding the resources of raw material containing rare shows, with a few exceptions, that the process of depletion of ores steadily continues [1]. The involvement of comparatively low-grade ores increases the processing, energy and transport expenses, which, together with increasingly rigorous environmental requirements, negatively affects the overall economics. To reduce the effect of this tendency on the economical efficiency of rare metal production new techniques need to be developed.

The development of integrated processes by the combination of leaching with solvent extraction (SX) seemed to be a promising route to improve the economics of hydrometallurgical processing. Thus, solvent-in-pulp (SIP) processing for uranium allows the elimination of the expensive process of filtration, however formation of interfacial cruds, stable extraction emulsions and, frequently, considerable losses of the extractant nullify the advantages of this technique [2]. These complications are largely related to the presence of silica in the ore. Thus in the course of acid leaching the silica forms polysilicic acids of various compositions and structures [3-6].

The recovery of metal values directly from the solid phase by an organic solvent (extractant) allows these difficulties to be avoided and simultaneously increases the economic efficiency of hydrometallurgical processing of raw materials containing rare metals, especially those with high silica contents [5,7-18].

It is worth mentioning that, in contrast to SIP processing, there is no clearly defined terminology in the literature devoted to such solid phase–organic solvent (extractant) processes. Terms such as extractive leaching, non-aqueous leaching, direct leaching with organic solvent, and extractive dissolution can be found. Extractive leaching (EL) seems to be the most suitable term to designate processes that involve direct recovery of metal values from solids by organic solvents or mineral acid-containing extractants in absence of water as a macro-phase.

A tolerable level of the extractant loss is one of the most important indices that determines the economics of uranium recovery in the SIP process [2]. The loss of the extractant in this process generally occurs by:

- solubility in the aqueous phase;
- entrainment with the strip solution;
- adsorption on the surface of the solid phase;
- formation of stable emulsions and cruds.

In EL processes, the loss of organic solvents will be probably be mostly associated with adsorption on the surface of the solid phase. The nature of the solvent (extractant) used is also of great importance [2,7]. In contrast to liquid-liquid systems, the rate of recovery of the target components in the system mineral-organic solvent depends on numerous factors, which are difficult to generalise. The processes in these systems are very complicated and, as a rule, are limited by the kinetics of interfacial interaction and by diffusion in solid phase. Therefore, the acceleration of such processes is achievable mainly by improving the reactivity of the solid phase. Mechanical activation could be a promising technique for this purpose [19-22].

The aim of the present review is to discuss the opportunities and limitations of EL for several types of oxide and silicate raw materials of rare metals as an alternative to conventional hydrometallurgical techniques, and to show the influence of preliminary mechanical treatment of solid phase on the process efficiency.

## EXTRACTIVE LEACHING OF OXIDE RAW MATERIALS

The studies on EL of uranium from various raw materials were the first in this field, originating in the late 1940s from a desire to minimise the cost of hydrometallurgical processing, first at the leaching stage [7-14].

Sulphating treatment of the ores of the Colorado plateau was associated with high consumption of  $H_2SO_4$  (sometimes exceeding 250 kg/t) [7]. The replacement of acid leaching by EL with alkylphosphoric acids for the recovery of uranium from carnotite and uranite ores resulted in a significant decrease of acid consumption (from 180 to 15-20 kg/t) [8]. Concentrated  $H_2SO_4$  added to the extractant or to its pulp with the ore before contact resulted in the formation of a gypsum layer that coated the calcite particles thus preventing excessive acid consumption. Stripping of uranium was carried out by HCl solution. The extractant captured and separated from the solid residue by flushing with a fresh portion of solvent, which was recycled from the tailings by distillation. In the absence of added  $H_2SO_4$  to isoctylphosphoric acid, the extractant loss with tailings increased considerably because of the formation of the insoluble calcium salt. Fine grinding of the ore (up to –50 mesh) promoted recovery, especially for uranite ore, however this sometimes caused further problems associated with precipitation of fine particles and subsequent filtering. The authors indicated that EL was an effective technique only in case U(VI)-containing minerals with large amounts of calcite as well as for the ores forming the pulps, which are difficult to thicken and to filter.

Similar EL processes for uranium using tri-*n*-butylphosphate (TBP) in hexane combined with preliminary mixing with concentrated H<sub>2</sub>SO<sub>4</sub> and then with HNO<sub>3</sub> [9-11] or by acetone combined with mixing with a concentrated HCl/H<sub>2</sub>SO<sub>4</sub> mixture were tested on a pilot-industrial scale [12,13]. According to Magnér [7], these versions have no advantages in minimising acid consumption in comparison with acid leaching.

A percolating leach of uranium from the product of a mixture of ground superphosphate by 1 to 2% octylpyrophosphoric acid (OPPA) solution in hexane (O:A = 1:1) resulted in a 30 to 40% increase in recovery in comparison with SX from phosphoric acid [14]. The extractant captured by the residue was washed with hexane, which was then distilled from the residue at 80°C. Uranium was stripped by HF, HCl, etc., and the OPPA recycled. It was also noted that the recovery increased with a decrease of superphosphate particle size.

Total dissolution of uranium dioxide in 0.1 mol dm<sup>-3</sup> TBP and di(2-ethylhexyl)phosphoric acid (DEHPA) kerosene solutions and 0.1 mol dm<sup>-3</sup> tri-octylamine solution in xylene, all saturated with concentrated HNO<sub>3</sub>, under conditions allowing oxidation of the metal was shown by Filippov and Strelkov [15]. The higher oxidative ability of HNO<sub>3</sub> in the organic phase was attributed to occurrence of the acid predominantly in the non-dissociated form.

EL using organophosphorous compounds of niobium and tantalum from a microlite concentrate (31.4% Ta<sub>2</sub>O<sub>5</sub>, 16.5% Nb<sub>2</sub>O<sub>5</sub>) that was resistant to decomposition was shown by Mineev *et al.* [16]. The extractants dibutyl methylphosphonate (DBMP), dioctyl butylphosphonate (DOBp) and TBP were first saturated with 20% HF (O:A = 1:1). Maximum recovery (81% Ta and 74% Nb) was obtained on initially ground (-200 mesh) concentrate by 100% DBMP (A:O=1:10, 20°C, 4 h). Multistage processing (A:O=1:5, 55-60°C, 4 h) resulted in practically total recovery of both metals (80 to 90 g dm<sup>-3</sup> Me<sub>2</sub>O<sub>5</sub>). Some impurities (Si, Sn, Fe and Ti) also partially passed into the organic phase and were separated in the course of subsequent washing. Niobium and tantalum were stripped using NH<sub>4</sub>NO<sub>3</sub> and NH<sub>4</sub>F solutions, respectively. The combination of stages led to a two-fold decrease in the amount of HF required and the use of H<sub>2</sub>SO<sub>4</sub> was avoided. Grinding the concentrate allowed a two-fold increase of Nb and Ta recovery into DOBp.

Extractive leaching of molybdenum (60°C, 5 h) from a molybdenite concentrate, as received and mechanically activated in an EI-2 planetary mill (60 g, 10 min), using organic solvents containing 1 mol dm<sup>-3</sup> acids (HClO<sub>4</sub>, H<sub>2</sub>SO<sub>4</sub>, HCl, HNO<sub>3</sub>) has been discussed [17]. Propylene carbonate (PC), acetonitrile (AN), dimethylsulfoxide (DMSO) and dimethylformamide (DMFA) were tested as the organic solvents. Maximum recovery was achieved for the mechanically activated concentrate using a HNO<sub>3</sub>-containing solvent; the acid acting as an oxidant. According to increasing molybdenum recovery, these solvents were put into the following series: AN > PC > DMSO > DMFA. The following phenomena were observed in the course of this extractive leaching of the molybdenite concentrate:

- a significant increase in the viscosity of PC solutions as a result of propyleneglycol formation, that also impeded subsequent filtration and analysis of the products;
- destruction of the solvent lead to formation of resin-like products under long-term contact with H<sub>2</sub>SO<sub>4</sub>;
- stratification of the organic phase into two because the products formed mixed badly with AN.

At the same time, in the opinion of the authors, slight hydrolysis of PC by nitric acid leading to propyleneglycol formation may promote the leaching of Mo(VI) from molybdenite. The possibility of EL of molybdenum from molybdenite concentrate using alcohols (allyl, propyl, butyl, heptyl) and esters such as ethyl acetate, butyl acetate, and TBP containing HNO<sub>3</sub> was also established [17]. The maximum Mo(VI) recoveries (60°C, 5 h) were observed for the mechanically activated concentrate using propanol (23.6%) and ethyl acetate (42.3%), whereas the values for the non-activated concentrate were 1.8 and 0.7%, respectively.

Studies on the effect of mechanical treatment on the efficiency of EL processes are for the most part phenomenological. Frequently even those authors who use the term mechanical activation (MA) do not discuss the influence of mechanical treatment on transformations in the structure of main and admixture minerals, their morphology, particle size and other factors that determine reactivity to organic solvents as well as losses of the latter. In the last 30 to 40 years, a considerable number of studies illustrating the efficiency of MA for increasing of reactivity of solids have been published (a number of them have been cited, e.g., monographs [19,20]). MA not only increases the specific surface of solids but also significantly affects the structure by deformation and partial destruction of the crystal lattice forming various types of defects thus influencing the kinetics of the leaching processes. The efficiency of MA is to a large extent determined by the type of device used as well as by regime of action on the material subjected to the treatment: attrition, vortex and impact. The material of construction and geometry of the equipment and the acting bodies, the medium of the process, the mass ratio of acting bodies and the material being treated are also of considerable importance. The planetary type apparatus has been shown to be efficient for mechanical activation of resistant raw materials. Depending on the aim of the treatment, each material requires an optimum selection of specific activation conditions.

## EXTRACTIVE LEACHING OF SILICATE RAW MATERIALS

Extractive leaching is a very effective technique for selective recovery of metal values (Zr, REE) from low-grade high-silica mineral raw materials such as eudialyte [5,6,21-26]. Eudialyte is a complex zirconosilicate containing, along with rare elements (Zr, Hf, Nb, Ta, REE), large amounts of silica ( $\geq 50\%$  SiO<sub>2</sub>). Considerable resources of this mineral are available in Russia, USA, Canada, Greenland, Sweden, Australia and the Republic of South Africa. The use of this mineral resource is limited by the absence of an economically suitable technology. All known methods of acid leaching of eudialyte proposed its "total dissolution", associated with large amounts of silica passing into solution and characterised by high cost of leaching agents, energy and lengthy processing.

EL of eudialyte by 100% TBP saturated with concentrated HNO<sub>3</sub> practically eliminates the dissolution of silica and the phases are easy to separate [5,6]. Preliminary short-term mechanical activation (1 min) in a high-energy AGO-2 activator under regimes that preserve the main structure of the mineral results in a three-fold increase of the recovery of metal values (Zr, REE) in the organic phase and a reduction by half of the organic phase capture by the solid cake. Combination of mechanical activation and EL actually allows total selective recovery of REE and 50% of zirconium in 10 min [5].

It was shown with quantitative IR spectroscopy that the extracts obtained by EL from eudialyte using 100% TBP ( $C_{HNO_3}^{org} = 4$  to 5.5 mol/l) contain the complex  $[TBP \cdot H_3O^+ \cdot (H_2O)_n]Zr(NO_3)_5^-$  as a major product [27]. This complex is formed from  $[TBP \cdot H_3O^+ \cdot (H_2O)_2] \cdot NO_3(HNO_3)_p^-$  ionic pairs and  $Zr(NO_3)_5^-$  anions through an ion-exchange mechanism.

Regrettably, it is not possible to discuss in the scope of this review interesting results of other recent studies on EL of rare and non-ferrous metals from, for example, intermediate products of chlorinating or sulphating of ores (concentrates) [18], secondary raw materials [28], as well as the studies on adsorption of extractants on solid particles related to the problem of crud formation and our own studies, in particular, on the effect of the nature of eudialyte concentrate on extractant losses.

## CONCLUSIONS

This review illustrates that very interesting results of the studies on EL of uranium from ores performed in 1950s, which regrettably have not been further applied to industry, promoted studies on recovery of rare and non-ferrous metals from natural and secondary raw materials, products of decomposition of ores and concentrates as well as investigations into the problems of extractant losses.

EL is a complex process, whose efficiency depends on a number of factors such as: the nature of the ore; the amount of admixture minerals (first of all, silicates); extent of embedding of the minerals into barren rock; particle size; the nature of the organic phase used, hydrodynamics of the process, temperature as well as some other less obvious factors. Nevertheless, in our opinion, the accumulated experience on SIP processes as well as in the field of intensification of mineral raw material treatment by mechanical activation enables the consideration of EL techniques as an alternative to conventional hydrometallurgical processes to solve the problems of extractant losses.

EL provides a significant decrease in the consumption of chemicals and energy; reduces the number of stages in the process by recovering target components directly from solid phase; permits the change of redox equilibria in the system thus controlling the mechanism and kinetics of the recovery processes; and enables the recycling of organic solvents thus protecting the environment.

In connection with the increasing use of relatively low-grade raw material resources, the EL technique will be of growing importance. Therefore, in our opinion, it seems reasonable to include this technique into the group of solvometallurgical methods [1,29]. Solvometallurgy gathers together the recovery of metal values from raw materials using chemical reactions in organic, inorganic or mixed non-aqueous media in absence of water as the macro-phase. The comprehensive development of the theoretical and applied aspects of solvometallurgy will provide the basis for development of principally new techniques for treating primary and secondary raw materials as an alternative to those currently in use.

## ACKNOWLEDGEMENT

The studies of mechanical activation on EL of eudialyte have been supported by ISTC (Grant 1332-99).

# DEVELOPMENT OF A SOLVENT EXTRACTION PROCESS FOR THE PRODUCTION OF PURE NEODYMIUM OXIDE FROM SYNTHETIC MT WELD PROCESS LIQUOR

**Chu Yong Cheng, Karin Sodenhoff\*** and **Mike Vaisey†**

AJ Parker CRC for Hydrometallurgy / CSIRO Minerals, Australia

\*Australian Nuclear Science and Technology Organisation, Australia

†Lynas Corporation Pty Ltd, Australia

The objective of the current project was to develop a solvent extraction process for the production of pure Nd oxide (98%) from Mt Weld leach liquor. Ionquest 801 was chosen as extractant and Shellsol D70 as diluent. pH isotherms were obtained from batch tests. Semi-continuous tests were carried out to develop the solvent extraction process in three separate circuits. In circuit 1, almost all middle and heavy rare earths were extracted. The co-extracted light rare earth metals were effectively scrubbed. In circuit 2, the Nd/(La-Nd) ratio increased from 15% in the feed to 44% in the loaded strip solution. In circuit 3, the Nd/(La-Nd) ratio was further increased to 71% by extraction and from 71% to 97.5% by scrubbing. The goal to obtain a Nd/(La-Nd) ratio of 98%, is thought to be achievable with the present flowsheet by increasing the number of scrub stages in Circuit 3.

## INTRODUCTION

The Mt Weld Rare Earths Project is based upon a world-class resource of rare earths near Laverton in Western Australia. The resource contains approximately 2 million tonnes at 18% rare earth oxide in phosphate mineralisation [1]. The Mt Weld deposit is unique in that it has a low level of radioactivity compared to other monazite concentrates. Lynas Corporation and its joint venture partners expect project development to commence in 2002. The Australian Nuclear Science and Technology Organisation (ANSTO) was contracted to carry out the pilot plant program. One of the objectives of the program was to develop a solvent extraction (SX) process for the separation of rare earths from a chloride solution. In February 2000, ANSTO, in partnership with the AJ Parker Cooperative Research Centre for Hydrometallurgy, was commissioned to develop an SX process for the production of pure neodymium oxide (98%).

A comprehensive literature review was conducted. The emphasis was to review commercial processes [2-5] and research work with D2EHPA (di-2-ethylhexyl phosphoric acid) [6-7] and EHEHPA (2-ethylhexyl phosphonic acid mono-2-ethylhexyl ester) [8-10] for the production of pure rare earth products, especially Nd oxide [11]. EHEHPA was found to be a better extractant compared with D2EHPA due to the reduced tendency for gel formation, lower acid concentration required for stripping, and larger separation factors for the separation of Nd from other light rare earths (LRE). Based on the literature review and assessment of previous ANSTO work [12], Ionquest 801 (EHEHPA) was chosen as the extractant with Shellsol D70 as the diluent.

## EXPERIMENTAL

The synthetic rare earth chloride solution contained (in g/L) La (41.6), Ce (1.21 in circuit 1 and 41.2 in circuit 2), Pr (6.82), Nd (22.4), Sm (3.67), Eu (0.32), Gd (1.30), Tb (0.09), Dy (0.27), Y (0.56) and Er (0.04). The organic solution contained 0.6 M Ionquest 801 in Shellsol D70.

### Batch Tests

Shakeout tests were conducted using plastic rectangular boxes and overhead stirrers. Hydrochloric acid (100 g/L) and ammonia solution (10%) were used to adjust the solution pH as required. Aqueous solution sample and organic strip raffinate were analysed.

### Semi-continuous Tests

The term "semi-continuous" is relative to "fully-continuous". In a semi-continuous counter-current solvent extraction test, extraction, scrubbing and stripping circuits are operated independently. Two mini rigs of 10 mixer-settlers each with mixer volume of 0.16 litre and settler volume of 0.38 litre were used to conduct semi-continuous tests. All tests were conducted at 22°C.

## SEPARATION OF LIGHT FROM MIDDLE AND HEAVY RARE EARTHS (CIRCUIT 1)

### pH Isotherms

pH isotherms of the rare earth metals (Figure 1) were obtained from batch tests. It was found that:

- The pH for the separation of light from middle and heavy rare earths should be around 1.0.
- The pH for the separation of Nd from La, Ce and Pr should be around 1.4.
- The separation of Nd from Ce and Pr would require many extraction and scrubbing stages.

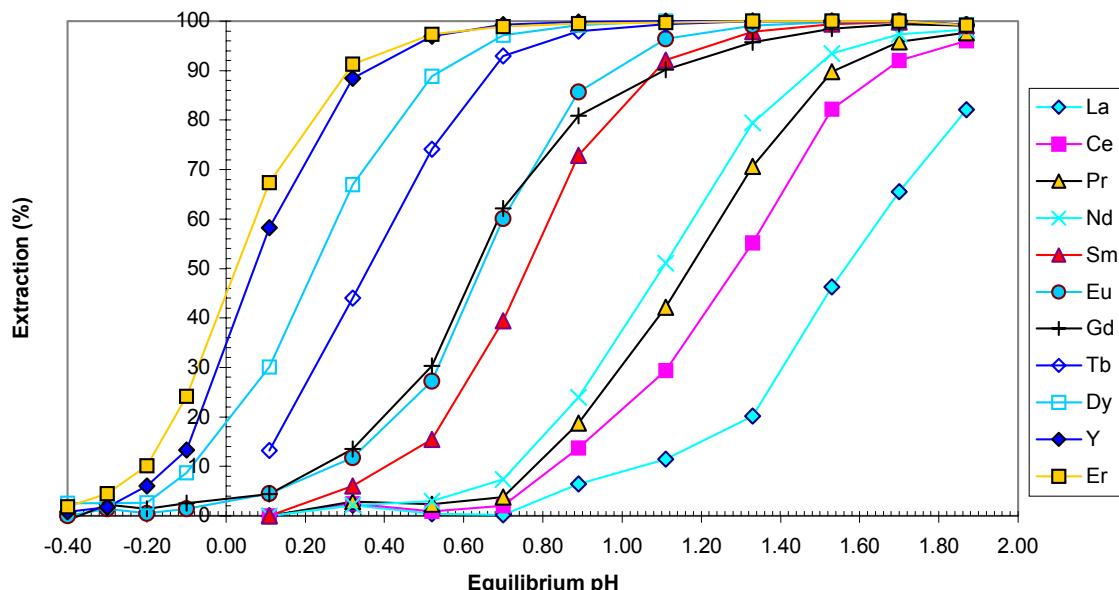

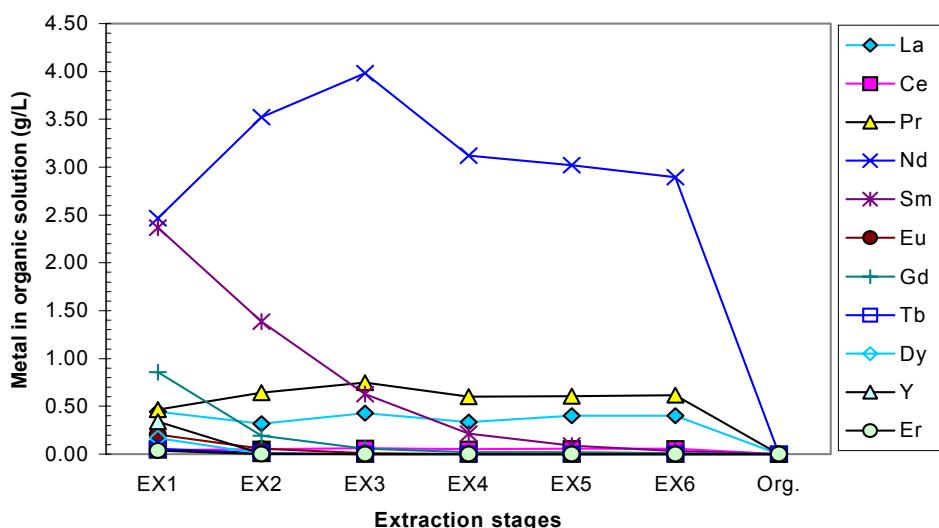

Figure 1. pH isotherms of rare earths with 0.6 M (20% v/v) Ionquest 801 in Shellsol D70.

### Semi-continuous Extraction

Distribution isotherms were determined and the McCabe Thiele diagrams indicated that four theoretical stages were needed to separate Sm and Nd. Therefore in circuit 1, a total of six extraction stages were used. The pH in stages 1, 3 and 6 was controlled at 1.0 and the A/O flowrate ratio was 1:1.5. Almost all middle and heavy rare earths were extracted. The Sm concentration in the raffinate was as low as 17 mg/L with a 99.5% extraction (Table 1). Some 18% Nd, 11% Pr, 5.5% Ce and 1.7% La were co-extracted. Figure 2 shows that some Nd extracted was crowded out by middle and heavy rare earths in stages 2 and 1 where the concentration of middle and heavy rare earths was high.

*Table 1. Metal concentration and extraction in circuit 1.*

Element	Concentration (g/L)			Extraction (%)
	Feed	Raffinate	Loaded organic	
La	41.6	37.6	0.445	1.74
Ce	1.21	1.04	0.040	5.45
Pr	6.82	5.58	0.465	11.11
Nd	22.4	16.7	2.47	18.13
Sm	3.67	0.017	2.37	99.53

Tb	0.090	0.000	0.055	100.00
Dy	0.270	0.000	0.165	100.00
Y	0.560	0.000	0.340	100.00
Er	0.040	0.000	0.035	100.00

*Figure 2. Metal concentration in organic solution in extraction stages in circuit 1.*

### Semi-continuous Scrubbing

Pre-loaded organic phase was scrubbed at an A/O flowrate ratio of 1:5 using a scrub solution containing 12 g/L HCl, 5 g/L Sm and 2 g/L Gd. Almost all LRE were scrubbed with the concentration of La, Ce, Pr and Nd in the scrubbed organic phase being 2, 2, 1 and 4 mg/L respectively (Table 2). Figure 3 shows that displacement of Nd by Sm occurred in the first two stages. In stages 3-6, the concentration of both Sm and Nd in the organic phase dropped due to the higher acidity in the scrub solution.

Table 2. Metal concentration and scrubbing efficiency in circuit 1.

Element	Concentration (g/L)				Total scrub efficiency (%)
	Scrub solution	Loaded organic	Scrubbed organic	Spent scrub liquor	
La	0.034	0.330	0.002	1.62	97.39
Ce	0.000	0.045	0.002	0.204	96.22
Pr	0.003	0.555	0.001	2.65	99.76
Nd	0.020	2.89	0.004	13.3	99.71
Sm	4.83	2.63	2.25	4.05	10.57
Eu	0.001	0.230	0.190	0.106	17.38
Gd	2.03	1.01	1.45	0.309	-31.54
Tb	0.000	0.065	0.060	0.008	7.69
Dy	0.003	0.200	0.200	0.008	0.00
Y	0.000	0.415	0.400	0.001	3.61

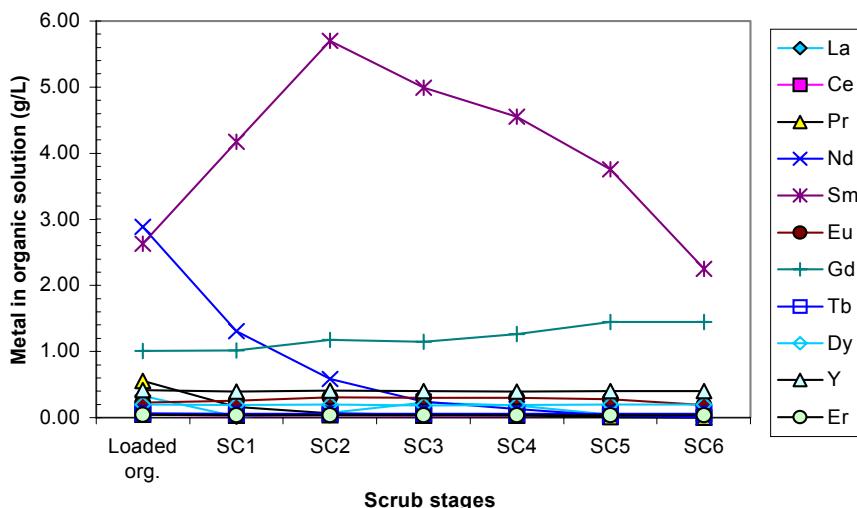

Figure 3. Metal concentration in organic solution during scrubbing in circuit 1.

### Semi-continuous Stripping

The semi-continuous stripping test in circuit 1 was conducted in 6 stages of which the first three stages were used for selective stripping to obtain a Sm, Eu and Gd product, and the remaining three stages were used for bulk stripping. The strip test was conducted at an A/O flowrate ratio of 1:5. HCl solutions of 1 M and 3 M were used in the selective and bulk stripping, respectively. In the selective strip stages, over 96% Sm, 98% Eu and 94% Gd were stripped and smaller fraction of heavy rare earths were stripped, indicating the possibility of obtaining a Sm, Eu, Gd product via selective stripping (Table 3). All middle and heavy rare earths were stripped with 3 M HCl in bulk stripping.

Table 3. Metal concentration and stripping efficiency in circuit 1.

Element	Concentration (g/L)			Strip efficiency (%)	
	Scrubbed organic	Loaded strip liquor 1	Loaded strip liquor 2	Selective	Total
Sm	4.44	20.7	0.863	96.15	100.00
Eu	0.230	1.01	0.048	98.08	100.00
Gd	1.72	6.91	0.387	94.58	100.00
Tb	0.100	0.226	0.066	75.09	100.00
Dy	0.195	0.188	0.330	34.48	100.00
Y	0.420	0.097	1.24	5.24	100.00
Er	0.040	0.004	0.118	7.86	100.00

## SEPARATION OF NEODYMIUM FROM OTHER LRE (CIRCUIT 2)

During the course of this work, the projected Ce concentration in the feed was increased from 1.2 g/L to 41.2 g/L. Therefore, the Ce concentration in the extraction raffinate of circuit 1 (feed for circuit 2) was similarly affected, increasing the difficulty in the separation of Nd from the light rare earths, due to the closeness of the pH isotherms of Nd and Ce (Figure 1).

### **Semi-continuous Extraction**

The semi continuous extraction test in circuit 2 was conducted at pH 1.4 with an A/O flowrate ratio of 1:3. A total of 10 stages were used and the pH was controlled at stages 1, 5 and 10. The ratio of Nd/(La-Nd) increased from 15% in the aqueous feed solution to 44% in the loaded organic solution (Table 4). This indicates that it would be very difficult to scrub the organic solution to obtain a Nd/(La-Nd) ratio of 98% in the scrubbed organic solution. A decision was made to strip the loaded organic solution and to re-load it with the strip raffinate in a third circuit.

*Table 4. Metal concentration and extraction in circuit 2.*

Element	Concentration (g/L)			Extraction (%)	Separation factor ( $\beta_{Nd/M}$ )
	Feed	Raffinate	Loaded		
La	33.3	24.2	0.45	4.01	179.7
Ce	41.2	20.0	4.05	29.49	16.3
Pr	4.90	1.20	0.98	59.69	4.1
Nd	14.8	1.30	4.30	87.06	1.0
Nd/(La-Nd) (%)	15.7	2.8	43.9		

## SEPARATION OF NEODYMIUM FROM OTHER LRE (CIRCUIT 3)

### **Semi-continuous Extraction**

The semi continuous extraction in circuit 3 was conducted, again, at pH 1.4 with an A/O ratio of 1:3. A total of 15 stages were used with pH controlled in stages 1, 13 and 15. After 15 stages of extraction, the ratio of Nd/(La-Nd) increased from 50% in the synthetic feed to 71% in the loaded organic, with 97% Nd extraction (Table 5). The cumulative separation factor of Nd/La (359) and Nd/Ce (32) was much larger than Pr (5.7), indicating that in the extraction stages, Nd was mainly separated from La and Ce. Figure 4 shows that the Nd concentration increased constantly from stage 15 to stage 1 while the Ce concentration increased initially and then dropped, indicating that the Nd crowded out the Ce from the organic solution.

*Table 5. Metal concentration and extraction in circuit 3.*

Element	Concentration (g/L)			Extraction (%)	Separation factor ( $\beta_{Nd/M}$ )
	Feed	Raffinate	Loaded organic		
La	3.01	2.54	0.08	7.48	359.0
Ce	14.0	5.24	1.77	37.82	31.5
Pr	4.36	0.53	0.99	67.78	5.7
Nd	21.1	0.67	7.05	96.95	1.0
Nd/(La-Nd) (%)	49.7	7.4	71.4		

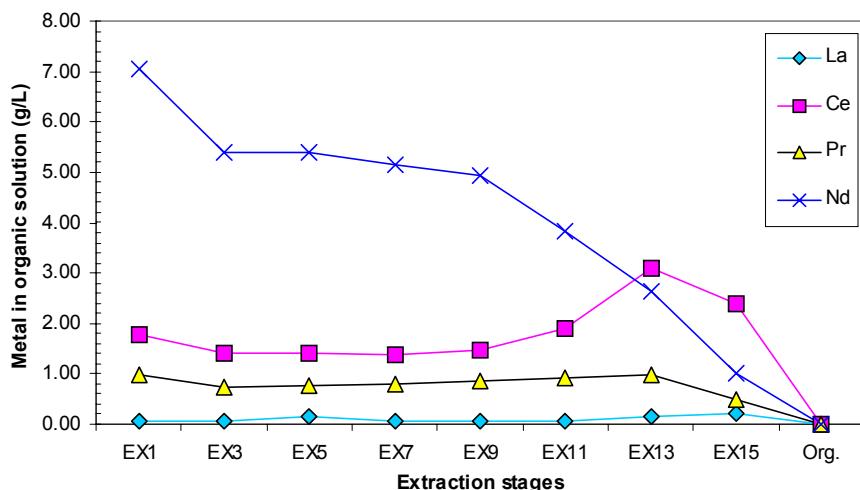

Figure 4. Metal concentration in organic solution in extraction stages in circuit 3.

### Semi-continuous Scrubbing

The semi continuous scrub test was conducted without pH control. The scrub solution, made from a very pure Nd oxide (99.9%), contained 15 g/L Nd at pH 1.4. A total of 20 scrub stages were used at an A/O flowrate ratio of 1:5. The Nd/(La-Nd) concentration ratio in the scrubbed organic reached 97.5% with the total concentration of the other three LRE (La, Ce and Pr) being 0.215-0.225 g/L (Table 6).

Table 6. Metal concentration and scrubbing efficiency in circuit 3.

Element	Concentration (g/L)				Scrub efficiency (%)
	Loaded organic	Scrub solution	Spent scrub liquor	Organic scrubbed	
La	0.075	0.002	0.311	0.015	80.00
Ce	1.77	0.005	7.53	0.100	94.33
Pr	0.985	0.038	4.24	0.110	88.83
Nd	7.05	15.5	7.37	8.80	-24.82
Nd/(La-Nd) (%)	71.4	99.7	37.9	97.5	

### CONCLUSIONS

pH isotherms of the rare earth elements were obtained with 0.6 M lonquest 801 (EHEHPA) in Shellsol D70 by shakeout tests to determine the pH for the separation of Sm from Nd (1.0) and the pH for the separation of Nd from other LRE (1.4). Semi-continuous extraction tests in circuit 1 showed that almost all middle and heavy rare earths were extracted at pH 1.0 in six stages at an A/O ratio of 1:1.5. The raffinate contained only 17 mg/L Sm. After six stages of scrubbing with a solution containing middle rare earths, almost all co-extracted light LRE were scrubbed, indicating an over 99% LRE recovery in the raffinate in circuit 1. The Nd/(La-Nd) ratio increased from 15% in the feed to 44% in the loaded organic solution in circuit 2 by extraction at pH 1.40 in 10 stages. In circuit 3, the Nd/(La-Nd) ratio was further increased to 71% in the organic solution by extraction at pH 1.4 in 15 stages and from 71% to 97.5% by scrubbing with pure Nd solution in 20 stages. This work has shown that the goal of obtaining a 98% Nd/(La-Nd) ratio is achievable and pilot trials were conducted to confirm the technical feasibility of the process.

## **ACKNOWLEDGEMENTS**

The provision of Ionquest 801 by Albright and Wilson Australia Limited and Shellsol D70 by The Shell Company of Australia Limited is acknowledged. The authors thank the management and staff of ANSTO and The AJ Parker CRC (CSIRO Minerals and Murdoch University) for carrying out and supporting the project.

## SEPARATIONS AND RECOVERY OF URANIUM, THORIUM AND LANTHANIDES FROM MONAZITE USING CYANEX 923

Bina Gupta, Poonma Malik and Akash Deep

Department of Chemistry, University of Roorkee, Roorkee, India

The extraction behaviour of uranium, thorium and lanthanides, represented by cerium and ytterbium, has been investigated in Cyanex 923. Effect of different variables like the concentration of acids, metal ion and extractant, nature of diluent and temperature has been studied. The composition of the extracted U(VI) and Th(IV) species has been proposed. Based on the partition data some important ternary separations involving the aforesaid metal ions have been achieved. The proposed procedure has been applied for the recovery of uranium, thorium and lanthanide fraction from monazite sand. Stability and regeneration capacity of the extractant have been evaluated.

### INTRODUCTION

Uranium and thorium are the two most vital elements for nuclear energy programme. Their natural sources generally contain a sizeable fraction of lanthanides which in their own right have diverse technological applications. Thus the methodology adopted for the separation of these metal ions from different ores has always attracted the attention of separation scientists. Over the years a variety of extractants such as high molecular weight amines, carboxylic acids, tributylphosphate (TBP), di-2-ethylhexylphosphoric acid (DEHPA) and tri-*n*-octylphosphine oxide (TOPO) have been more frequently used for the attainment of these separations. However, they have their own limitations such as aqueous miscibility, low hydrolytic stability, interference from  $\text{CO}_3^{2-}$ ,  $\text{SO}_4^{2-}$  and  $\text{PO}_4^{3-}$  anions, emulsion formation and poor selectivity. Lately Cyanex 923, a mixture of four tri-alkylphosphine oxides ( $\text{R}^1\text{P}=\text{O}$ ,  $\text{R}_3\text{P}=\text{O}$ ,  $\text{R}^1\text{R}_2\text{P}=\text{O}$ ,  $\text{R}^1\text{R}_2\text{P}=\text{O}$  where  $\text{R}^1 = n\text{-octyl}$  and  $\text{R} = n\text{-hexyl}$ ) has come up on the forefront as a good extractant [1-3] because of its poor aqueous solubility and resistance to hydrolysis. Its major advantages over the widely used Cyanex 921(TOPO) are that it is completely miscible with all common hydrocarbon diluents even at low ambient temperatures, is liquid whereas TOPO is solid at room temperature and shows better selectivity than TOPO because it is structurally more hindered than TOPO. The present paper embodies the extraction behaviour of U(VI), Th(IV) and the lanthanides being represented by Ce(III), Ce(IV) and Yb(III) in toluene solution of Cyanex 923 from  $\text{HNO}_3$  and  $\text{H}_3\text{PO}_4$  media. Phosphate is an integral part of one of the enriched sources of these elements namely monazite, its effect on the extraction of said metal ions has also been studied. The effect of equilibration time, nature of diluent, temperature and concentration of acids, extractant and metal ion on the extraction has been investigated. Loading and recycling capacities of the extractant are assessed. Based on the partition data some important ternary separations involving U(VI), Th(IV) and Ce(III)/Ce(IV)/Yb(III) have been achieved. The practical utility of the proposed procedure has been demonstrated by separating uranium, thorium and the lanthanide fraction from the solution of monazite sand.

## EXPERIMENTAL

Equal volumes (10.0 ml) of the aqueous phase ( $1.0 \times 10^{-4} M$  or any other concentration of metal ion) and organic phase (appropriate concentration of Cyanex 923 in toluene) were shaken at room temperature ( $25 \pm 2^\circ C$ ) for five minutes to ensure complete equilibration. The two phases were separated and suitable aliquots of each phase were assayed for gamma activity or the aqueous phase was employed for determination by ICP-AES. Based on five observations the value of percent extraction for U(VI) ( $0.008 M$  Cyanex 923) and Th(IV) ( $0.01 M$  Cyanex 923) at about 60 % extraction exhibits a coefficient of variation of  $\pm 3\%$ .

About 0.1 g sample of monazite sand was digested with 25 ml mixture of concentrated HF,  $HNO_3$  and  $HClO_4$  (3:1.5:0.5) in a teflon vessel for twenty four hours at  $80^\circ C$  [4]. After complete evaporation to dryness, the mass was dissolved in 100.0 ml solution of  $5.0 M$  nitric acid and the solution was labelled as (A).

## RESULTS AND DISCUSSION

### Extraction Behaviour

The extraction behaviour of U(VI), Th(IV), Ce(III), Ce (IV) and Yb(III) from  $1.0 \times 10^{-3}$  to  $10.0 M$   $HNO_3 / H_3PO_4$  in a  $0.10 M$  toluene solution of Cyanex 923 is given in Table 1. The extraction of U(VI) and Th(IV) is almost quantitative ( $\approx 99\%$ ) in the entire investigated range of  $HNO_3$  molarity, while with increasing  $H_3PO_4$  molarity it shows a decreasing trend. Ce(III) and Ce(IV) show maximum extraction at  $0.5 M$  nitric acid but are negligibly extracted ( $\leq 5\%$ ) over the entire range of  $H_3PO_4$  concentration. It is interesting to note that at  $5.0 M$   $HNO_3$  Th(IV) is quantitatively extracted into  $0.1 M$  Cyanex 923 solution leaving Ce(IV) un-extracted. This is probably due to the reduction of Ce(IV) to Ce(III) by commercial grade Cyanex 923 as reported by Jun *et al.* [3] also. The extraction of Yb(III) is around 45 % at  $1.0 \times 10^{-3} M$   $HNO_3$  and  $H_3PO_4$ . It decreases with the increasing  $H_3PO_4$  molarity, however, in case of nitric acid medium the percent extraction of Yb(III) again increases to around 30 % at  $0.5 M$ .

From Table 1 it is apparent that U(VI) and Th(IV) can be separated from the lanthanide fraction beyond  $2 M$   $HNO_3$  by extracting them selectively in Cyanex 923 and leaving the lanthanide fraction in the aqueous phase. The effect of phosphate ions on the extraction of U(VI) and Th(IV) from nitric acid medium was also investigated using  $Na_3PO_4$  to maintain  $PO_4^{3-}$  ion concentration. The phosphate ion concentration was varied from  $1.0 \times 10^{-3}$  to  $0.80 M$  keeping nitric acid concentration constant at  $5.0 M$  and using  $1.0 \times 10^{-4} M$  U(VI) / Th(IV). The extraction of U(VI) and Th(IV) remains quantitative ( $\approx 99\%$ ) in this investigated range of  $PO_4^{3-}$  ion concentration. Monazite generally contains around 26 % phosphate, 0.3 % uranium and 8.1 % thorium [5] therefore it can be concluded that the extraction of U(VI) and Th(IV) from  $5.0 M$   $HNO_3$  will not be affected at the phosphate ion concentration in ratio to the metal ion expected to be encountered in the solution of the monazite sand. The effect of different parameters on the extraction of U(VI) and Th(IV) was investigated from  $0.50 M$   $HNO_3$  at  $25 \pm 2^\circ C$  employing a  $1.0 \times 10^{-4} M$  metal ion and  $0.10 M$  toluene solution of Cyanex 923 unless otherwise stated.

*Table 1. Percent extraction of metal ions in 0.1 M Cyanex 923 at different molarities of HNO<sub>3</sub> and H<sub>3</sub>PO<sub>4</sub>.*

Metal ion	Acid molarity (M)

(a = HNO<sub>3</sub> and b = H<sub>3</sub>PO<sub>4</sub>)

### Diluent Effect

Cyclohexane, xylene, toluene, chloroform and cyclohexanone were employed as diluents for investigating their effect on the distribution ratio. There is a decreasing trend in the distribution ratio with increasing dielectric constant of the diluent. Toluene, xylene, and cyclohexane show almost quantitative extraction and toluene was used for all further studies.

### Effect of the Temperature and Equilibration Time on the Partition of U(VI) and Th(IV)

The effect of temperature (10 – 70 °C) on the extraction of U(VI) and Th(IV) was investigated. There is a decrease in extraction with increasing temperature indicating the process to be exothermic. Studies further reveal that two minutes equilibration time is necessary to achieve the limiting extraction and prolonged shaking has no adverse effect on the extraction.

### Composition of the Extracting Species and Loading Capacity

The effect of concentration of Cyanex 923 (1.0 × 10<sup>-3</sup> – 5.0 × 10<sup>-2</sup> M) on the extraction of U(VI) and Th(IV) (Figure 1) was studied. The distribution ratio increases with the increasing concentration of the extractant. A slope of around two for U(VI) and three for Th(IV) suggests the involvement of two and three molecules of Cyanex 923 in the formation of the extracting species which may be proposed as UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>.2R and Th(NO<sub>3</sub>)<sub>4</sub>.3R (R = Cyanex 923). A similar species for the extraction of Th(IV) in Cyanex 923 has been proposed by Lu *et al.* [6]. The extraction equilibrium can be written as

Partition studies carried out with varying U(VI) and Th(IV) concentrations (1.0 × 10<sup>-6</sup> M – 0.10 M) using 0.01 M toluene solution of Cyanex 923 show maximum loading at 0.005 M U(VI) and 0.003 M Th(IV), i.e., 0.34 g U(VI) and 0.20 g Th(IV) can be loaded per gram of the extractant.

### Stripping Reagents for Uranium and Thorium

Various stripping reagents were examined for the back extraction of Th(IV) and U(VI) from the organic phase. The results of the efficiency of stripping reagents are given in Table 2. 2 M HCl (5 volumes) and 0.5 M H<sub>2</sub>SO<sub>4</sub> (4 volumes) were found effective for the quantitative stripping of Th(IV) whereas U(VI) is stripped almost completely with 0.5 M H<sub>2</sub>SO<sub>4</sub> (5 volumes).

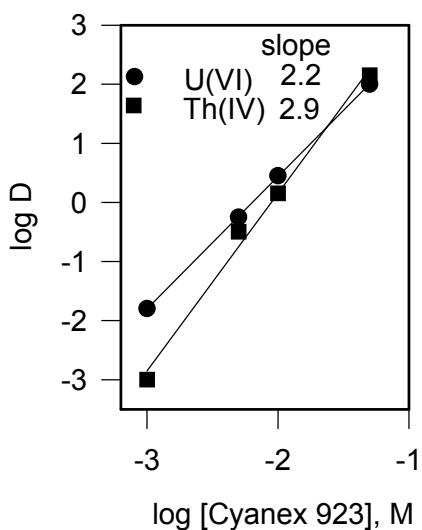

Figure 1. Effect of Cyanex 923 concentration.

Table 2. Stripping efficiency of different reagents for Th(IV) and U(VI).

Reagent	Recovery (%)		Reagent	Recovery (%)	
	Th(IV)	U(VI)		Th(IV)	U(VI)
0.5 M malonic acid	0.0	2.6	0.1 M HCl	0.0	0.0
0.1 M citric acid	24.6	17.6	1.0 M HCl	30.0	0.0
0.1 M EDTA	6.2	2.0	2.0 M HCl	50.0	0.0
1.0 M NH <sub>4</sub> NO <sub>3</sub>	1.5	0.0	0.5 M H <sub>2</sub> SO <sub>4</sub>	68.0	55.0
0.1 M tartaric acid	0.0	0.0	1.0 M H <sub>2</sub> SO <sub>4</sub>	30.0	0.0

[Metal ion] = 1.0 × 10<sup>-4</sup> M, [HNO<sub>3</sub>] = 5.0 M, [Extractant] = 0.1 M.

### Stability and Regeneration Capacity of the Extractant

The stability of Cyanex 923 towards nitric acid was determined by keeping a toluene solution of the extractant in contact with 5.0 M HNO<sub>3</sub> solution and checking the percent extraction of U(VI) and Th(IV) periodically after a gap of five days. No significant decrease in the extraction of either of the metal ions is observed even after a contact of 50 days. Experiments were also carried out to determine the recycling capacity of the extractant by first loading it with a mixture of Th(IV) and U(VI) and then stripping them with 2.0 M HCl (5 volumes) and 0.5 M H<sub>2</sub>SO<sub>4</sub> (5 volumes), respectively. The organic phase after stripping was regenerated by washing it with water till the washings were neutral. The recovery at each step is calculated from the amount of metal ions which get extracted in that particular cycle. No significant change was observed in the percent extraction and recovery of U(VI) and Th(IV) solutions up to fifteen cycles.

### Separtions

Based on the partition data some important ternary separations involving U(VI), Th(IV) and lanthanides were attained. The lanthanide fraction (represented by cerium and ytterbium) was separated from U(VI) and Th(IV) at 5.0 M HNO<sub>3</sub>. However, the mutual separation of U(VI) and Th(IV) was feasible at 2.0 M HCl. Table 3 illustrates the conditions and results of these separations.

*Table 3. Ternary separations of uranium, thorium and lanthanides from 5.0 M HNO<sub>3</sub> using 0.10 M Cyanex 923.*

Metal ions separated	Molar ratio (10 <sup>-4</sup> M)	Ce(III)/Ce(IV)/Yb(III) remaining in aqueous phase	Th(IV) <sup>a</sup> recovered from organic phase	U(VI) <sup>b</sup> recovered from organic phase
Ce(III):Th(IV):U(VI)	10:1:1	99.6	99.	99.6
	1:10:1	99.2	99.4	99.8
	1:1:10	99.5	99.6	99.7

#### **Recovery of Uranium, Thorium and Lanthanides from Monazite**

Ten milliliters of (A) were equilibrated with an equal volume of 0.10 M Cyanex 923. Thorium and uranium were quantitatively ( $\approx$ 99 %) extracted in the organic phase leaving behind the lanthanide fraction ( $\approx$ 99 %) in the aqueous phase. The organic layer was then washed with double distilled water till the washings were neutral. Th(IV) was recovered from the organic phase using 2.0 M HCl (5 volumes). The organic phase was again washed with double distilled water till the washings were neutral and then U(VI) was recovered employing 0.5 M H<sub>2</sub>SO<sub>4</sub> (5 volumes). (B) and (C) refer to the recovered solutions of thorium and uranium. The organic phase after stripping was regenerated by washing it with double distilled water. Table 3 presents the composition of (A), (B) and (C). The overall recovery and purity of each fraction is more than 98%. In order to show the efficacy of the above procedure for separation of uranium and thorium from lanthanides from monazite solution, the initial and final concentration of other lanthanides namely lanthanum, neodymium, europium and gadolinium is also shown in Table 4.

#### **CONCLUSIONS**

The present investigations have resulted in offering a convenient liquid-liquid extraction method for separating uranium, thorium and lanthanides. The presence of phosphate ions does not affect the separations from nitric acid medium. The recovery of metals is almost quantitative and the purity of each fraction is also high. Strict control of the acidity, of the aqueous phase is not required to achieve the separations. The extractant offers a good loading and recycling capacity. The stripping agents used for U(VI) and Th(IV) are simple and convenient for the subsequent processing of the recovered metal ions.

# SOLVENT EXTRACTION PILOT PLANT RESULTS FOR RECOVERY OF COPPER AND NICKEL FROM AN AMMONIACAL LEACH OF DEEP-SEA MANGANESE NODULES

Gale L. Hubred

Retired, Brea, California, USA

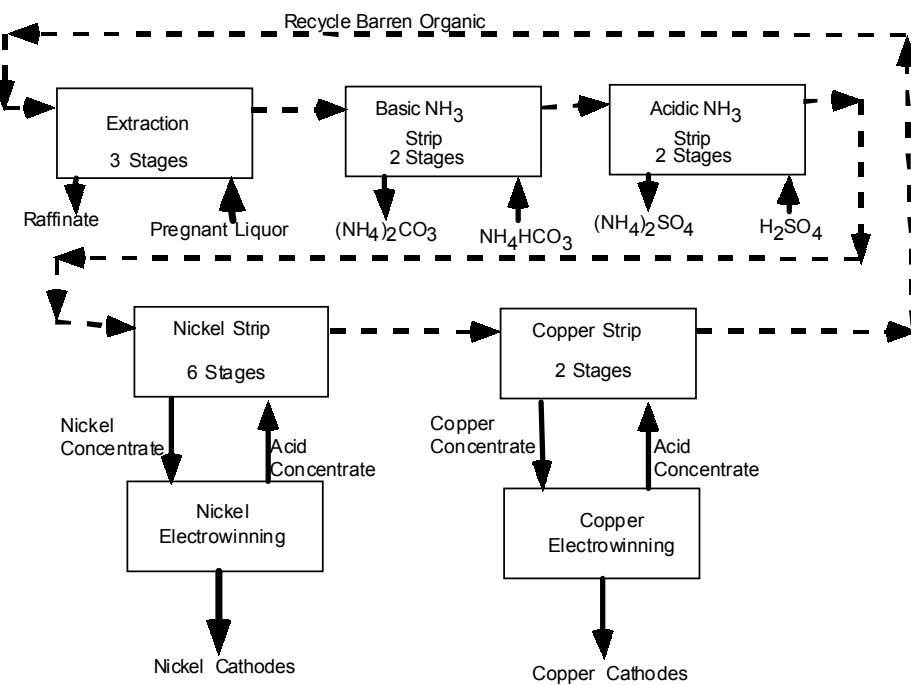

A LIX-64N® solvent extraction pilot plant was operated for 20 days to co-extract nickel and copper from an ammonium carbonate leach liquor. Data includes: trace element monitoring, a steady state balance, and individual stage equilibrium approach measurement. Ammonia extraction and stripping were measured. All extractions and copper stripping were fast and complete. Nickel stripping was slower and further study is needed. The feed solution contained 90 g/l NH<sub>3</sub>, 6.2 g/l Ni, 5.7 g/l Cu, and was pregnant liquor from a deep-sea manganese nodule leach. The pregnant liquor contained 200 mg/l cobalt, some of which extracted, and accumulated on the organic. Thallium leached from the nodules, extracted and was stripped in the acidic ammonia strip. Boron extracted from the nickel strip solution and stripped into the raffinate.

## INTRODUCTION

In the 1970s, Kennecott Corporation developed a deep-sea manganese nodule extraction process [1]. This paper presents the solvent extraction data gathered in 1974 during extensive pilot-plant operations. Most of the other aspects of the process development program and description and operation of the complete pilot plant are not available. The data is old, and interest in manganese nodules has subsided, but the trace element tracking and stage equilibrium data might be useful.

## PROCESS DESCRIPTION

Figure 1 shows the solvent-extraction process. The process co-extracted copper and nickel in three stages. Extraction conditions determined the copper and nickel recoveries. The process stripped ammonia in two sections, one basic to allow ammonia recovery and the second acidic to allow thorough ammonia removal. Nickel was stripped using nickel electrowinning acid concentrate and copper was stripped in an analogous way. The nickel/copper separation was controlled by the acidity of the nickel stripping solution. All stages operated at 40 C. in acrylic mixer settlers with a cubic mixer box and a settler volume three times the mixer volume. Flows determined the external phase ratio. The internal phase volume phase ratio was forced to 1 by recycle from the settler to the mixer of some of the aqueous phase.

*Figure 1. Solvent extraction process.*

### Extraction

The Kennecott Cuprion Process was a reducing ammonia carbonate leach to dissolve manganese nodules. Copper, as Cu(I), reduced the tetravalent manganese oxide of the nodule. Copper, nickel and cobalt were dissolved as divalent ammines. Mn(II) precipitated as manganese carbonate. The Co(II) ion was air oxidized to Co(III) that was known to extract little or slowly. The ammonia concentration was a key parameter to the liquid ion exchange process. Some of the ammonia extracted. Extraction consisted of three stages, each with 3 minutes contact time and  $1.3 \text{ m}^3/\text{h}/\text{m}^2$  settler flux.

### Ammonia Stripping

Ammonia was stripped with two stages of basic  $1 \text{ M } \text{NH}_4\text{CO}_3$  solution. This ammonia was then recovered by distillation. Contact time was 3.75 min and settler flux was  $1.0 \text{ m}^3/\text{h}/\text{m}^2$ . Ammonia left on the organic was stripped with two stages of pH 2  $\text{H}_2\text{SO}_4$  solution. Contact time was 3 minutes and settler flux was  $1.3 \text{ m}^3/\text{h}/\text{m}^2$ . A trace of ammonia left on the organic is stripped with nickel and leads to the accumulation of nickel ammonium sulfate, often a contaminant in nickel extractive metallurgy.

### Nickel Stripping

Nickel was produced by electrowinning. Semi-batch nickel electrowinning was operated in parallel to the pilot plant to remove the nickel from the nickel concentrate solution and to provide a nickel acid electrolyte to drive nickel stripping. Nickel was stripped in preference to copper by controlling the nickel concentrate between pH 2.9 to 3.0. The pH controlled the flow of the nickel acid electrolyte to nickel stripping. Contact time was 3 minutes in each of six stages. The approach equilibrium is slow, relative to copper stripping. A Ni:Cu ratio of about 25,000:1 was achieved while stripping 98.8% of the nickel. Interstage samples showed three stages should be adequate.

### Copper Stripping

The copper-loaded organic containing 0.04 g/l Ni passed to two copper stripping stages with contact times of 3.75 minutes and specific settler flux of  $1.0 \text{ m}^3/\text{h}/\text{m}^2$ . Copper was produced by electrowinning. Semi-batch copper electrowinning was operated in parallel to the pilot

plant to remove copper from the copper concentrate and to provide a copper acid concentrate to drive copper stripping. A Cu:Ni ratio of about 75:1 was achieved while stripping > 99.9% of the copper which had been extracted in a particular cycle or organic.

## RESULTS

Table 1 summarizes the process performance during the pilot plant operation.

*Table 1. Pilot-plant steady-state profile.*

	Extraction				Basic ammonia strip

### Mass Balance

With few exceptions, flows throughout the LIX® plant were held constant for the entire 20-day run. The flows were measured by volumetric calibration and were maintained by positive displacement pump with hourly rotameter checks. Metal concentrations were obtained by atomic absorption. In some cases, such as the cobalt on the barren organic, steady state was not achieved. Values for the nickel stripping were taken from the last two days of the run because they were closest to the run plan. Most of the mass balances were within 1%, reflecting careful planning of the operation and close attention by the operators. Only a few of the calculated values require further comment.

### Ammonia mass balance

The results depend upon which analysis is trusted and if entrainment is considered. For example, the ammonia loss from the raffinate (2.16 g/min) is compared to the calculated ammonia gain by the organic (1.86 g/min) showing a 13.9% loss. The loss would be even larger if the ammonia analysis of the loaded organic were used directly. Instead, 2.49 g/l was calculated based upon the ammonia transferred to the basic NH<sub>3</sub> strip. Alternatively, the organic analysis could have been retained and the excess ammonia deposited in the aqueous basic ammonia strip solution could have been attributed to entrainment. However, there was no recycle of this basic solution making it difficult to estimate entrainment based on a tracer element build-up. Therefore, no entrainment was assumed. The NH<sub>3</sub> entering nickel strip is off balance 11.8% based upon accumulation of ammonia in the nickel strip solution. This is equivalent to an acidic ammonia strip organic effluent of 0.01 g/l NH<sub>3</sub> as compared to the reported 0.005 g/l. Entrainment seems likely but could not be estimated because the acidic strip solution contained no element useful as a tracer. Ammonia absorption from the air was considered by assuming the absorption for the six stages of

nickel strip solution could be at the most three times the ammonia accumulation in the more acid two-stage copper system. Such an assumption will not account for the imbalance and seems unlikely because the mixers and settlers were covered.

#### **Nickel mass balance in copper stripping**

The mass balance on the nickel entering the copper stripping unit has been forced to balance by adjusting the nickel concentration of the organic from 0.026 g/t to 0.04 g/t Ni. This value is based on the nickel accumulation in the copper electrolyte. Entrainment was estimated to be insignificant based on the sodium accumulation in the copper strip electrolyte.

#### **Cobalt mass balance over-all**

A small fraction of the cobalt (6 of 200 mg/l) extracted from the pregnant liquor and accumulated on the organic. The barren organic cobalt loading increased from 24 to 76 mg/l over the 20 day run. The reductive Cuprion leaching process leached cobalt in a cobaltous ammine state. We did not investigate whether the cobalt extraction was due to the rapid extraction of some remaining cobaltous ammine or due to slow extraction of cobaltic ammine. The stability of cobalt on the organic is probably due to the cobaltic-LIX® compound whether directly extracted or formed by oxidation of the organic phase as it passes through the system. Further study is needed to deal with this issue. 65 g cobalt was extracted over the 20-day run; 40 g accumulated on the barren organic; 11.5 g deposited as nickel cathode and 4.5 g deposited as copper cathode. This result means a cobaltic removal step needs to be found and tested [2]. It is expected to include: reduction of cobaltic complex on a slip stream of barren organic, followed by cobalt stripping and return of the cleaned organic to the barren organic.

#### **Trace Element Analysis**

The results for the trace element analysis are shown in Table 2.

*Table 2. Trace elements balance.  
Total amount transferred during 20 day pilot plant run (g).*

Metal	Extraction circuit	Strip circuit				
		Basic strip	Acidic strip	Nickel strip	Copper strip	Other
Co	65	0	3	4.5	4.5	4.0*
Mn	828	0	31	770	16.2	
Zn				3.1		
Fe	31	0	0	0	30	
Pb	0					
Mo	0					
Tl	83	43	43	7	0	
B	-560			-128		293*

\* Accumulated on barren organic phase

\*\* Based on a later set of analyses

\*\*\* Stripped from loaded organic: Analyses suspect.

#### **Thallium**

Mass spectrophotometry revealed that significant amounts of thallium leached from manganese nodules and was extracted into the SX circuit. All of the thallium (7 mg/l) in the pregnant liquor extracted, but only a little more than half (4.6 mg/l) could be accounted for. 1.3 mg/l and 2.8 mg/l, stripped in the basic and acidic NH<sub>3</sub> strips. About 0.5 mg/l was found in the nickel concentrate electrolyte and it all deposited on the nickel cathode. The thallium was unexpected so little analysis was done. The results suggest that thallium can be stripped in the acidic ammonia circuit and removed there. We suspect the thallium in the nickel circuit is due to entrainment of the ammonia strip solution in the loaded organic and carryover into the nickel electrolyte.

### **Boron**

Boric acid is typically used in nickel electrowinning for cathode control. Some boron extracted from the nickel electrolyte. The mass balance was not good, but the evidence indicated that more than 200 g B left the nickel circuit in the raffinate. The copper circuit also contained 0.6 g B at the end of the run but it is suspected this is due to entrainment.

### **Manganese**

A small amount of manganese was present in the pregnant liquor and was completely extracted at the rate of .030 g/min. Most of this manganese was recovered in nickel stripping (0.028 g/min) based on daily electrolyte analysis. About 0.002 g/min accumulated in the acidic ammonia strip based upon the total accumulation during the run. An even smaller amount (0.0006 g/min) reported to copper stripping, based on daily electrolyte analysis. The manganese mass balance thus shows 0.030 g/min extracted and 0.031 g/min stripped. The manganese stripped in the nickel circuit subsequently precipitates at the anode and will be an issue there.

### **Iron**

The pregnant liquor contained about 0.0025 g/l Fe that extracted and accumulated in copper strip during the run. The total iron extracted, 31 g, is in good agreement with that accumulated in the copper strip circuit. The iron would probably not be a problem in the operation because the nickel bleed from the copper circuit would limit the accumulation.

### **Zinc**

The zinc content of the pregnant liquor increased from 0.15 g/l to 0.18 g/l during the 20-day run. Zinc extraction increased with zinc concentration. Only a small amount of the zinc was extracted so that rather than a mass balance over the entire LIX section, only the increment in the nickel strip circuit, 0.001 g/l, was detectable. This increment is equivalent to a cathode content of about 40 mg/l that is in good agreement with the cathode analysis. The first cathode was 43 mg/l Zn and the second cathode 50 mg/l. No accumulation of zinc was noted in the acidic ammonia strip. Zinc extraction is probably sensitive to the extraction conditions and bears watching in future evaluation runs.

### **Molybdenum**

Molybdenum concentration of the pregnant liquor increased throughout the pilot plant run, but none was extracted because it is present an anion.

### **Crud**

Crud accumulated at the interface and was measured and sampled at the end of the run. All crud samples represent the accumulation from all pilot plant runs. Attempts to analyze the crud by mass spectrometer and x-ray fluorescence failed. The total crud was not enough to affect the mass balance of the major components. Atomic absorption analysis for Cu, Ni, Co indicated that the sum of these metals constituted about 0.5 wt % of the various cruds.

### **Interstage Equilibrium**

One goal of the pilot plant run was to obtain interstage equilibrium data. Samples of all interstage streams were taken at least once and analyzed. Then the samples of streams exiting a stage were contacted together with the proper O/A ratio for 30 minutes (to obtain equilibrium), separated, and analyzed again. The measurement then indicates how close to equilibrium any particular stage operated. The results are provided in Table 3 based on the organic analysis. Some impossible values of greater than 100% are tabulated, but these were obtained in stages where only a small amount of the mass transfer took place. The efficiency can be based on organic analysis, aqueous analysis, or the position of the operating point relative to the equilibrium line. All methods should be equivalent, but due to analytical and sampling problems, differences will exist. The efficiencies are better when based on the organic analysis than when based on the aqueous. This is evidently due to erroneous analytical results for some of the values, but a systematic error is not evident. The

following considerations were made to identify the source of the problem but were unsuccessful. Entrainment, if it were a serious problem, should decrease the organic based efficiencies in the stripping sections as the aqueous stream contains more than 10 times as much metal as the organic. An improper duplication of the O/A ratio would be detectable from the ratio of the incremental mass transfer to each phase during the equilibrium shakeout. There is scatter in the data, but the values do not indicate a consistent error. Usually each Interstage stream was sampled twice, once during the run and once at the end of the run. Only one stage was sampled at a time to insure that samples were not distorted because of upsets in adjacent stages. Samples were withdrawn directly from the settler with a 50-ml pipette and placed directly in screw cap glass bottles. Some samples were accidentally broken after the first analysis so an equilibrium shakeup was not possible. In these cases the equilibrium value was determined by contacting the two feed streams to that stage in the appropriate A/O ratio or a sample from another time was used.

*Table 3. Interstage equilibrium.*

Operation	Stage	Approach to equilibrium (%)	Transferred in stage (%)	Operation	Stage	Approach to equilibrium (%)	Transferred in stage (%)
Extraction	1	<b>Ni/Cu</b> 90/100	<b>Ni/Cu</b> 34/98	Nickel strip	1	<b>Ni</b> 150	<b>Ni</b> 0.9
	2	93.5/100	58/0.9		2	106	20
	3	108/100	8.3/0.9		3	59	3/8
					4	71	30
					5	86	10
					6	58	0.5
Basic NH <sub>3</sub> strip	1	<b>NH<sub>3</sub></b> 98.3	<b>NH<sub>3</sub></b> 92.5	Copper strip	1	<b>Cu</b> 92	<b>Cu</b> 85
	2		7.7		2	86.7	13
Acid NH <sub>3</sub> strip	1	91.5	98				
	2	31	1.9				

### ***Extraction***

Nearly all (98%) of the copper extraction occurs in the one stage, but some nickel extraction occurs in all three stages; 34%, 58%, and 8.3% respectively. It may be possible to shorten the contact time and this should be evaluated.

### ***Ammonia stripping***

Most of the mass transfer occurs in the first stage in both the basic and acidic strip sections. The efficiency is over 90% in those stages. Elimination of the second stage basic strip should be considered. It is considered essential to lower the NH<sub>3</sub> content organic as low as possible because this concentration determines the size of the bleed stream on the nickel electrolyte. The calculated efficiency of the second stage is low probably because of entrainment of the aqueous stream that contains 27 g/l NH<sub>3</sub>. Nearly half of the analyzed organic ammonia is entrained judging from analysis after deentrainment.

### ***Nickel stripping***

Most of the mass transfer takes place in the middle stages. This is because the mass transfer is pinched on both ends. In the first stages there is almost no hydrogen ion left in the aqueous phase to transfer to the organic phase. In the last stages there is very little nickel left in the organic to transfer into the aqueous. Stage efficiencies are low in the main mass transfer stages. This is interpreted as evidence that more contact time is needed in the mixing stage. In the laboratory equilibrium studies, it was evident that the nickel strip needs considerably longer contact times. The necessary contact time varied with the O/A ratio, but significant mass transfer occurred for up to 12 minutes. The first stage in the nickel strip operation may be better viewed as a part of the control system as opposed to a mass transfer stage. It is in the first stage where the copper loaded onto the aqueous is squeezed back onto the organic and the copper to nickel ratio in the nickel strip solution is determined.

The McCabe Thiele stage calculation indicates only two equilibrium stages of nickel stripping are necessary. The nickel strip operation should be simulated using three stages with variable minutes contact time in each stage.

### **Copper stripping**

85% of the copper stripping mass transfer occurs in the first stage with a 92% approach to equilibrium based on the organic analysis. The second stage is nearly as efficient in completing the mass transfer. Residual copper is recycled in the barren organic and is not lost. The copper strip staging and contact time seem to be close to optimum.

## **CONCLUSIONS AND RECOMMENDATIONS**

1. Greater than 99.9% extraction of copper and nickel was achieved.
2. Critical nickel copper separation was achieved by means of a pH control process with a Ni to Cu transfer ratio of greater than 25,000 to 1.
3. Cobalt extraction did occur, resulting in accumulation of 0.076 g/l Co in the organic phase.
4. Approach to equilibrium was generally better than 90% except in nickel stripping, where it was much less.
5. The quantitative behavior of several trace elements (Fe, Pb, Zn, Mn, Mo, Cd, B, Ti, and Zr) was measured.
6. The mass balance closed to less than 1% for copper and nickel.
7. The fundamentals of cobalt extraction and stripping should be studied and a method devised to deal with cobalt accumulation.
8. Nickel stripping should be studied with a goal of reducing the number of stages to as few as three.

Processes using solvent extraction from ammonia liquor have since started up [3].

## **ACKNOWLEDGEMENTS**

Many individuals contributed to the effort, but only the leaders will be acknowledged here: Dr. J. Agarwal (Ledgemont Laboratory Development Division Director), Dr. N. Beecher (Manganese Nodule Team Manager), and Dr. H. Barner, Dr. R. Kust, and Mr. D. Davies who headed the engineering, chemistry and pilot plant teams. Mr. R. Skarbo and Mr. D. Natwig did most of the solvent extraction process development and piloting. I had the good fortune to arrive in time to help run the pilot plant and to write the report on the solvent extraction results.

# POSSIBLE APPLICATION OF OFFSHORE OIL & GAS PHASE SEPARATION TECHNOLOGY TO HYDROMETALLURGICAL SOLVENT EXTRACTION

David Stanbridge and John Sullivan\*

CDS Engineering, Arnhem, The Netherlands

\*J. D. Sullivan & Associates, Perth, Australia

This paper explores the potential for extending high efficiency separator design as applied in the oil and gas industry to improve the equivalent processes within minerals processing. Test cases from both Oil and Gas and Hydrometallurgy applications will be compared to illustrate some of the weaknesses of current minerals processing designs. Computational Fluid Dynamics (CFD) techniques have been used to model both applications. The CFD approach used in this paper was presented at the 1999 World CFD conference in Melbourne.

There are many offshore oil and gas applications requiring very efficient liquid from liquid separation in order to meet strict environmental limitations. These applications involve both the reduction of water in the hydrocarbon phase and the process of reducing the hydrocarbon content within the water prior to the disposal of it to sea. In these disposal applications an entrainment level below 40 ppm is required.

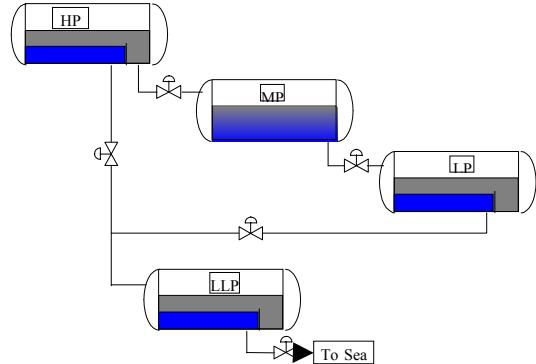

## INTRODUCTION

CFD techniques have been used widely within the oil and gas market to troubleshoot under performing processes/equipment. One of the specialised areas in which CDS Engineering are involved is that of equipment used for both liquid from gas and liquid from liquid separation.

This paper outlines the modifications to main line separation equipment that led to a substantial reduction in the hydrocarbon within the water phase. A comparison will then be drawn between this process and a settler tank within a copper production circuit in order to show the savings that could be made if a similar oil and gas market approach was adopted.

## BACKGROUND TO OFFSHORE PROBLEM

The offshore application that is to be considered is summarised in Figure 1. The system is typical of an offshore oil production application with 3 stages of pressure let down. Within these systems it is then also general for the HP and LP separators to be 3 phase, that is separating the oil, water and gas. The water streams from these separators can then be treated with further equipment in order to meet the environmental constraints prior to disposal to the sea. Currently this limit in the North Sea is 40 mg/l.

*Figure 1. Typical offshore water processing scheme.*

For the actual system covered by this paper this environmental constraint was not being met without further treatment of the water. It was thus decided to see if something could be done to better the performance. For this system the main loading to the water treatment facility came from the HP Separator with typical figures in the range 300-950 mg/l oil in water entrainment. In order to find the causes of this poor performance a three-dimensional CFD simulation of the liquid section of the vessel was carried out; the results of which are presented below.

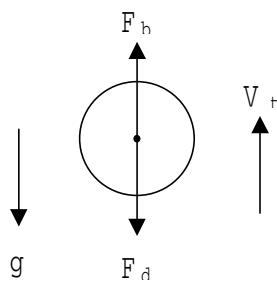

### FINDINGS FROM THE CFD SIMULATION

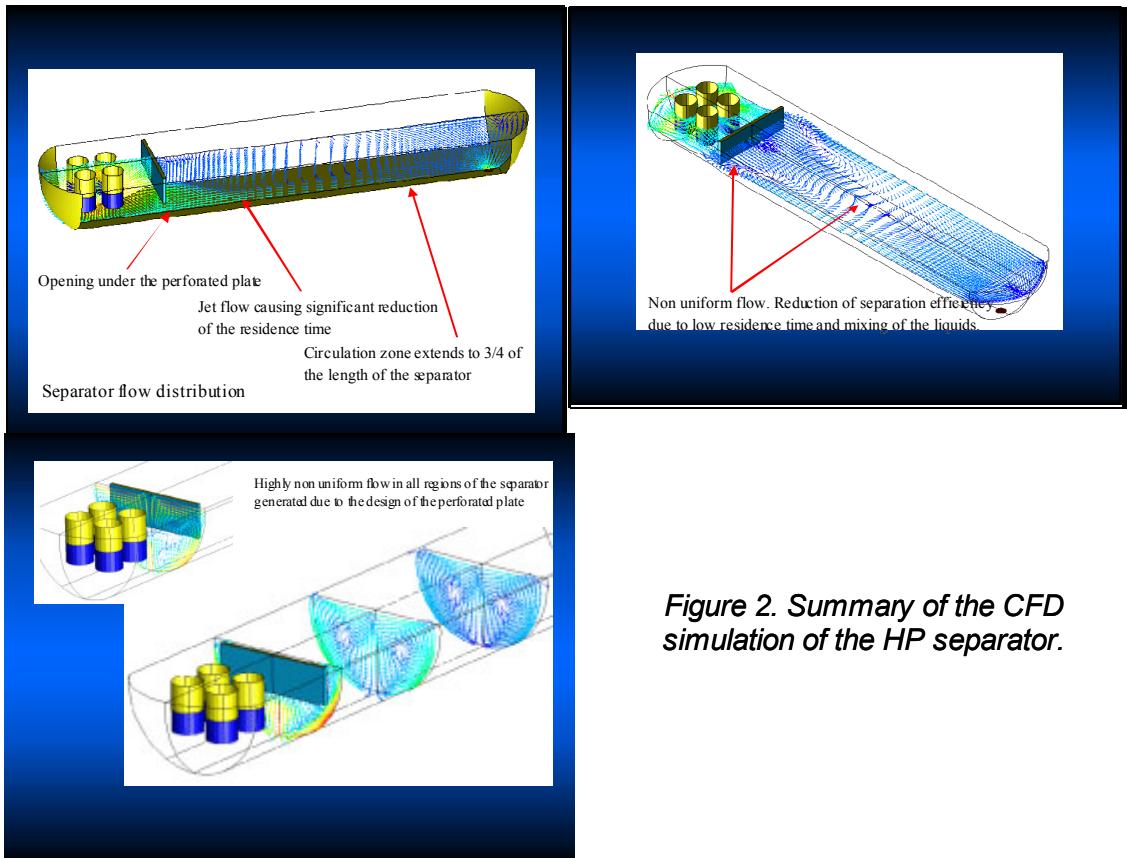

Figure 2 summarises the results obtained from the three-dimensional CFD model. In summary, the vessel had a cluster of four inlet cyclones followed by a perforated distribution baffle. However, the perforated plate did not extend fully to the bottom of the vessel and so an even distribution was not found down stream of it. It is easy to see that with the flow distribution shown Figure 2 optimal conditions for separation have not been set up and therefore better performance should be achievable.

In order to improve the performance of the separator then the jet of liquid flowing inside of the vessel needs to be removed. In this way the theoretical residence of the fluids will increase thereby maximising the droplet separation within the vessel. Also by removing the jet from the vessel the re-circulation will also disappear that again contributes to an increased residence time of the fluids.

### Effect of Increased Residence Time

Reviewing the equations governing the removal of a dispersed phase from a continuous one can see the benefit of increasing the residence time of the fluid. Ignoring the effects of turbulence and surface tension the forces governing the gravity settling of a droplet are shown in the diagram below. The directions of  $F_b$  and  $F_d$  relate to whether the droplet is rising or falling. However when determining if a droplet can be separated it is usual only to find the terminal velocity of the droplet. This being the point at which  $F_b = F_d$  where steady state conditions exist.

**Figure 2. Summary of the CFD simulation of the HP separator.**

$$F_b = \frac{M_d |(\rho_c - \rho_d)| g}{\rho_d} \quad (1)$$

$$F_d = \frac{1}{2} C' \rho_c V_t^2 A_d \quad (2)$$

If the droplet is assumed to be a solid sphere then the drag coefficient can be determined from the Reynolds number. Equating the above gives:

$$V_t = \sqrt{\frac{2gM_d |(\rho_c - \rho_d)|}{\rho_c \rho_d A_d C'}} \quad (3)$$

Or in terms of droplet diameter:

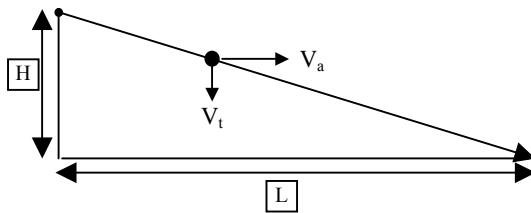

$$V_t = \sqrt{\frac{4gD_d |(\rho_c - \rho_d)|}{3\rho_c C'}} \quad (4)$$

Rearranging to determine the droplet diameter gives

$$D_d = \frac{3\rho_c C' V_t^2}{4g |(\rho_c - \rho_d)|} \quad (5)$$

For a vessel of a given length the minimum available  $V_t$  is determined by the following equation assuming that there is no slip between the continuous and dispersed phase:

$$V_t = \frac{HV_a}{L} \quad (6)$$

The minimum available  $V_t$  enables the calculation of the minimum droplet size that can be separated. Assuming that the Reynolds number of the droplet is less than 1 then Stokes Law gives the following:

$$C' = \frac{24}{Re} \quad (7)$$

Combining equations (5), (6) and (7) leads to the following relationship:

$$D_d = \sqrt{\frac{0.018\mu_c HV_a}{gL(\rho_c - \rho_d)}} \quad (8)$$

Therefore assuming that all parameters in the RH side of equation (8) are the same other than  $V_a$  then  $D_d = k\sqrt{V_a}$ . So if a liquid jet has a velocity 10 times higher than that of the theoretically attainable velocity then the droplet size removed will be approximately 3.2 times as large.

### Modifications made to the Vessel

In order to remove the jet flow from the liquid section the perforated plate was extended to the bottom of the vessel. However due to the location of the liquids entering the vessel, at the bottom of the inlet cyclones, the pressure drop over the perforated plate also had to be increased to ensure that an even distribution was achieved.

With an even flow distribution, the next consideration was to determine the droplet size that can be separated within the vessel. As shown in equation (8) above the main parameters that are changeable to achieve a specified droplet removal are the separation height H, the separation length L and  $V_a$ , the axial velocity. However, for this vessel all of these parameters were set by the existing design. Although the performance would have improved just by the amendments to the perforated distribution baffle it was decided to maximise the achievable separation.

Since a better degree of separation was required than could be given by the existing design further internals were needed within the vessel. These took the form of parallel plates. As

shown in equation (8),  $D_d = k\sqrt{\frac{H}{L}}$ . So if the ratio H/L is reduced then so is the droplet size

removed within the vessel. For the existing vessel H/L was in the order of 0.08. With parallel plates of 10 mm spacing and a length of 2000 mm H/L becomes 0.005 thus providing a 4 times reduction in the droplet size removed. Figure 3 shows the arrangement of these parallel plates.

### Results after the Modification

After the new equipment had been fitted into the separator results typically in the range 18-25 mg/l oil in water entrainment. As can be clearly seen these results show a considerable improvement compared to the original design. This led to the disposal of the water directly to sea, without further treatment.

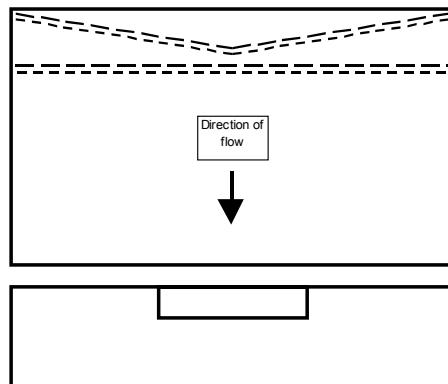

*Figure 3. Photograph of parallel plate arrangement.*

## APPLICATION TO HYDROMETALLURGY

One of the areas that we see can benefit from the approach described above is within the mixer / settler combinations of existing hydrometallurgy plants. In this part of the process substantial savings can be made if the carryover of both the organic and aqueous can be minimised from the settler. Generally, these settler tanks are large with a volume approximately 10 times higher than those installed offshore in order to achieve the same degree of separation. Unfortunately as shown above this large volume does not always guarantee adequate separation.

It should also be noted that within the combined mixer / settler process the mixer tank is providing a sufficiently fine droplet size distribution to ensure that a high degree of mass transfer occurs. The design of the settler therefore must ensure that the droplet size distribution generated within the mixer will be separated within the settler.

In order to see if such improvements are possible within Hydrometallurgy we shall review the design of the new Cu SX settler tanks at the WMC Olympic Dam location. The design comprises a large rectangular vessel with vertical mounted pickets at the inlet end of the tank to act as a distribution device. An outline sketch of this part of the vessel is given in Figure 4. The sketch is split in two parts, the upper half showing the top view of the vessel whilst the lower gives the relative location of the inlet from the upstream mixer. Towards the back of the vessel there is a bucket weir arrangement in order for the organic to leave the vessel followed by an overflow weir for the removal of the aqueous phase.

*Figure 4. Sketch of the settler inlet configuration.*

### CFD Analysis of the Settler Vessel

As this vessel is essentially a two-phase separator then a two-phase CFD model is preferred allowing for the flow of both the organic and aqueous liquids. However since little is known regarding the flow in these settler vessels a single-phase model will initially be solved in order to see the general flow patterns that are created within the vessel. After this stage then a strategy shall be developed in order to model the vessel with two liquid phases, if necessary.

In order to investigate this vessel in detail a three-dimensional model has been set up using Gambit. The solution itself will be found using the Fluent 5 CFD code. It should be noted that only one half of the vessel has been modelled since the central vertical axis can be taken as a symmetry plane. The whole model is shown in Figure 5. The grey areas depict the wall of the vessel, the inlet from the upstream mixer is shown in blue whilst the symmetry is in yellow. What is not clear in the above picture is that each individual picket has been modelled. In this way a very accurate representation of the inlet flow distribution can be achieved within the model, something that is beneficial if any optimisations are to be performed. A close up of the pickets is shown in Figure 6.

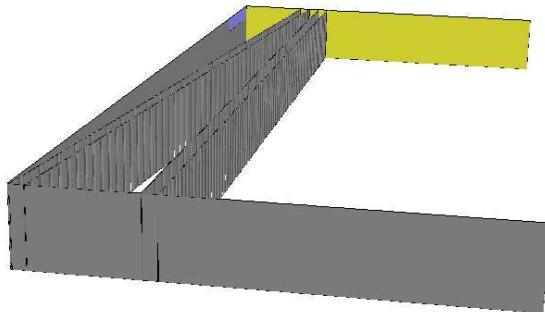

Figure 5. Picture of the settler model generated within Gambit.

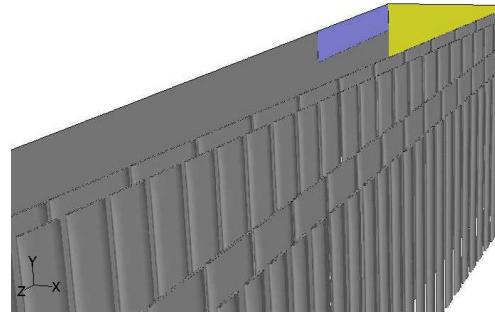

Figure 6. Close up of the pickets clearly showing that each was modelled individually.

### Findings from the CFD Simulation of the Settler Vessel

The result from the simulation shows that the flow in the vessel is not distributed well. What is seen at the inlet is that the flow enters the vessel, strikes the pickets opposite and subsequently starts rotating (Figure 7). Although the pickets then show a distributing effect the overall effect is not optimal with the simulation showing a velocity range of  $-0.93 \text{ m/s}$  to  $1.0 \text{ m/s}$  in the flow direction.

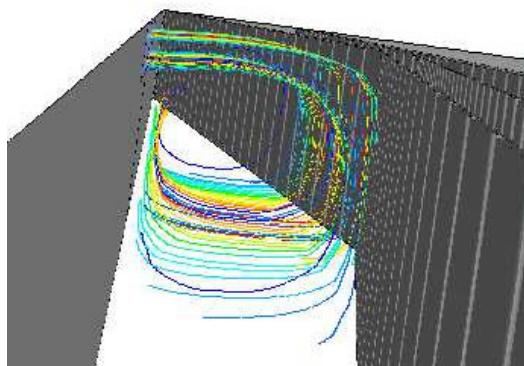

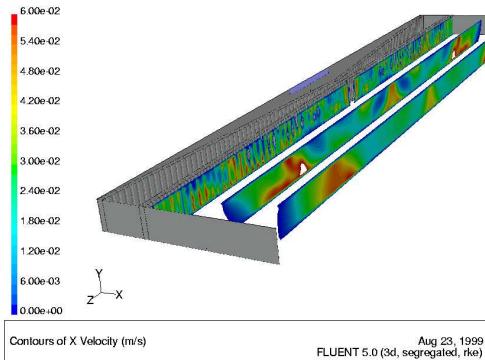

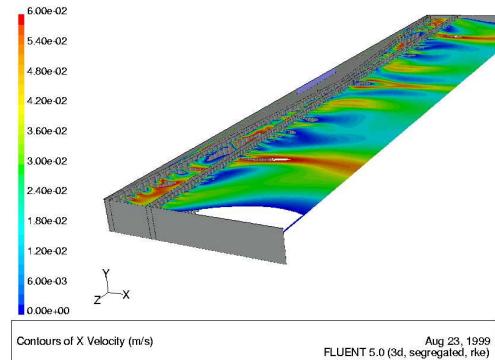

Figure 7. Picture showing the path lines of the fluid after it enters the vessel. A corkscrew motion is clearly seen.

Figures 8 to 10 show further distributions in the vessel. In all cases the velocity range has been restricted between 0 m/s to 0.06 m/s in the flow direction. Although these findings are true only of a single-phase flow we would expect that a similar profile would be found in a two-phase flow simulation of both the organic and aqueous phase. A single-phase simulation was performed initially both due to a quicker convergence and also if the flow distributes evenly for a single-phase it is generally found that it will do so also for a multiphase flow.

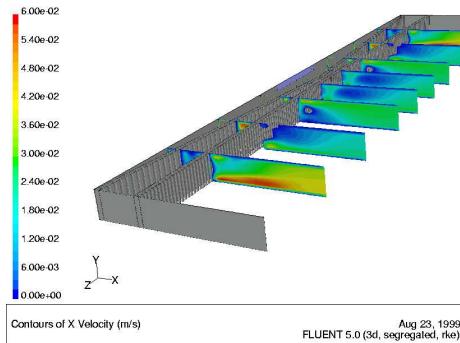

In order to prevent the maldistribution shown above then it will be necessary to firstly simulate the settler but with a two-phase flow. After this then a definitive upgrade strategy can be determined in order to solve the maldistribution and hence optimise the gravity separation from the settler.

*Figure 8. Picture showing the x velocity profile along the length of the vessel.*

*Figure 9. Picture showing the x velocity profile in the plane through the centre of the inlet.*

*Figure 10. Picture showing the x velocity profile along the length of the vessel.*

## CONCLUDING REMARKS

From this preliminary investigation it is seen that the flow distribution within the settler is not optimal. This means that increased separation should be achievable if a different arrangement to the currently installed picket arrangement is used. In order to quantify this further is will be necessary to perform a two-phase simulation of the settler and from there determine a suitable upgrade strategy.

## VIRTUES AND VICES OF REAGENTS FOR ACTINIDE PARTITIONING IN THE 21<sup>ST</sup> CENTURY

Kenneth L. Nash

Chemistry Division, Argonne National Laboratory, Argonne, Illinois, USA

The viability of nuclear power as an electricity generation technology in the 21<sup>st</sup> Century depends to a great degree on the development of efficient new separations technologies that conform to contemporary requirements for protection of the environment. Both the high throughput of solvent extraction and the more than 50 years of accumulated experience for processing of radioactive materials ideally qualify this science and technology for solving the problems of actinide and fission product isolation, recycle, and disposal. In this report, the continuing development of new reagents and processes for the isolation of actinides from nuclear fuels will be discussed with emphasis on how they respond to the demands for environmental stewardship in the 21<sup>st</sup> Century.

### INTRODUCTION

During the first half century of large-scale actinide production, recovery, and recycle, the combined influence of incomplete understanding of the chemistry of the byproducts of nuclear energy and the political imperatives of the arms race led to the creation of some daunting environmental cleanup challenges. In response, the past decade has seen a considerable emphasis, both scientific and financial, on developing new technologies to clean up the aftermath of the Cold War. These environmental insults, combined with continued difficulties in siting and licensing a high level waste repository, stand as significant obstacles to the continued development and application of nuclear energy in the U.S.

While the research establishment in the U. S. has expended considerable effort during the past decade on environment restoration, the rest of the world has continued to research techniques for actinide recycle. Some of this work is based on fundamental studies conducted at ANL on CMPO extractants and the TRUEX process during the 1980s and 1990s. Others have elected to develop alternatives for hydrometallurgical separations of actinides. Some new reagents (and classes of reagents) have been developed. A number of process flowsheets based on a variety of different extractant molecules (some new, some old) have been demonstrated [1]. In this report, selected characteristics of a variety of different classes of reagents designed for enhancing the efficiency of actinide separations by solvent extraction (and related methods) are discussed. The emphasis will be on highlighting the positive features of new reagents for actinide partitioning while simultaneously recognizing the limitations of the new compounds and their application. Coverage of the subject area will not attempt to be comprehensive but rather will focus on selected reagents and processes.

## EXTRACTANT MOLECULES

While the PUREX extractant, tributylphosphate (TBP), has provided exemplary performance for selective isolation and partitioning of Pu and U from dissolved spent fuel, it exhibits little ability to extract trivalent actinides (Am and Cm) from an acceptable aqueous solution. During the first 30 years or so of actinide processing, this was not considered a fault of the system, as the minor actinides (Np, Am, Cm) simply were routed to the waste. Unfortunately, the comparatively long radioactive lifetime of these elements and their radiotoxicity greatly complicates efforts to provide assurance that a geologic repository will adequately isolate high level radioactive wastes from the hydrosphere for a sufficient time to protect the biosphere (and thus the human food chain). Substantial research has been conducted over the past 20 years seeking to develop new extractants for isolation of the minor actinides.

The most extensively developed class of reagents for recycle and isolation of the minor actinides are the carbamoyl phosphonates and phosphine oxides [2], whose existence can be traced to the seminal work of Siddall in the mid-1960s [3]. Nearly 100 different derivatives of these bifunctional extractants have been prepared and characterized. The TRUEX extractant, octyl(phenyl)-N,N-diisobutylcarbamoylmethyl phosphine oxide (CMPO) is the most studied of these reagents. The positive features of CMPO-class reagents are their moderate affinity for trivalent actinides, comparatively flat acid dependencies for extraction of tri-, tetra-, and hexavalent actinides, adaptability to a variety of different acid media, and the extent of their process/pilot-scale demonstration. On the other hand, the reagents tend to be moderately expensive to synthesize, experience some limitations in their phase compatibility, and introduce phosphate into the waste stream. This latter feature is considered somewhat problematic at present because of the tendency of metal phosphates to form crystalline inclusion in radioactive waste glasses, thus decreasing their long-term stability. Continuing research on alternate waste forms for actinide isolation indicate the possible utility of phosphate glasses and crystalline ceramics [4], which could reduce the importance of this feature.

Two other organophosphorus extractant molecules have also received substantial interest during the past several years. To overcome the comparative expense of the CMPO-class extractants, Chinese researchers have developed a total actinide recovery system based on a trialkylphosphine oxide extractant (commercially available as Cyanex 923) [5]. The TRPO system can readily accommodate extraction of tri-, tetra-, and hexavalent actinide ions in a comparatively straight-forward flowsheet. The principal negative feature of this extraction system is the narrow range of nitric acid concentration in which the extraction of trivalent actinides is most efficient. This feature of TRPO reflects the high affinity of phosphine oxide extractant molecules for nitric acid, which compete with the actinide. The bifunctional extractant CMPO was designed to overcome this limitation. For recycle of actinides from dissolved spent fuel, the process flowsheet requires both dilution of feedstock (by a factor of 10) and denitration. Each of these requirements amplifies the volume of wastes created. Researchers at the Japan Atomic Energy Research Institute (JAERI) have demonstrated a total actinide recycle process based on di(isodecyl)phosphoric acid (DIDPA), an acidic extractant [6]. Among the current solvent extraction processes for actinide partitioning, this one is unique in that it incorporates into the basic separation scheme a reverse TALSPEAK separation for partitioning of trivalent actinides from lanthanides. Aside from the phosphate waste issue, this extraction system suffers the principle defect of requiring lower nitric acid concentrations than are typically produced during fuel dissolution, hence must include denitration as a first step. As was noted for the TRPO system, denitration can amplify the volume of wastes created during processing.

To accommodate a desire for waste volume reduction within a total actinide recycle fuel cycle, Musikas [7] initially proposed the CHON (carbon, hydrogen, nitrogen, oxygen) concept for extractant design. The idea is to only employ reagents containing these elements to minimize the amount of ash produced when the extractant is incinerated upon the conclusion of its useful life. Subsequent research has led to the development of a series of extractant molecules based on amides of carboxylic acids. Both mono- and diamide reagents have been synthesized and their extraction characteristics profiled. Presently, the most investigated reagent is N,N'-dimethyl-N,N'-dibutyltetradecyl malonamide, DMDBTDMA. This reagent extracts tri-, tetra-, and hexavalent actinides from nitric acid solutions more concentrated than 4 M into conventional (normal or branched alkane) diluents. Among the advantages of this class of reagents are the relatively innocuous nature of extractant degradation products and their "ash-free" incineration character. Drawbacks of the malonamides are the comparative complexity of the reagent (similar to CMPO's), and the somewhat narrow range of nitric acid concentrations from which trivalent actinides are extractable. Recent reports from Japan indicate some interesting variations in actinide selectivity for the tetraoctyl diamide of diglycolic acid, though this reagent has been subject to only laboratory-scale investigations [8].

In addition to these more mature extractant systems, research continues around the world on the development of new extractant systems for actinide partitioning. Dozol and co-workers [9] have initiated studies on the development of actinide-specific extractants based on calixarenes. These molecular-inclusion reagents can be functionalized to enhance their affinity for actinide metal ions. One possible drawback of these compounds is their comparatively large molecular size which may inhibit phase compatibility and thus limit solubility. They have the advantage of being synthesized in moderately high yields of relatively pure compounds from inexpensive starting materials. Another class of extractants that have been known for a number of years but not extensively investigated for their actinide separation efficiencies are the mono- and bis-phosphine oxides of pyridine-N-oxides synthesized by Paine and coworkers [10]. We have recently initiated a program at ANL to evaluate the actinide partitioning potential of this class of extractants. We have also examined the actinide extraction performance of dialkyl esters of diphosphonic acid chelating agents in various potential metal ion coordination geometries [11]. These extractant molecules exhibit high affinity for actinide ions in the important oxidation states, though they are typically too strong to be applied as the principal extractant in an actinide partitioning scheme. Another class of special-purpose "extractants" are the functionalized polyethylene-imine ultrafiltration polymers reported by Jarvinen and coworkers [12]. Applications of cation binding ultrafiltration polymers for the cleaning of aqueous waste streams has been demonstrated.

## AQUEOUS COMPLEXANTS

In hydrometallurgical separations of actinides, strong mineral acids (nitric, hydrochloric, sulfuric) are the most common media from which actinides are extracted. The respective electroneutral actinide complexes are carried into the extractant phase by solvating extractants like TBP. The electroneutral actinide complexes are not usually present in the aqueous solution. In operation of the PUREX process, oxalic and hydrofluoric acids have been employed as holdback reagents to prevent extraction of zirconium and molybdenum, which can be present at sufficiently high concentrations to interfere with actinide extraction. For solvent reconditioning prior to recycle, sodium carbonate is typically employed to remove traces of uranium that are not stripped by the dilute acid contact. A report on the development of a TRUEX flowsheet in Japan relies on the use of hydrazine oxalate and hydrazine carbonate for reductive stripping of TRUEX process solvent prior to recycle [13]. The TALSPEAK process for trivalent actinide-lanthanide separation relies on both lactic acid

and diethylenetriamine-N,N,N',N'',N''-pentaacetic acid (DTPA) as aqueous complexing agents to accomplish this difficult separation. DTPA has been proposed for actinide selective stripping of trivalent actinides in a CMPO-based extractant system (SETFICS) [14]. Other aminopolycarboxylic acids (HEDTA, EDTA, NTA) have been employed in various operations within the Department of Energy complex to enhance selectivity for some separations. This latter group of complexing agents have proven somewhat problematic, as they are moderately resistant to degradation (their presence is associated with the generation of H<sub>2</sub> in underground waste tanks at Hanford [15]) and have been associated with radionuclide mobility in the environment [16].

To respond to the need for actinide complexing agents in processing, we have characterized the actinide complexing characteristics of a series of derivatives of water-soluble diphosphonic acids ((X,Y)C(PO<sub>3</sub>H<sub>2</sub>)) [17]. These chelating agents exhibit exceptional affinity for actinide cations (even in moderately acidic media) making them particularly useful as potential stripping or decontaminating reagents for actinide processing. By altering the composition of the X and Y substituents on the methylene backbone, we have demonstrated that these reagents can be made to readily decompose (called Thermally Unstable Complexants or TUCS) producing H<sub>2</sub>O, CO<sub>2</sub>, and H<sub>3</sub>PO<sub>4</sub> as byproducts. For actinide processing, this can be expected to lead to generation of an actinide phosphate solid that could in principle be incorporated into an appropriate waste form. Though these reagents do not conform to the CHON principle of complexant design, their actinide complexing ability in strong acid qualifies them as uniquely capable reagents for stripping of extractant solutions prior to their recycle in a process.

## APPROACHES TO ACTINIDE OXIDATION STATE CONTROL

With most classes of extractants employed for actinide partitioning, tetra- and hexavalent actinide ions are considerably more strongly extracted than the trivalent actinides which in turn are extracted much more strongly than the pentavalent actinide ions. For acidic extractants like DIDPA, An(IV) is most strongly extracted, while for solvating extractants like TBP the hexavalent nitrate complexes are most strongly partitioned to the organic phase under most process conditions. The moderate differences in extractability of the oxidation states can be used to selectively partition actinide ions from a loaded extractant solution. In the PUREX process, as in most actinide recycle streams, U(VI) and Pu(IV) are co-extracted away from most fission products. Pu is selectively stripped by introducing a reagent that takes Pu(IV) to the considerably less extractable trivalent state, which reports to the aqueous medium. In PUREX, either Fe(II) or U(IV) are used for the reduction. Efficient separation of U from Pu is attained in practice.

In contrast to plutonium, neptunium oxidation state control at process scale has proven moderately difficult. Neptunium is typically found in dissolved fuel initially in the hexavalent oxidation state, which is readily extractable by typical reagents. However, Np(VI) is a moderately strong oxidant, and so readily reduced during processing to the poorly extracted pentavalent oxidation state, which can disproportionate in acidic aqueous solutions producing Np(IV) and Np(VI). As a result neptunium is often observed to distribute between phases in a somewhat irregular fashion. In a combined PUREX-TRUEX flowsheet, researchers in India have introduced K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub> to improve consistency in Np extraction then stripped Np and Pu together using H<sub>2</sub>O<sub>2</sub> and ascorbic acid for reduction [18]. In this process, the separation of Np and Pu is accomplished using extraction chromatography on a CMPO-based resin. In the TRPO process, Np is electroreduced to the tetravalent state and subsequently stripped with oxalic acid [5].

Two water-soluble organic reagents have been tested for Np oxidation state control in recent years. Taylor *et al.* [19] have reported that the combined complexation and redox action of formo- and acetohydroxamic acids ( $\text{HC}=\text{O}(\text{NHOH})$ ,  $\text{H}_3\text{CC}=\text{O}(\text{NHOH})$ ) can effectively assist in the control of neptunium partitioning in PUREX (and presumably in other nitric acid based) processing. Butyraldehydes have been known for some time to have an impact on actinide oxidation state control in PUREX processing. A more recent report from Japan has revealed a difference in redox chemistry for *n*-butyl and isobutyl derivatives [20].

## TRIVALENT ACTINIDE-LANTHANIDE SEPARATIONS REAGENTS

Within the broad concept of actinide recycle, there is not universal agreement on the desirability of isolating and transmuting the trivalent transplutonium actinides. The argument in favor of transmutation is that it will reduce the long-term radiotoxicity of the wastes from spent fuel. The principal argument against transmutation is the difficulty of efficiently separating trivalent lanthanides and actinides. The several examples of successful group separations (chloride based ion exchange or alkylamine solvent extraction, TALSPEAK) succeed based on the slight enhancement in covalency in the bonding of trivalent actinides relative to lanthanides [21]. Such effects are not manifested in oxygen-donor extractant systems, presumably because of the strongly electrostatic nature of their bonding. In these “reference” extraction systems, group separation factors average about 10.

During the past two decades of research on actinide-lanthanide separations, new examples of extraction systems have been reported in which higher group separation factors are observed. Ensor *et al.* [22] reported Am/Eu separation factors of about 100 for the synergistic extraction of these metal ions using a combination of 4-benzoyl-2,4-dihydro-5-methyl-2-phenyl-3H-pyrazol-3-thione (BMPPT) and 4,7-diphenyl-1,10-phenanthroline (DPPHEN), neither of which reagents extracts either of these metal ions significantly separately. Musikas separately reported separation factors of nearly 100 for the thiolated analog of HDEHP, though the hydrolytic instability of the extractant compromised the utility of the extraction system [7]. While these extraction systems have not received substantial attention due to reagent instability or low solubility, the importance of the separations target has precipitated a moderate amount of research seeking suitable materials for this inherently difficult separation.

The Musikas report was the first to enunciate the CHON principle, introducing the polyaza ligand trimethylpyridyltriazine (TPTZ) as a potential usable extractant that in principle yielded no ash upon incineration. In the final analysis, TPTZ proved too hydrophilic to be truly useful as an actinide/lanthanide separations reagent. A European consortium has conducted additional research on the efficacy of polyaza ligands as extractants. Kolarik *et al.* have identified the compound 2,6-di-(5,6,-dipropyl-1,2,4-triazin-3-yl)pyridines (DPTP) as a reagent providing Am/Eu separation factors of 100-120 in extraction from an aqueous medium of 1.9 M  $\text{HNO}_3/\text{NH}_4\text{NO}_3$  [23]. The *n*-propyl derivative self-associates (dimers and trimers) in a solution of branched alkanes with 2-ethyl-1-hexanol as a phase modifier. The extracted complexes have the stoichiometry  $\text{M}(\text{NO}_3)_3 \cdot \text{HNO}_3 \cdot 3\text{DPTP}$ . The extraction and separation efficiency is strongly dependent on the diluent. Jensen *et al.* have examined the complexation thermodynamics and structural details of complexes of trivalent lanthanide and actinide complexes with tetramethylpyridyl-N,N,N',N'-ethylene diamine (TPEN) [24]. This structural analog to EDTA forms hexadentate complexes with six metal-nitrogen bonds to both lanthanides and actinides. The actinide complex is 100-fold stronger than that of the lanthanide of comparable cation radius with a more exothermic complexation enthalpy, possibly indicating greater covalency in the actinide-nitrogen bonds. In both the DPTP and TPEN systems, the 6 M-N bonds can account for only 11-12 kJ/mol of enhanced selectivity, indicating that the separation is derived from a very subtle bonding difference between the lanthanides and actinides.

The largest trivalent actinide/lanthanide separation factors have been reported for systems based on dialkyldithiophosphinic acids. Zhu *et al.* [25] reported Am/Ln separation factors between  $2 \times 10^3$  and  $1 \times 10^4$  for the commercially available extractant Cyanex 301 (bis(2,4,4-trimethylpentyl)dithiophosphinic acid). The extractant must be rigorously purified from all acidic oxygenated impurities and the extraction reaction must be run from dilute acid media. Numerous derivatives of dialkyldithiophosphinic acid extractants have been prepared and evaluated, though to date few exceed the capabilities of Cyanex 301. The substitution of C-P for C-O-P bonds in the extractant greatly enhanced hydrolytic stability of the extractant (relative to the dialkyldithiophosphoric acids originally reported by Musikas. Recently completed research in our laboratories has apparently resolved some inconsistencies in the literature regarding extracted complex stoichiometries in extracted complexes [26].

## PHASE COMPATIBILITY, DILUENTS AND PHASE MODIFIERS

Because solvent extraction is fundamentally a mass transfer process, developing an understanding of the basic chemistry of metal complex formation and ligand design is in actuality only a small (but necessary) component of the overall picture. Even with appropriately designed and proven reagents, a solvent extraction separation can still fail if the solutes prove incompatible with the matrix or if the reagents prove incompatible with the mixing equipment. In hydrometallurgical processing of spent nuclear fuels, the most common media of choice are nitric acid (stainless steel is more-or-less inert toward HNO<sub>3</sub>) and low-volatility normal alkane solvents (e.g., kerosine). As extracted complexes and extracting reagents are often quite polar, maintaining these solutes in the non-polar organic solution can be a challenge, particularly at higher loading of solutes in the extractant phase. Maintaining phase compatibility in nuclear separations is particularly important, as it is possible to unintentionally assemble a critical mass of either <sup>239</sup>Pu or highly enriched uranium with potentially disastrous consequences.

Extractant molecules for such applications are usually designed to maintain good compatibility with the organic medium. Occasionally, the ideal metal ion coordination environment cannot be created in a geometry fully compatible with the diluent. In this case, polar phase modifiers are employed to assist in maintaining phase integrity. The most common phase modifiers employed in nuclear separations are TBP, long-chain alcohols (e.g., octanol), and trialkyl amines. Addition of phase modifiers can increase the capacity of the organic phase for the polar species being separated, but not without limits. Even with such additives, occasionally the organic phase will split, forming a "third" liquid phase. Though third phase formation has been studied for more than 40 years, laboratory investigations of the phenomenon have focused on identifying those characteristics that lead to phase splitting so that they can be avoided. Because of the variety of materials that can be made to undergo phase splitting, no universal description of third phases has emerged. Recent advances in analytical methodologies have created an opportunity to investigate the physical and chemical characteristics of this phenomenon in greater detail than was possible in prior studies. It is expected that a more complete understanding of the phenomenon will emerge from these ongoing studies [27,28].

## CONCLUSION - A VIEW TO THE FUTURE?

Under the potentially critical threat of global warming to modern society, nuclear power should be viewed as perhaps the most environmentally friendly technology for electricity production. However, the longevity of the radioactive wastes (more than  $10^5$  years at higher levels than that in natural uranium ore without processing and transmutation of actinides) and the absence of a clear disposal pathway that can be "guaranteed" to protect the environment

(atmosphere, hydrosphere, biosphere) stand in the way of this solution. Closing the loop on nuclear fuel and transmuting actinides and long-lived fission products using the proven technology of solvent extraction could improve the acceptability of this technology if we can learn to do it cleaner than we did during the past 50 years. The continuing development of new reagents and processes for their use, combined with new techniques for waste minimization, environment restoration, and waste form development could make important contributions toward this goal. Some of these new technologies have been described above. Others are found in the literature dedicated to environment cleanup and protection. There is also a major opportunity for computational science to contribute to both ligand/process design and to on-line monitoring of processes for improved efficiency. All that is required is to think somewhat outside of the box and apply the new ideas to solving the outstanding issues of hydrometallurgical separations. Opportunities abound for improved waste handling procedures.

## ACKNOWLEDGEMENT

The submitted manuscript has been created by the University of Chicago as Operator of Argonne National Laboratory ("Argonne") under contract No. W-31-109-ENG-38 with the U.S. Department of Energy. The U. S. Government retains for itself, and others acting on its behalf, a paid-up, non-exclusive, irrevocable worldwide license in said article to reproduce, prepare derivative works, distribute copies to the public, and perform publicly and display publicly, by or on behalf of the Government.

## UPDATE ON THE SCIENCE AND TECHNOLOGY OF TRIBUTYL PHOSPHATE

James D. Navratil

Department of Environmental Engineering and Science, Clemson University,  
Anderson, South Carolina, USA

Although tri-*n*-butyl phosphate (TBP) has a dominant position in solvent extraction applications in the nuclear industry, it is also an important reagent in many non-nuclear hydrometallurgical applications. Since the first work on TBP research was conducted as part of the U.S. Manhattan Project in 1944, numerous scientists and engineers in many countries have examined almost every aspect of TBP. Many of the results of these studies have been published in the open literature, but there has also been a great deal of useful knowledge about TBP whose availability is difficult to locate. To solve this problem, various authors over the last 55 years have reviewed parts of the science and/or technology of TBP, including a four-volume set of books containing a systematic, comprehensive, and critical account of all aspects of TBP. This paper provides a selected update on the science and technology of TBP since this set of books was published.

### INTRODUCTION

Since World War II, tri-*n*-butyl phosphate (TBP) has been the subject of continuous research and development. During this time a vast scientific literature has accumulated dealing with all aspects of TBP related to the science and technology of solvent extraction processes. Although most review articles on solvent extraction, which are quite numerous, devote considerable space to a description of the more common properties and reactions of TBP, there has been no single monograph until 1984 devoted solely to an extensive review of TBP. Between 1984 and 1991 CRC Press, Inc., Boca Raton, Florida, published a four-volume set of books containing a comprehensive account of all available data on the science and technology of TBP [1-4]. The purpose of these books was to bring together in an organized form as much as possible of the then-known accumulation of facts pertaining to the properties, reactions, and uses of TBP.

*Science and Technology of Tributyl Phosphate*, Volume I, reviews the fundamental chemistry of TBP (analysis, behavior in nuclear solvent extraction systems, physical properties, reactions with various inorganic reagents, and synthesis), diluents (types, properties and reactions of various organic compounds) and radiolysis of TBP. Volume II, published in 1987, gives a detailed account of TBP in hydrometallurgical process applications, miscellaneous non-nuclear industrial uses, and analytical applications. Volume III, published in 1990, is devoted to various aspects of nuclear applications: PUREX and THOREX processes, French experience in recovering plutonium from metallurgic scrap, and the development and application of computer codes to simulate PUREX process operations; miscellaneous nuclear applications are also covered in Volume III. Volume IV addresses the extraction of water and mineral and organic acids from aqueous media by TBP-diluent solutions.

This paper provides an update on the science and technology of TBP since this series of volumes was published; selected advances in the nuclear and non-nuclear applications of TBP for solvent extraction processes are highlighted. This review is dedicated to the late Professor A. Steven Kertes. Dr. Kertes was on the editorial board of the TBP books and served as a co-editor of Volume IV. The following quote is from his Foreword to Volume I: "The Editors should be congratulated for conceiving this project and for their success to recruit as contributing authors many top experts in the field, most of whom with many years of first-hand experience in basic and applied research involving this important extractant. I believe that the compact and authoritative chapters written by them will orient and stimulate chemists and technologists in many branches of research in the general field of solvent extraction [1]."

### NUCLEAR APPLICATIONS OF TBP

In the nuclear field, spent nuclear fuel reprocessing plants employ the PUREX process to separate plutonium and uranium from fission products as well as to purify the separated uranium and plutonium. PUREX (Plutonium Uranium Recovery by EXtraction) typically uses TBP in a hydrocarbon diluent. TBP is applied similarly, but much less widely, to the reprocessing of spent nuclear fuels containing thorium. Recovery of plutonium from nuclear weapons scrap materials has also utilized the PUREX process.

Oak Ridge National Laboratory (ORNL), faced with the problem of recovering uranium from wartime reprocessing plant wastes, initially developed the PUREX process. Several PUREX process flowsheets were investigated around 1950 at ORNL, with varying proportions of TBP to diluent. As a result of these investigations, 30% TBP-diluent flowsheets were operated at ORNL and in large plants at Savannah River from 1954 and at Hanford from 1956 [1-4].

In addition, there are many other applications of TBP in the nuclear industry including the production of nuclear-grade uranium from "yellow cake," the separation of neptunium and the separation of an actinide-lanthanide fraction from reprocessing wastes. Owing to its many uses, and also the stringent requirements of the nuclear industry, TBP has been thoroughly researched [1-4].

The first paper on the use of TBP, based on work performed in 1944 as part of the U.S. Manhattan Project, was published by Warf in 1949 [5]. At that time there were no citations in *Nuclear Science Abstracts* (NSA) under the heading "butyl phosphate." In 1961 there were over 210 entries under this heading in the indices of Volumes 11 to 15 of NSA. The replacement of NSA, the International Nuclear Information System (INIS), compiled and published by the International Atomic Energy Agency, has 252 and 245 entries under the heading of TBP for the last two respective decades, indicating a sustaining research and development interest in TBP.

Table 1 summarizes the various TBP subject areas found in the INIS citations from 1990 to the present. Since these citations came from INIS, they mainly relate to TBP science and technology in the nuclear field and related areas. The only significant review published in this period outlined the current status of the chemistry of nuclear fuel reprocessing [6].

*Table 1. Number of papers cited in INIS 1990-2000 by major subject area.*

Nuclear waste processing/partitioning	43
Purex solvent degradation/stability/clean up	28
Non-nuclear	27
General chemistry	27
Analytical applications	22
Miscellaneous	18
New diluents/solid supports	16
Purex development	15
Health and safety	10
General chemistry of TBP	6
Equipment	4
Analysis of TBP	3

Table 1 shows that the major area of TBP publication during the last decade involved high-level nuclear waste treatment and partitioning, *i.e.*, the separation of long-lived actinides from shorter life fission products. TBP has been utilized as a phase modifier in several new organic systems. Amines and bifunctional organophosphorous extractants, mixed with TBP, have mostly been reported [7,8]. The chemistry of these extractant systems has been studied for not only actinides, but also fission products including technetium and rhenium [9,10]. No further details on nuclear waste partitioning processes will be given here since they are extensively reviewed by Nash [8].

The second highest publication area noted in Table 1 deals with TBP solvent degradation/stability/cleanup [11-15]. Some of these studies were a result of safety concerns relating to TBP degradation products [16,17]. Several studies have been reported on third phase formation caused by saturation of plutonium species in the organic phase [18,19]. A noteworthy advance deals with the regeneration of PUREX solvent by vacuum distillation, developed and implemented in a French reprocessing plant [20].

Other work on Purex process improvements has involved new redox reagents for partitioning actinides [21]. An improved Purex process, Impurex, was reported based on the extraction of U(VI) and Pu(IV) from 5M nitric acid at elevated temperature (50C) [21]. Reports also appeared for processing highly burned fuel, better U/Th separation and neptunium separation [22-25]. Further, troublesome fission product decontamination continues to be studied, in particular zirconium, niobium and ruthenium; recent work showed that Zr(IV) present in the fuel solution causes extraction of technetium from the solution [26].

Alternative reagents continue to be tested to find an improved extractant for the PUREX process. Various amines and organophosphorous compounds have recently been tested but none have come close to matching all the excellent properties of TBP [7,27]. These favorable solvent properties include suitable extraction of Pu and U with good fission product decontamination, reasonable stability, good physical properties, and no requirement for salting agents other than nitric acid [1].

Another active area related to Purex process improvement has been diluent development and testing. Besides fluorinated solvents, supercritical carbon dioxide shows promise for selected applications [28-31]. Various solid supports have been utilized for both process development and analytical separations; the sorbents have employed various materials, such as commercial styrene divinyl benzene resins, inorganic materials, etc. [32]. Work on membranes as solvent supports continues to be reported [33].

Analytical applications in the nuclear area have included a variety of pre-analysis separation methods utilizing supported TBP. One report used reverse phase chromatography for uranium analysis [34]. New analysis methods for TBP and its degradation products have also been reported [35,36].

In this review, uranium was found to be the most common element studied in nuclear technology during the past decade, including recent work on improvements to processes for the recovery of uranium from ores [37]. Plant-scale use of TBP to purify crude uranium recovered from its ores began in the U.S. in 1953; similar uranium refineries based upon the use of TBP were also constructed in Canada and the U.K. in the early 1950s. Today, TBP extraction technology and processes continue to be applied worldwide for purification of crude uranium as well as thorium. The extraction of zirconium into TBP is also in use as a purification step in the production of high-purity zirconium metal from its ores.

### NON-NUCLEAR APPLICATIONS OF TBP

TBP first became available as a commercial product because of its use in the plastics industry as a plasticizer. TBP also has important industrial applications as an antioxidant, an antifoaming agent, a catalyst and a corrosion inhibitor. There are few operating plants designed for the use of TBP in the extraction of non-nuclear metals and other materials. Perhaps one of the main reasons for this is that TBP operates through a solvating mechanism of extraction, and, therefore extraction is highly dependent upon the ionic strength of the anion. Major process metallurgy flowsheets utilizing solvent extraction involve extraction from a sulfate medium. Very few plants have gone on-stream employing chloride or nitrate systems, even though TBP is an excellent reagent from aqueous chloride and nitrate media. Non-nuclear industrial-scale hydrometallurgical applications of TBP include its use in the preparation of individual rare earths, the separation of zirconium and hafnium, and the removal of iron from chloride liquors containing copper, nickel, and cobalt [1,3].

The extent of early non-nuclear research and development on TBP can be represented by citations in *Chemical Abstracts* (CA). The CA Decennial (1937 to 1946) Index (Volumes 31 to 40) lists 13 entries under the heading “(BuO)<sub>3</sub>PO”, none of which pertain to use of TBP in solvent extraction systems. By contrast, the CA subject index of Volumes 51 to 55, 1957 to 1961, contains almost 400 entries for TBP, two-thirds of them concerning solvent extraction applications. During the past decade there have been over 700 citations of TBP with almost 300 of them relating to separations science and technology.

The recovery and purification of scandium, yttrium, and lanthanides continue to be the most cited research area during the past 10 years [38,39]. During the TBP extraction of scandium from industrial HCl solutions containing aluminum and iron, the loaded TBP is stripped with 1 M HCl to provide 100% scandium recovery. Recent work on yttrium has been reported [40]. For the separation of rare earths, generally alkylphosphorus acids have been used for extraction in chloride, nitrate, or sulfate media. However, in the past decade there has been much research on the use of TBP to extract rare earth elements, mostly from nitrate or chloride systems; in addition, attempts to enhance the separation of the chemically similar rare earths have been carried out, using TBP mixed with other extractants, such as acidic organophosphorous reagents, to promote synergistic interactions [38,39].

Only limited work has been reported on TBP extraction of alkali metals, and there are no industrial plants in operation. More attention has been given to TBP extraction of Group IIA metals, mainly because the alkaline earths are present in many minerals with important metallic values; TBP extraction of alkaline earth metals in nitrate systems follows the pattern Ca > Sr > Ba, but distribution coefficients are low [2]. Out of the Group IIIB elements (Al, Ga, In, Ti) only an excellent review of indium has recently appeared in the literature [41]. However, research activity is strong with Group IVB (Ti, Zr, Hf) as well as with vanadium,

niobium and tantalum [42-44]. New work with TBP extraction of Group VIB (Cr, Mo, W) and base metals, such as copper, nickel and zinc, from chloride media, has been reported [45-47]. Considerable attention has been given to the use of TBP for extraction and recovery of precious metals (Ag, Au, Platinum Metals Group), but currently there are only three known plants using this technology [48,49]. Other significant studies with metals have involved the extraction kinetics of iron [50].

In addition to being an excellent extractant for metallic species from aqueous solutions, TBP also extracts a number of other chemicals including organic compounds, mineral acids, etc. The use of TBP for the extraction of different phenolic compounds from aqueous effluents from various manufacturing processes has been reported [51]. TBP associates with phenols through a hydrogen bond, and the stability of the extracted species increases with increasing phenol acidity.

## CONCLUSIONS

TBP continues to be the dominant solvent extractant in nuclear and non-nuclear applications. Although more is known about TBP than any other metal liquid-liquid extraction reagent, new work continues to be reported at a sustained level of activity during the past decade. The future continues to look bright for the science and technology of tributyl phosphate.

## COMPOUNDS OF HEXAVALENT URANIUM AND DIBUTYL PHOSPHATE IN NITRIC ACID

Brian A. Powell, James D. Navratil, and Major C. Thompson\*

Department of Environmental Engineering and Science, Clemson University, Anderson, USA

\*Westinghouse Savannah River Company, Aiken, USA

Storage tanks at the Savannah River Site contain highly enriched uranyl nitrate and dibutyl phosphate (DBP), which can precipitate together as yellow solids. Accumulation of solids in these waste tanks presents a criticality hazard and must be avoided. In this work, uranium dibutylphosphate compounds were formed from batch reactions in 0.2 to 6.0 M HNO<sub>3</sub> and DBP concentrations both above and below its aqueous solubility limit. UO<sub>2</sub>(DBP)<sub>2</sub> precipitates from 0.2 M HNO<sub>3</sub> with DBP below its aqueous solubility limit. In 0.2 M HNO<sub>3</sub>, with DBP above its aqueous solubility limit, UO<sub>2</sub>(DBP)<sub>2</sub>(HDBP)<sub>x</sub> precipitates (where x = 1 or 2). Indications of nitrate complexation appear in precipitates from 0.8M HNO<sub>3</sub> for both DBP concentrations, however a 1:1 uranium:nitrate ratio is not reached until higher acid concentrations are used. UO<sub>2</sub>(NO<sub>3</sub>)(H(DBP)<sub>2</sub>)(HDBP)<sub>2</sub> precipitates from  $\geq$  3.0 M HNO<sub>3</sub> for high DBP concentrations. This compound is not formed until 6.0M HNO<sub>3</sub> is used for lower DBP concentrations. It is assumed that the change in physical characteristics of the compounds and addition of nitrate coincides with the breakdown of the UO<sub>2</sub>(DBP)<sub>2</sub> polymer. Supporting data for these findings are presented.

### INTRODUCTION

The purpose of this research was to gain a better understanding of the chemistry of solid uranyl dibutyl phosphate compounds forming within solutions in storage tanks located at the Savannah River Site (SRS) in South Carolina. These tanks were originally constructed for temporary storage of enriched uranium solutions that had gone through the second uranium cycle of the plutonium and uranium recovery by extraction (PUREX) process. Trace levels of the organophosphorus reagent tributyl phosphate (TBP), used in the PUREX process, present in the solutions undergo hydrolysis to form dibutyl phosphate (DBP) that facilitates the precipitation of uranium solids, thus causing a possible nuclear criticality hazard.

Analysis indicated DBP concentrations of 30-50 mg/L in the storage tanks [1]. It was inferred that all of the TBP has not yet hydrolyzed because of the slow hydrolysis reaction at ambient temperature and high acid concentrations. For complete hydrolysis of the TBP present an estimate of 158 mg/L was obtained using a psuedo-first-order rate constant for the decomposition of 30% (vol%) TBP in kerosene (reported as  $7.2 \times 10^{-8} \text{ h}^{-1}$  in water at ambient temperature [2]). Pierce *et al.* [3] noted that precipitation could occur from a solution containing 110 mg/L DBP. All compounds formed regardless of acid concentration have a limited solubility, but there is a slight increase in the solubility observed in compounds extracted from high acid concentrations [3].

Several areas governing the general solution chemistry between uranium and DBP remain unclear. Solids precipitated out of 0.2 M HNO<sub>3</sub> have been determined to have the formula UO<sub>2</sub>(DBP)<sub>2</sub>, which is present as a polymer structure [4-8]. Addition of nitrate and HDBP (dibutyl phosphoric acid) to UO<sub>2</sub>(DBP)<sub>2</sub> occurs when solids are prepared from 6.0 M HNO<sub>3</sub> [6]. UO<sub>2</sub>(DBP)<sub>2</sub> precipitates as a yellow powder, but as the acid concentration increases the precipitates become an oily mass. Krutikov and Solovkin reported that two compounds are extracted from 6.0 M HNO<sub>3</sub> with the formulas UO<sub>2</sub>(NO<sub>3</sub>)(H(DBP)<sub>2</sub>) and UO<sub>2</sub>(NO<sub>3</sub>)(H(DBP)<sub>2</sub>)(HDBP)<sub>2</sub> [6]. These compounds were both described as a "vitreous mass." DBP has the ability to dimerize so it could be present in these compounds as a dimer.

## EXPERIMENTAL METHODS

Four methods were employed in order to prepare uranium DBP compounds from 0.2, 0.5, 0.8, 1.0, 2.0, 3.0, 4.0, 5.0, and 6.0 M HNO<sub>3</sub>. All DBP additions were done with a 4:1 DBP:uranyl nitrate ratio. The samples are cited as UDBP-XXM-Suffix, where XX is the acid concentration from which the solids were prepared and the suffix refers to the method of preparation.

UO<sub>2</sub>(DBP)<sub>2</sub> was prepared by adding purified DBP (Acros Organics, New Jersey) to a stirring uranyl nitrate hexahydrate (UNH) (reagent grade, Alfa-Asear, Ward Hill, MA) solution and filtering the precipitate with a cellulose nitrate membrane filter. This solid was divided into nine portions that were added to the acid solutions listed above. After stirring for two hours, the solids were filtered, washed with isopropanol, and air-dried. These solids will be referred to as addition (-ADD) in the suffix.

Two sets of samples were prepared by adding purified DBP directly to a UNH solution dissolved in the acid concentrations listed above. One set used an aqueous volume where DBP could exist as a separate phase above its aqueous solubility limit. These solids will be referred to as extracted solids (-EXT) in the suffix. The second set of samples used a larger reaction volume where any residual DBP could be completely dissolved in the aqueous acid medium. These solids will be referred to as precipitated (-PPT) in the suffix. In both cases, the solids were washed with cold water and the solids were either filtered or the free liquid was decanted and the solids were allowed to dry on a watchglass overnight. Solids in three special cases (UDBP-0.2 M-EXT, UDBP-3.0 M-EXT, and UDBP-6.0 M-EXT) were re-crystallized from 2-ethylhexanol (Mallinckrodt, reagent grade, used as received, Paris, KY). The re-crystallized solids were filtered and the filtration apparatus was left overnight in order to remove all remaining 2-ethylhexanol.

Roughly 100 mg/L solutions of each sample were prepared for analysis. The solutions were analyzed using ion chromatography for nitrate concentrations (Dionex DX-100 IC, Sunnyvale, CA), liquid scintillation counting for uranium concentrations (Packard LS 2550 TR/AB Model B2555, Downers Grove) using Hi Safe III liquid scintillation cocktail (Wallac, Akron, OH) and a persulfate digestion followed by reduction of molybdophosphoric acid with stannous chloride for DBP concentrations [9]. Infrared spectra (IR) were obtained using a Nicolet IR-550 FT-IR (Masidon, WI) with KBr plates at 4 cm<sup>-1</sup> resolution and 64 scans. <sup>31</sup>P NMR was obtained in d2-methylene chloride (EM Science, Darmstadt, Germany) using a Bruker AC 300 MHz NMR at 129.49 MHz. UV-Vis spectroscopy was performed, by first dissolving the solids in chloroform, and then using a Beckman 640 DU (Schaumburg, IL) for analysis.

## RESULTS

Table 1 shows nitrate:uranyl and DBP:uranyl molar ratios for all synthesized compounds along with the main factor in the preparation of each compound. These ratios can be used to infer an empirical formula for each compound.

*Table 1. Molar ratios of uranyl DBP solids from chemical analysis.*

Sample	Preparation	DBP/UO <sub>2</sub>	SD (±)	NO <sub>3</sub> /UO <sub>2</sub>	SD (±)

### Solids Prepared via Addition

The chemical analysis of all –ADD compounds showed there was no nitrate present and the DBP:uranyl ratio was  $2.0-2.2 \pm 0.1$ , corresponding to UO<sub>2</sub>(DBP)<sub>2</sub> that has been well characterized as a polymer [5-7]. However, it is not consistent with other reported compounds where nitrate and additional DBP/HDBP modify UO<sub>2</sub>(DBP)<sub>2</sub> at higher acid concentrations. A pale yellow powder, characteristic of UO<sub>2</sub>(DBP)<sub>2</sub>, was initially added to each acid solution. As the experiments progressed a breakdown in the physical structure of the powder was observed. At acid concentrations  $>3.0\text{ M HNO}_3$  the yellow powder took on a viscous gel-like appearance. However, after filtration and washing with isopropanol, all solids changed back to a pale yellow powder. If the change in the visual appearance observed in some experiments is taken to represent the addition of nitrate groups, this could indicate that the solids were changed back to UO<sub>2</sub>(DBP)<sub>2</sub> when washed with an inert solvent like isopropanol. IR analysis of these compounds showed no evidence of nitrate coordination or –OH stretching (which would represent HDBP). There was a strong peak at  $1120\text{ cm}^{-1}$  corresponding to bound P=O, which is present in the polymer structure, and no evidence of unbound P=O at  $1234\text{ cm}^{-1}$ .

### Solids Prepared via Extraction (-EXT) and RE-Crystallization (-REC)

Table 1 indicates that UO<sub>2</sub>(DBP)<sub>2</sub>(HDBP) is present between  $0.2-0.8\text{ M HNO}_3$ , from the molar ratio 2.9 to  $3.2 \pm 0.1$ . Another shift occurs at  $1.0-2.0\text{ M HNO}_3$  acid to a DBP:uranyl ratio of  $3.2-3.3 \pm 0.1$ . This shift corresponds to the point where nitrate begins adding to the compound. The final shift occurs from  $3.0$  to  $6.0\text{ M HNO}_3$  when the DBP:uranyl ratio varies

from  $3.8 \pm 0.1$  to  $4.2 \pm 0.2$ , where four DBP molecules are present on each compound. Extraction data corresponding to the compound  $(\text{UO}_2(\text{DBP})_2(\text{HDBP})_x$ , with  $x = 1$  or  $2$ , have been previously reported, without rigorous chemical analysis [10]. The data presented here show that additional HDBP can add to the solids if DBP is initially present in a significant concentration. IR analysis of these compounds showed the presence of both bound and unbound P=O stretching at  $1120\text{cm}^{-1}$  and  $1234\text{ cm}^{-1}$  [7,11], respectively. There was also evidence of strong –OH stretching observed at  $2272\text{ cm}^{-1}$ ,  $2655\text{ cm}^{-1}$ , and  $>3200\text{ cm}^{-1}$ .

Nitrate groups begin to add to the solids extracted from  $0.8M\text{ HNO}_3$ , then increases until a 1:1 nitrate:uranyl ratio is reached. Nitrate begins adding with molar ratios significantly less than one ( $0.2 \pm 0.01$ ) from  $0.8\text{-}1.0 M\text{ HNO}_3$ . Then the nitrate:uranyl ratio steadily increases with acid concentration until it reaches  $0.9 \pm 0.02$  from  $5.0 M\text{ HNO}_3$ . The stepwise addition of nitrate as the acid concentration increases may indicate the constant breakdown of the polymer structure with an end group attack of nitrate. It is a possibility that some nitrate is extracted by DBP through hydrogen bonding but data on this extraction are unavailable. The molar ratios indicate the compound  $\text{UO}_2(\text{NO}_3)(\text{H}(\text{DBP})_2(\text{HDBP})_2$  in accordance with the previous work [6,7].

Nitrate coordination was observed in IR spectra at  $1529\text{ cm}^{-1}$  [7,11,12] for compounds extracted from  $0.8\text{-}2.0 M\text{ HNO}_3$ . When  $\geq 3.0 M\text{ HNO}_3$  was used, a peak began to appear at  $1636\text{ cm}^{-1}$  and the  $1529\text{ cm}^{-1}$  peak began to lose intensity. The free nitrate ion has two doubly degenerate fundamentals that split upon nitrate coordination [12]. There is also a corresponding shift in the asymmetric uranyl stretch from  $929\text{ cm}^{-1}$  to  $933\text{ cm}^{-1}$  at the same point where the nitrate shift occurs [7]. UV-Vis spectra also showed a change in the uranyl environment at UDBP-3.0 M-EXT through indications of nitrate complexation with uranyl [13].  $^{31}\text{P}$  NMR spectra indicated a very broad single peak that consistently shifted from  $6.2\text{ ppm}$  (UDBP-0.2 M-EXT) to  $3.5\text{ ppm}$  (UDBP-3.0-EXT) and remained steady as the acid concentration increased. A very small shoulder appeared around  $5.0\text{ ppm}$  for samples extracted between  $2.0\text{-}6.0 M\text{ HNO}_3$ . This shoulder is assumed to be present, but hidden, for other samples and was unable to be characterized.

As the acid concentration from which the solids were extracted increased, the transition from a pale yellow powder to a bright yellow gel progressed stepwise with nitrate addition. Therefore, if the visual changes in the solids are assumed to represent nitrate addition, then the solids formed via addition in higher acid concentrations were augmented but returned to  $\text{UO}_2(\text{DBP})_2$  after washing the solids with isopropanol or 2-ethylhexanol. All IR evidence of nitrate and –OH presence disappeared from the spectra after re-crystallization.

### Solids Prepared via Precipitation (-PPT)

$\text{UO}_2(\text{DBP})_2$  is precipitated from  $0.2 M\text{ HNO}_3$ , but the solids from higher acid concentrations have DBP:uranyl molar ratios  $>2$ . They also took on the visual changes as the extracted compounds, corresponding to the increasing nitrate:uranyl ratio. However at  $6.0 M\text{ HNO}_3$ ,  $\text{UO}_2(\text{NO}_3)(\text{H}(\text{DBP})_2)(\text{HDBP})_2$  was found for both compounds regardless of DBP concentration.

## DISCUSSION

When solids are extracted from solutions containing DBP in a separate organic phase and in nitric acid concentrations between  $0.2\text{-}0.5 M$ , the sticky compound  $\text{UO}_2(\text{DBP})_2(\text{HDBP})$  results. The additional DBP molecule must be protonated in order to maintain electro-neutrality of the extracted solids. The presence of –OH groups in these compounds is seen by the strong absorption of the IR regions  $1250\text{-}950\text{ cm}^{-1}$ ,  $2250\text{ cm}^{-1}$ , and  $2650\text{ cm}^{-1}$ . IR spectra of these solids also indicate that there is a mixture of bound and unbound DBP

groups because of a strong absorbance at  $1124\text{ cm}^{-1}$  in all spectra and a shoulder at  $1234\text{ cm}^{-1}$ , indicating unbound P=O. The presence of unbound P=O bonds indicates that HDBP could be adsorbed to the particle surface, present as an outer sphere complex, or it could be coordinated to uranyl by neutral ligand complexation. A possible explanation is that it represents resonance structures of HDBP, through O-P=O bonds, coordinated as a neutral ligand.

Nitrate ions begin adding to the extracted solids from  $0.8\text{ M HNO}_3$  and four DBP/HDBP molecules are present at  $\geq 2.0\text{ M HNO}_3$ , as the nitrate:uranyl ratio increases. The solids extracted between  $0.8\text{-}4.0\text{ M HNO}_3$  have the formula  $\text{UO}_2(\text{H(DBP)})_2(\text{NO}_3)_y(\text{HDBP})_2$ , where  $y$  steadily increases to one at high acid concentrations. The IR peaks corresponding to P=O bonding are the same as those observed for the lower acid extractions showing DBP remaining bound to uranyl. The IR spectra of the solids with nitrate:uranyl ratios  $<1$  show direct complexation of the nitrate group via a sharp peak at  $1528\text{ cm}^{-1}$  that decreases in intensity as the acid concentration increases. This decrease of the  $1528\text{ cm}^{-1}$  peak is in conjunction with an increase in the intensity of a  $1636\text{ cm}^{-1}$  peak, which corresponds to coordinated nitrate or free nitric acid. It is assumed that the  $1636\text{ cm}^{-1}$  peak represents a uranyl nitrate complex because of the indication of uranyl nitrate complexes observed in UV-Vis spectra for the same compounds where the  $1636\text{ cm}^{-1}$  peak is present. There is no observable change in the uranyl ion because the  $929\text{ cm}^{-1}$  peak, representative of  $\text{UO}_2\text{-O-P}$  bonding in  $\text{UO}_2(\text{DBP})_2$ , does not shift. Also, UV-Vis spectra were unable to resolve any effects of nitrate addition to uranyl for the solids formed between  $0.8\text{-}2.0\text{ M HNO}_3$ . Therefore, nitrate is only influencing a portion of the uranyl ions for those acid concentrations. This could represent a point where there is insufficient breakdown of the polymer to influence the uranyl bonding environment. The shift in the uranyl peak, when the nitrate:uranyl ratio is  $\geq 0.5$ , indicates the shift in the uranyl environment when a majority of uranyl ions are coordinated with nitrate, giving a strong indication that the increasing amounts of nitrate correspond to a breakdown of the polymer structure. The similarities in uranyl spectra for nitrate:uranyl ratios  $<0.5$  show that the majority of uranyl ions are still effected only by DBP/HDBP molecules. As the polymer breakdown occurs, then more uranyl ions are coordinated with nitrate, and there is a shift in the uranyl-bonding environment in  $3.0\text{ M HNO}_3$  loading, observed through IR and UV-Vis spectra.

$\text{UO}_2(\text{NO}_3)(\text{H(DBP})_2)(\text{HDBP})_2$  is extracted from  $>5.0\text{ M HNO}_3$ . This compound shows a shift in the uranyl chemical environment, via IR spectra, and a single DBP chemical environment via a single broad  $^{31}\text{P}$  NMR peak. A neutral ligand complexation of HDBP and rapid proton exchange with the one bound DBP molecule fit the interpretation of one DBP environment because the bound and unbound DBP could participate in the rapid proton exchange through its resonance structures. Therefore, the coordination number of uranyl could be increasing with HDBP binding as an inner sphere ligand and as the polymer structure breaks down, there is less steric hindrance around the uranyl ion.

$\text{UO}_2(\text{DBP})_2$  was precipitated from  $0.2\text{ M HNO}_3$  in accordance with the literature. However, there was a decrease in the extent of nitrate and HDBP addition to precipitated compounds when compared to extracted compounds, except for solids from  $6.0\text{ M HNO}_3$ . The excess HDBP present on extracted compounds could be causing stress on the P-O-U bond and making nitrate infiltration easier for extracted compounds. When  $6.0\text{M HNO}_3$  was used in both methods, solids with identical spectra and empirical formula were found.

The addition of DBP and nitrate, as well as the transition of the physical nature of the compounds from a solid to a gel are proposed to represent the breakdown of the  $\text{UO}_2(\text{DBP})_2$  polymer structure. This was also an assumption of other researchers [6]. The polymer may be initially forming in solution followed by a nitrate attack on the end of the molecule, where bulky DBP molecules that remain complexed with the uranyl ion will not cause hindrance.

However, further studies are required to verify the polymer breakdown. There is indication of DBP remaining complexed with uranyl because of the strong absorption at  $1124\text{ cm}^{-1}$  in the IR spectra of these samples. At least one DBP molecule must be bonded with uranyl in order to maintain electro-neutrality of the solid, since a maximum of one nitrate coordinates with each uranyl ion.

The IR spectra indicate that DBP can be present as a neutral ligand (indicated by  $-\text{OH}$  peaks), causing an increased coordination number in uranyl than that observed in the polymer structure. There is evidence of bound and unbound DBP presence but if it was present in both inner and outer sphere coordination then two strong  $^{31}\text{P}$  NMR peaks would appear. Therefore, it is proposed that any additional DBP is present as a neutral ligand capable of resonance structures, represented by the very broad NMR peak. Mono- or bidentate nitrate coordination has not been ascertained. However, the increased degree of splitting of the degenerate fundamental peaks in free nitrate observed in this research provide some indication of a further decrease in symmetry that would be caused by bidentate coordination.

## CONCLUSIONS

The formation of uranium DBP solids is highly dependent on the nature of the solution in which they are formed. At lower acid concentrations and lower DBP loadings, the well-characterized polymer  $\text{UO}_2(\text{DBP})_2$  precipitates as a pale yellow powder.  $\text{UO}_2(\text{DBP})_2(\text{HDBP})_x$  ( $x = 1$  to  $2$ ) precipitates with higher DBP loadings. However, when extracting from  $6.0\text{ M HNO}_3$ ,  $\text{UO}_2(\text{NO}_3)(\text{H}(\text{DBP})_2)(\text{HDBP})_2$  is formed, regardless of the initial DBP concentration, as a sticky solid or gel. The similarities in IR spectra indicate that the same  $\text{UO}_2(\text{DBP})_2$  monomer is present in all compounds and adds new ligands with increasing acid or DBP concentrations.

Nitrate addition to compounds can be detected in nitric acid concentrations as low as  $0.8\text{ M HNO}_3$ . However, nitrate does not add in a 1:1 stoichiometric ratio with uranium until  $5.0\text{ M HNO}_3$  is used with high DBP concentrations and  $6.0\text{ M HNO}_3$  in lower DBP concentrations. The addition of nitrate may affect DBP bonding to uranyl but there is still a strong complexation of DBP to a central uranyl ion, indicated by IR data. This addition of nitrate is assumed to accompany the breakdown of the polymer structure observed for  $\text{UO}_2(\text{DBP})_2$ . This phenomenon can be observed through changes in the physical appearance of the solids as they become more viscous with increasing acid concentrations. This change in physical appearance corresponds with the increasing nitrate: uranyl ratio, which is most likely responsible for the polymer structure breakdown. The increasing nitrate:uranyl ratio is also accompanied by a shift in the uranyl IR stretch, which corresponds to an increase in the ionic character of the uranyl bond. The coordination number of uranyl is most likely increased with nitrate and HDBP addition through neutral ligand coordination of HDBP. This will be an inner sphere complexation because phosphorous is indicated to be in one chemical environment from  $^{31}\text{P}$  NMR data. Compounds containing nitrate and additional DBP molecules can be easily converted to  $\text{UO}_2(\text{DBP})_2$  by re-crystallizing from 2-ethylhexanol or washing with isopropanol.

## EFFECT OF U(VI) CONCENTRATION ON EQUILIBRIUM AND KINETICS IN FLOW-EXTRACTION OF U(VI) IN HNO<sub>3</sub> / SUPERCRITICAL CO<sub>2</sub> + TBP SYSTEM

Yoshihiro Meguro, Shuichi Iso and Zenko Yoshida

Advanced Science Research Center, Japan Atomic Energy Research Institute,  
Tokai, Japan

The distribution ratio  $D$  of U(VI) was determined in the supercritical CO<sub>2</sub> extraction system with the nitric acid solution containing  $10^{-3}$  –  $10^{-1}$  M U(VI) and the supercritical CO<sub>2</sub> containing 0.1 – 0.5 M tributylphosphate (TBP) at 60 °C and 15 MPa. The distribution behavior was found to be practically independent on the U(VI) concentration, though the  $D$  decreased slightly with an increase of U(VI) concentration, which was attributed to a decrease of the equilibrium concentration of free TBP in the supercritical CO<sub>2</sub> phase. The solubility of UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>(TBP)<sub>2</sub> in the supercritical CO<sub>2</sub> phase was determined to be higher than  $7 \times 10^{-2}$  M and a suppression of the  $D$  due to the solubility limitation of the extracted complex in the supercritical CO<sub>2</sub> was unlikely to occur under the extraction condition examined. The extraction-rate curve was measured in the flow-extraction system. The distribution ratio  $D_{\text{flow}}$  of U(VI) in the flow-extraction system was calculated and compared with the  $D$ . The  $D_{\text{flow,max}}$  agreed well with the  $D$  indicating that the extraction equilibrium of U(VI) was attained rapidly even in the flow-extraction performance.

### INTRODUCTION

Supercritical fluid extraction (SFE) using the supercritical CO<sub>2</sub> instead of an organic solvent has several fundamental and practical advantages that the extraction efficiency or rate is enhanced due to the rapid mass transfer in the supercritical fluid phase, the rapid and complete recovery of the extracted substances from CO<sub>2</sub> is attained by gasification of CO<sub>2</sub>, and the solvent properties can be optionally changed by tuning pressure [1-3]. The use of SFE in the field of nuclear technology exhibits a particular significance for minimizing the amount of the radioactive solvent waste [4]. The authors have developed the SFE of U(VI) and Pu(IV) from nitric acid solution using the supercritical CO<sub>2</sub> containing tributylphosphate(TBP) [2, 4-7].

For the assessment of a feasibility of the SFE to the process-scale separation of a large amount of an objective metal, e.g., the separation of uranium for reprocessing the spent nuclear fuel, the distribution behavior of the metal of high concentration needs to be elucidated. In this connection, the distribution behavior of the metal of a large amount is suppressed due to the solubility limitation of the metal-extractant complex in the supercritical CO<sub>2</sub>, which is observed in the SFE of the metal [8] and is considered to be one of the main disadvantages with the SFE process. In addition, the extraction behavior of the metal in the flow SFE system, in which the metal is extracted into a stream of the supercritical CO<sub>2</sub> phase flowing through the aqueous solution, needs to be studied, since the flow extraction system will be adopted in a practical SFE process [9].

In the present study, the equilibrium distribution ratio  $D$  of U(VI) of relatively high concentration was determined by the batchwise extraction procedure with the  $\text{HNO}_3$  solution containing  $10^{-3}$  -  $10^{-1}$  M U(VI) and the supercritical  $\text{CO}_2$  phase containing 0.1 - 0.5 M TBP, for the elucidation of the dependence of  $D$  on the concentration of U(VI). The extraction behavior of U(VI) in the flow SFE system was also investigated for the elucidation of the parameters determining the flow-extraction rate.

## EXPERIMENTAL

### SFE Apparatus and Procedure

#### *Batchwise extraction*

The batchwise extraction experiment for the determination of the distribution ratio  $D$  under SFE equilibrium condition was conducted using the apparatus identical to that reported previously [6]. The main part of the apparatus consisted of a stainless steel extraction vessel of ca. 50 ml of inner volume, a sampling vessel, a restrictor and a pump. Twenty five ml of  $\text{HNO}_3$  solution containing U(VI) was taken in the extraction vessel. An appropriate volume of TBP was added to the extraction vessel to which the  $\text{CO}_2$  was introduced using the syringe pump. The volume of the  $\text{CO}_2$  phase was 25 ml. The two phases were allowed to stand for 60 min at  $60^\circ\text{C}$  (extraction temperature,  $T_{\text{ex}}$ ) and 15 MPa (extraction pressure,  $P_{\text{ex}}$ ) with stirring by the use of a magnetic stirrer. After the SFE equilibrium was attained, 5 ml of the aqueous phase was taken quickly using the sampling vessel. The concentration of U(VI) in the sampled solution was determined by ICP-AES and the  $D$  of U(VI) was calculated as the ratio of the concentration of U(VI) in the supercritical  $\text{CO}_2$  phase to that in the aqueous phase.

#### *Flow extraction*

The flow extraction experiment was conducted with the apparatus which was essentially identical to that reported previously [6] but with the extraction vessel of approximately 40 ml of inner volume, 500 mm of inner height and 10 mm of inner diameter. Thirty ml of the  $\text{HNO}_3$  solution was taken in the extraction vessel through which a mixture of the supercritical  $\text{CO}_2$  and TBP was forced to flow at a constant flow rate,  $f$ . The  $T_{\text{ex}}$  and  $P_{\text{ex}}$  were  $60^\circ\text{C}$  and 15 MPa, respectively. The supercritical  $\text{CO}_2$  phase eluted from the extraction vessel was introduced into the collection vessel kept at ca.  $60^\circ\text{C}$  and an ambient pressure. The extracted substances were collected on the quartz wools packed in the collection vessel. The collection vessel was replaced by new one at intervals of 10 min during the continuous flow SFE. The amount of uranium in each 10 mins' fraction was determined by ICP-AES after the U(VI) recovered as the  $\text{UO}_2(\text{NO}_3)_2(\text{TBP})_2$  complex was completely decomposed and dissolved into the aqueous solution by mixing the  $\text{UO}_2(\text{NO}_3)_2(\text{TBP})_2$  complex with 1 M  $(\text{NH}_4)_2\text{CO}_3$  aqueous solution. The extraction-rate curve was established by plotting the extraction efficiency (E%) calculated from the integrated amount of U(VI) collected against the integrated amount of  $\text{CO}_2$  employed for the flow SFE.

## RESULTS AND DISCUSSION

### Distribution Ratio D of U(VI)

The distribution ratio  $D$  of U(VI) was determined in the SFE at  $60^\circ\text{C}$  and 15 MPa using 3 M  $\text{HNO}_3$  solution containing  $2 \times 10^{-3}$  -  $1 \times 10^{-1}$  M U(VI) and the supercritical  $\text{CO}_2$  containing 0.1 - 0.5 M TBP. The logarithmic plots of  $D$  and the initial concentration of TBP in the supercritical  $\text{CO}_2$ ,  $C_{\text{TBP,SF}}$ , are shown in Figure 1. The slope of the plot is  $2.0 \pm 0.2$  indicating that the extracted species involves two TBP molecules, i.e.,  $\text{UO}_2(\text{NO}_3)_2(\text{TBP})_2$  [5,6], independently on the concentration of U(VI) in the range examined.

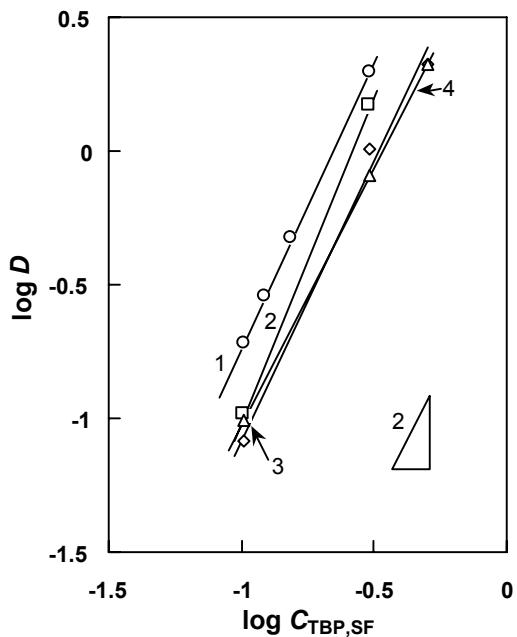

Figure 1.  $\log D$  vs.  $\log C_{TBP,SF}$  plots in the SFE of U(VI).

Aqueous phase; 3 M  $HNO_3$  + (1)  $2 \times 10^{-3}$  M U(VI),  
 (2)  $1 \times 10^{-2}$  M U(VI), (3)  $5 \times 10^{-2}$  M U(VI), (4)  $1 \times 10^{-1}$  M U(VI),  
 $C_{TBP,SF}$ ; 0.1 – 0.5 M,  $T_{ex}$ ; 60 °C,  $P_{ex}$ ; 15 MPa.

With an increase of the initial concentration of U(VI) in the aqueous solution,  $C_{U(VI)}$ , the  $D$  decreases gradually. This is attributable to the decrease of the concentration of free TBP in the supercritical  $CO_2$  phase after the extraction equilibrium of a large amount of U(VI) is attained. It is concluded that the solubility of  $UO_2(NO_3)_2(TBP)_2$  complex into the supercritical  $CO_2$  phase is enough high and the solubility limitation of the complex does not disturb the SFE equilibrium. The SFE condition under which the highest  $D$  and the highest U(VI) concentration in the supercritical  $CO_2$  were obtained was  $C_{U(VI)} = 1 \times 10^{-1}$  M and  $C_{TBP,SF} = 0.5$  M ( $T_{ex} = 60$  °C,  $P_{ex} = 15$  MPa). The solubility of  $UO_2(NO_3)_2(TBP)_2$  in the supercritical  $CO_2$  is estimated from these results to be still higher than  $7 \times 10^{-2}$  M.

### Flow SFE of U(VI)

The extraction-rate curve for the flow SFE of U(VI) was measured with the 3 M  $HNO_3$  solution containing  $1 \times 10^{-2}$  M or  $5 \times 10^{-2}$  M U(VI) and the supercritical  $CO_2$  phase containing 0.1, 0.3 or 0.5 M TBP which was forced to flow through the aqueous solution in the extraction vessel at  $f = 2.0$  ml/min. The results are shown in Figure 2. The extraction rate increases with an increase of  $C_{TBP,SF}$  and does not depend strongly on  $C_{U(VI)}$ . The increase of the extraction rate with  $C_{TBP,SF}$  is attributable to the increase of  $D$  of U(VI).

In order to clarify whether or not the distribution equilibrium is attained in the flow SFE of U(VI), an apparent distribution ratio in the flow system,  $D_{flow}$ , was defined and compared with the  $D$  determined under the equilibrium condition. The  $D_{flow}$  is expressed by the ratio of the concentration of U(VI) in the supercritical  $CO_2$  phase,  $C_{U(VI),SF,flow}$ , to the concentration of U(VI) in the aqueous phase,  $C_{U(VI),aq,flow}$ , at a given period of time during the continuous flow SFE and calculated from the results of the amount of U(VI) extracted,  $m_{U(VI),SF}$  (in mole), as expressed by eq. (1).

$$D_{flow} = C_{U(VI),SF,flow} / C_{U(VI),aq,flow} = m_{U(VI),SF} / (V_{CO_2} C_{U(VI),aq,flow}) \quad (1)$$

where  $V_{\text{CO}_2}$  denotes the total volume (in liters) of the supercritical  $\text{CO}_2$  fed to the flow SFE system for a given time. In the present work, the results shown in Figure 2 were used for the calculation of  $D_{\text{flow}}$ . The average of the concentrations of U(VI) remaining in the aqueous solution before and after each 10 mins' flow SFE was employed as  $C_{\text{U(VI),aq,flow}}$ .

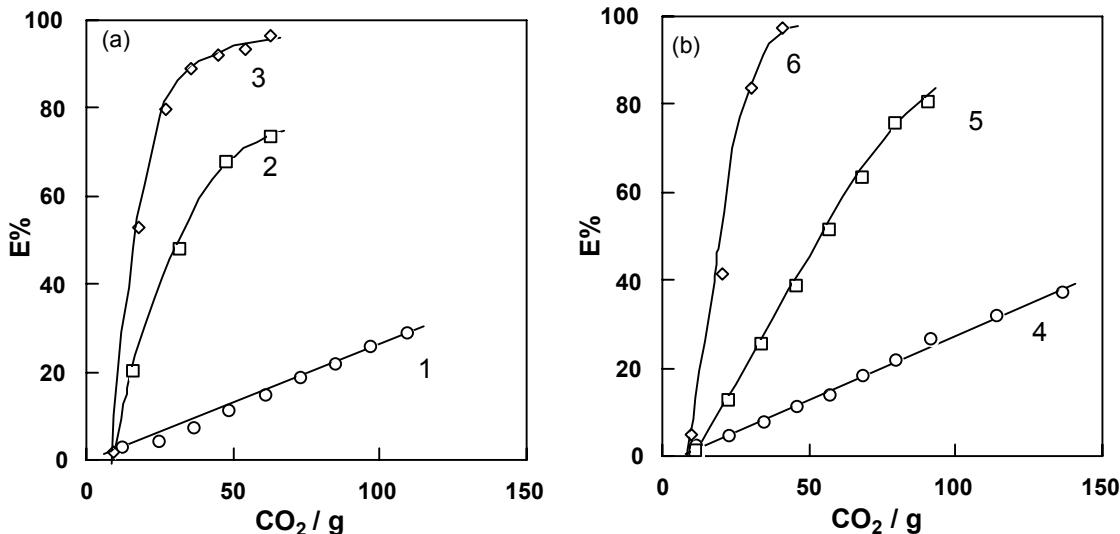

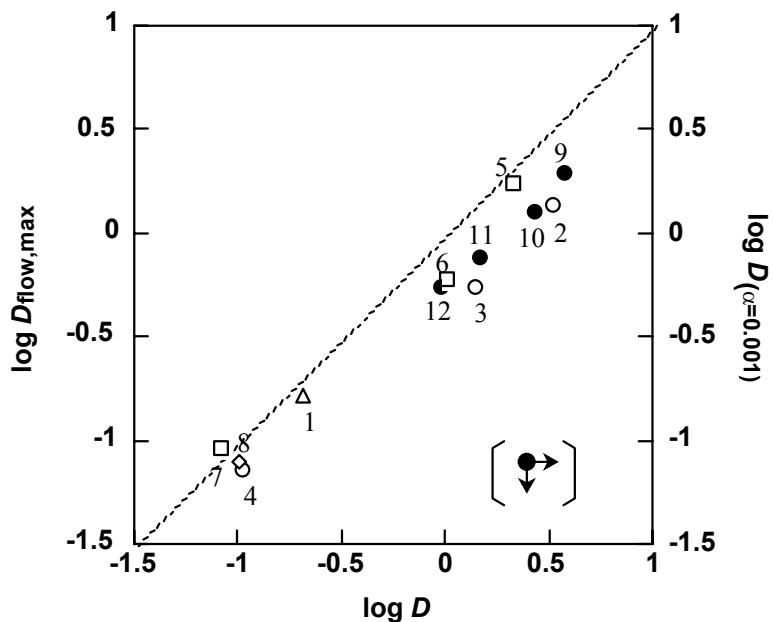

Figure 2. Extraction-rate curve for the SFE of U(VI).  
Aqueous solution; 3 M  $\text{HNO}_3$  + (a)  $1 \times 10^{-2} \text{ M}$  U(VI), (b)  $5 \times 10^{-2} \text{ M}$  U(VI),  
 $C_{\text{TBP,SF}}$ ; (1,4)  $1 \times 10^{-1} \text{ M}$ , (2,5)  $3 \times 10^{-1} \text{ M}$ , (3,6)  $5 \times 10^{-1} \text{ M}$ ,  $f$ ; 2.0 ml/min,  
 $T_{\text{ex}}$ ;  $60^\circ\text{C}$ ,  $P_{\text{ex}}$ ; 15 MPa.

The  $D_{\text{flow}}$  calculated using the results given in Figure 2 exhibits a general tendency which reflects a situation varying through the flow SFE. The  $D_{\text{flow}}$  calculated from the results in the earlier stage of the flow SFE were slightly smaller than those in the successive stages. This results from the situation that a steady-state condition is not attained yet at the earlier stage of the flow SFE. The  $D_{\text{flow}}$  increases gradually as the flow SFE proceeds and shows a maximum,  $D_{\text{flow,max}}$ . Further proceeding of the flow SFE leads to a decrease of the U(VI) concentration in the aqueous phase; under this condition,  $D_{\text{flow}}$  becomes smaller than  $D_{\text{flow,max}}$ , which is due to the situation that a diffusion of U(VI) in the aqueous phase controls partly the extraction rate of U(VI).

The  $D_{\text{flow,max}}$  determined at various  $C_{\text{U(VI)}}$  and  $C_{\text{TBP,SF}}$  are listed in Table 1. The  $D_{\text{flow,max}}$  and the  $D$  under the identical conditions of  $C_{\text{U(VI)}}$  and  $C_{\text{TBP,SF}}$  are compared with each other in Figure 3.

Table 1. The distribution ratio  $D_{\text{flow,max}}$  of U(VI) in the flow SFE.

$C_{\text{U(VI)}} / \text{M}$	$C_{\text{TBP,SF}} / \text{M}$	$D_{\text{flow,max}}$
$2 \times 10^{-3}$	0.1	0.163
$1 \times 10^{-2}$	0.1	0.073
$1 \times 10^{-2}$	0.3	0.562
$1 \times 10^{-2}$	0.5	1.39
$5 \times 10^{-2}$	0.1	0.092
$5 \times 10^{-2}$	0.3	0.60
$5 \times 10^{-2}$	0.5	1.73
$1 \times 10^{-1}$	0.1	0.080

*Figure 3. Comparison between  $D_{\text{flow},\text{max}}$  and  $D$  for the SFE of U(VI) in 3 M  $\text{HNO}_3$  solution.*

$C_{\text{U(VI)}}$ ; (1)  $2 \times 10^{-3}$  M, (2, 3, 4)  $1 \times 10^{-2}$  M, (5, 6, 7)  $5 \times 10^{-2}$  M, (8)  $1 \times 10^{-1}$  M.

$C_{\text{TBP,SF}}$ ; (1, 4, 7, 8) 0.1 M, (3, 6) 0.3 M, (2, 5) 0.5 M.

●;  $D_{(\alpha=0.001)}$  calculated for SFE of U(VI) with  $C_{\text{TBP,SF}} = 0.5$  M.

$C_{\text{U(VI)}}$ ; (9)  $5 \times 10^{-2}$  M, (10)  $1 \times 10^{-1}$  M, (11)  $2 \times 10^{-1}$  M, (12)  $3 \times 10^{-1}$  M.

The dotted line in the figure indicates a complete agreement between  $D_{\text{flow},\text{max}}$  and  $D$ . The  $D_{\text{flow},\text{max}}$  is slightly smaller than the  $D$ .

In principle, the distribution ratio  $D$  can be expressed by eq. (2) using the extraction constant  $K_{\text{ex}}$ .

$$D = K_{\text{ex}} [\text{NO}_3^-]^2 [\text{TBP}]_{\text{SF}}^2 \quad (2)$$

where  $[\text{NO}_3^-]$  and  $[\text{TBP}]_{\text{SF}}$  are activities of  $\text{NO}_3^-$  in the aqueous phase and TBP in supercritical  $\text{CO}_2$  phase, respectively, at the SFE equilibrium and given by eqs. (3) and (4) using the initial concentration,  $C_{\text{U(VI)}}$ ,  $C_{\text{NO}_3}$ , and  $C_{\text{TBP,SF,eq}}$  and the ratio of the volume of the supercritical  $\text{CO}_2$  phase to that of the aqueous phase,  $\alpha$ . Here the activity coefficients of U(VI) and TBP in both phases are approximated to be unity for simplicity.

$$[\text{NO}_3^-] = C_{\text{NO}_3} - C_{\text{U(VI)}} \{ x \alpha D / (1 + \alpha D) \} \quad (3)$$

$$[\text{TBP}]_{\text{SF}} = C_{\text{TBP}} - C_{\text{U(VI)}} \{ (yD / (1 + \alpha D)) \} \quad (4)$$

where  $x$  and  $y$  are the number of  $\text{NO}_3^-$  ions and TBP molecules involved in the SFE reaction, and  $x = 2$  and  $y = 2$  for the SFE of U(VI) studied in the present work. In the flow SFE system, the distribution reaction occurs between the aqueous phase and the supercritical  $\text{CO}_2$  phase which is a small bubble dispersed in the aqueous phase. Under such extraction condition, the ratio of the phase volume  $\alpha$  affects the distribution behavior appreciably. The  $D$  at  $\alpha = 0.001$ , as an example, was calculated using eqs. (2) – (4) and the results are plotted by closed circle in Figure 3. The value of  $K_{\text{ex}}$  used for the calculation was 2.35 which was determined from the experimental  $D$  value in the batchwise extraction of 0.002 M U(VI) from the 3 M  $\text{HNO}_3$  solution into the supercritical  $\text{CO}_2$  containing 0.1 M TBP (cf. Figure 1). The  $D_{(\alpha=0.001)}$  is obviously

smaller than the  $D$  which is obtained usually at  $\alpha = 1$ . The experimental  $D_{\text{flow,max}}$  scatters around the plots of  $D_{(\alpha=0.001)}$ . Therefore, the smaller  $D_{\text{flow,max}}$  than  $D$  can be also attributable to the effect of  $\alpha$ , which is very small in the flow SFE, on the distribution ratio. Finally, it is concluded that the distribution equilibrium of U(VI) is attained almost completely even in the flow SFE system examined in the present work.

## CONCLUSION

The distribution ratio  $D$  for the SFE of U(VI) between 3 M  $\text{HNO}_3$  and supercritical  $\text{CO}_2 + 0.1 - 0.5$  M TBP does not depend on the concentration of U(VI) upto 0.1 M. The solubility of  $\text{UO}_2(\text{NO}_3)_2(\text{TBP})_2$  to be extracted in the supercritical  $\text{CO}_2$  is sufficiently high. These results imply that the SFE using TBP is feasible to the separation of a large amount of U(VI) in the aqueous sample solution. The distribution equilibrium is attained efficiently even in the flow SFE of U(VI). The larger extraction rate of the flow SFE of U(VI) can be attained using the supercritical  $\text{CO}_2$  containing TBP of higher concentration, which enhances the distribution ratio of U(VI).

## NEW INSIGHTS IN THIRD PHASE FORMATION IN THE U(VI)-HNO<sub>3</sub>, TBP-ALKANE SYSTEM

Mark P. Jensen, Renato Chiarizia, John R. Ferraro, Marian Borkowski,  
Kenneth L. Nash, Pappanan Thiagarajan\* and Ken C. Littrell\*

Chemistry Division, Argonne National Laboratory, Argonne, Illinois, USA  
\*IPNS Division, Argonne National Laboratory, Argonne, Illinois, USA

In this work, the system U(VI)-HNO<sub>3</sub>-tributylphosphate (TBP)-*n*-dodecane has been revisited with the objective of gaining coordination chemistry and structural information on the species that are formed in the organic phase before and after third phase formation. Chemical analyses, spectroscopic and EXAFS data indicate that U(VI) is extracted as the UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>•2TBP adduct, while the third phase species has the composition UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>•2TBP•HNO<sub>3</sub>. Small-angle neutron scattering (SANS) data reveal the presence in the organic phase, both before and after phase splitting, of ellipsoidal aggregates whose formation seems to depend more on the extraction of HNO<sub>3</sub> than that of U(VI).

### INTRODUCTION

The phenomenon of third phase formation in solvent extraction is well known and has been investigated in a number of studies. Excellent reviews, one of which is quite recent, have summarized the most important aspects of this phenomenon [1,2]. The main focus in previous works has been on the conditions under which third phase formation is observed and avoided, and on the composition of the species present in the heavy organic phase. Very little information is available on structural aspects of third phase formation.

A recent work has reported that, in the case of HNO<sub>3</sub> extraction by a diamide extractant in *n*-dodecane, small-angle X-ray scattering measurements revealed the onset of extensive aggregation of the organic phase species when phase splitting was approached [3]. Similar observations have been reported by some of the present authors in small-angle neutron scattering studies (SANS) of metal extraction by dialkyl-substituted alkylidendiphosphonic acids [4]. Large cylindrical aggregates form in toluene solutions of the extractants when they are loaded with progressively higher concentrations of certain metal ions such as Fe(III) and Th(IV). The aggregation eventually leads to the separation of a gelatinous material that can be considered a particular case of third phase formation.

In an attempt to verify that the formation of large aggregates in the organic phase before phase splitting is a general feature shared by most if not all solvent extraction systems, we have revisited the U(VI)-HNO<sub>3</sub>-tributylphosphate (TBP)-*n*-dodecane system from the standpoint of third phase formation. We chose this system because, in spite of its technological importance, very few detailed studies are available on third phase formation when U(VI) is extracted by alkane solutions of TBP [5-7]. The objective of this work was to gain information on coordination chemistry and morphology of the species present in the organic phase before and after third phase formation.

## SAMPLE PREPARATION AND CHARACTERIZATION

*n*-Dodecane solutions containing 20% (v/v) TBP (0.73 M) and varying concentrations of HNO<sub>3</sub> and U(VI) were prepared by contacting at 23 ± 1 °C a small volume of the TBP solution, preequilibrated twice with 10 M HNO<sub>3</sub> (phase ratio = 1), with an equal volume of 10 M HNO<sub>3</sub> solutions containing progressively increasing concentrations of UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub> (from 0.040 to 0.66 M). When contacting the 20% TBP organic phase with an aqueous solution that was 0.66 M in UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub> and 10.5 M in HNO<sub>3</sub>, a third phase was obtained having a volume of about 13% of the original organic phase volume, and a density of 1.26 g/mL. The solutions containing the U(VI) limiting organic concentration (LOC), that is, the highest metal concentration in the organic phase that could be achieved under the selected experimental conditions without phase splitting, was obtained by first causing formation of the third phase and then adding very small amounts of lean organic phase and/or water until the third phase disappeared, as indicated by the absence of turbidity in the organic phase. The samples for the SANS measurements were prepared by following an identical procedure, with the exception that the diluent was *d*<sub>26</sub>-deuterated dodecane.

After centrifugation and phase separation, aliquots of the various phases were analyzed. The aqueous phase HNO<sub>3</sub> concentrations were determined by titration to pH ~6 with standard base after appropriate dilution and after making the solution 0.2 M in (NH<sub>4</sub>)<sub>2</sub>C<sub>2</sub>O<sub>4</sub>. The aqueous U(VI) concentration was determined by ICP-AES. The organic HNO<sub>3</sub> and U(VI) were first stripped by contacting an aliquot of the organic phases diluted 10-fold with dodecane with a larger and known volume of 0.1 M (NH<sub>4</sub>)<sub>2</sub>C<sub>2</sub>O<sub>4</sub>. HNO<sub>3</sub> and U(VI) in the stripping solution were then determined as above. The TBP concentration in the heavy and light organic phases resulting from phase splitting were determined, after HNO<sub>3</sub> and U(VI) stripping, from the distribution ratio (D) of <sup>233</sup>U between the organic phase and 3 M HNO<sub>3</sub> by using an *ad hoc* calibration curve of D<sub>U</sub> vs. TBP concentration.

Table 1 summarizes the composition of the organic phases investigated in this work. The table also reports the concentration of TBP bound to U(VI) (assuming that the U(VI) exists as UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>•2TBP in the organic phase), the concentration of the excess TBP, (that is, the TBP not bound to U(VI)), and the ratio of the HNO<sub>3</sub> to the excess TBP.

*Table 1. Composition of the U(VI)-TBP samples investigated.*

Sample	[TBP] mol/L	[U] mol/L	[HNO <sub>3</sub> ] mol/L	[TBP] <sub>bound to U</sub> mol/L	[TBP] <sub>excess</sub> mol/L	[HNO <sub>3</sub> ] / [TBP] <sub>excess</sub>
1	0.73	-	-	-	-	-
2	0.73	-	0.74	-	-	-
3	0.73	0.032	0.72	0.064	0.67	1.1
4	0.73	0.23	0.27	0.47	0.26	1.0
5	0.73	0.26	0.22	0.52	0.21	1.0

TBP is known to form complexes with HNO<sub>3</sub> having the composition TBP•(HNO<sub>3</sub>)<sub>n</sub>, with *n* equal to 1 through 4 [8]. Under our experimental conditions (equilibrium aqueous phase 10 M in HNO<sub>3</sub>), the data in Table 1 indicate that HNO<sub>3</sub> exists in the organic phase predominantly as the 1:1 HNO<sub>3</sub>:TBP complex. Also, as more and more U(VI) is extracted from 10 M HNO<sub>3</sub>, the data in Table 1 show that U(VI) displaces the acid from the phosphoryl group of TBP, forming the well-known UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>•2TBP adduct [9], while the excess TBP remains in the form of TBP•HNO<sub>3</sub>. Finally, the data in Table 1 indicate that the third phase is highly concentrated in TBP and U(VI). Karl Fisher titrations of the third phase samples provided a

water concentration of 0.4 M. Based on the results shown in Table 1, the composition of the third phase species can be expressed as  $\text{UO}_2(\text{NO}_3)_2 \cdot 2\text{TBP} \cdot \text{HNO}_3$  (neglecting water), in agreement with previous findings [6].

## RESULTS AND DISCUSSION

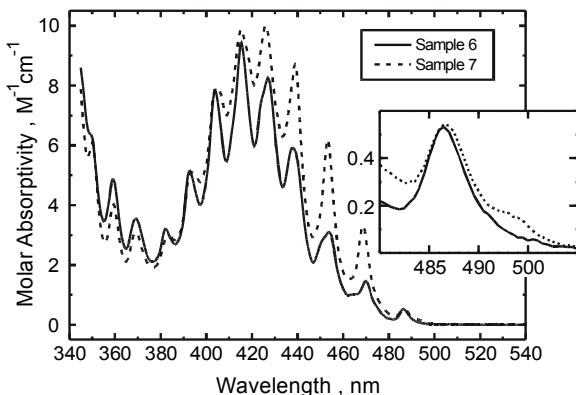

### Infrared Spectroscopy

IR spectra of the samples in Table 1 were collected using a Nicolet Nexus 870 FTIR Spectrometer equipped with a HATR Attenuated Total Reflectance accessory containing a diamond resolution element. The results will be treated in more detail elsewhere [10]. However, several important features of the IR spectra that give insight into the nature of the third phase are summarized here. Overall, the shifts of the P=O stretching vibration upon U(VI) extraction by TBP ( $\sim 100 \text{ cm}^{-1}$ ) provide clear evidence that the P=O oxygen is strongly coordinated to U(VI). Also, the magnitude of the frequency separation ( $\sim 250 \text{ cm}^{-1}$ ) between the asymmetric and symmetric stretching vibrations of the  $\text{NO}_2$  group of the nitrate ion indicates a bidentate coordination of the nitrates in the organic complex [11].

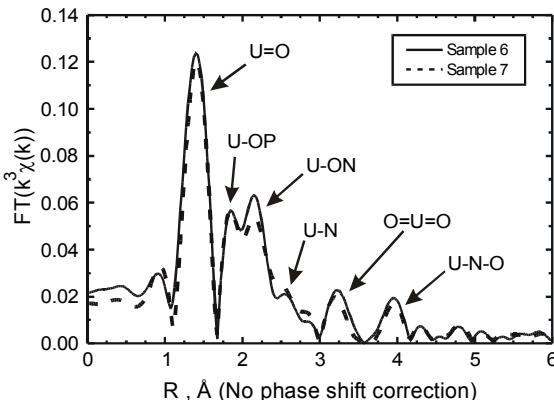

A marker band for molecular  $\text{HNO}_3$  ( $1672 \text{ cm}^{-1}$  [12]) is present in the spectra of samples 2 through 8. This band exhibits two peaks indicating that two forms of  $\text{HNO}_3$  occur in these solutions: the lower energy vibration ( $1648 \text{ cm}^{-1}$ ) can be attributed to strongly hydrogen-bonded acid, while the higher energy one ( $1671 \text{ cm}^{-1}$ ) is associated with unbonded or weakly bonded acid. Sample 7 (third phase) exhibits a much stronger  $1671 \text{ cm}^{-1}$  band than the other samples, thus providing support to the conclusion that in  $\text{UO}_2(\text{NO}_3)_2 \cdot 2\text{TBP} \cdot \text{HNO}_3$ , the third phase species, the  $\text{HNO}_3$  molecule is not in the primary coordination sphere of the uranyl ion, in agreement with previous results [5]. Other studies, however, concluded that the trinitrato complex,  $\text{HUO}_2(\text{NO}_3)_3 \cdot 2\text{TBP}$ , exists in the third phase [6,7].

### Visible Spectroscopy

Spectra of the organic phases (Figure 1) were obtained using a Cary-14 spectrophotometer and quartz cells of various pathlengths. Before phase splitting (Samples 3-6), the shape, energy, and intensity of each of the absorption bands is invariant and in complete agreement with literature reports of the spectrum of  $\text{UO}_2(\text{NO}_3)_2 \cdot 2\text{TBP}$  [13]. After phase splitting, the light phase (Sample 8) displays the same spectrum as the pre-splitting samples (represented in Figure 1 by Sample 6). However, the spectrum of the third phase (Sample 7) is distinctly different from the rest, indicating that the coordination of U(VI) is unique in the heavy phase. The intensity differs for most of the heavy phase absorption bands, the shape and energy of each peak change, and a weak new band appears at 494 nm. Taken together, this indicates that the U(VI) complex in the third phase has a lower symmetry [14,15] than  $\text{UO}_2(\text{NO}_3)_2 \cdot 2\text{TBP}$ . This could be accounted for by any number of complexes, not only the trinitrato complex  $\text{HUO}_2(\text{NO}_3)_3 \cdot 2\text{TBP}$ , as previously postulated based on the modest resemblance of the spectra of the third phase and  $\text{UO}_2(\text{NO}_3)_3^-$  [6,7]. The abrupt change in the spectrum on phase splitting suggests that in this system, third phase formation is *not* driven by progressive assembly of discrete molecules of the extracted complex into large aggregates that are insoluble in the original organic solvent.

**Figure 1.** Visible absorption spectra of the limiting organic concentration (LOC) and third phase samples.

**Figure 2.** Fourier transformation of  $k^3$  weighted uranium  $L_3$  edge EXAFS for the LOC and third phase samples.

### EXAFS Measurements

Extended X-ray absorption fine structure (EXAFS) measurements of the organic phases were made on the BESSRC-CAT bending magnet beamline of the Advanced Photon Source at the uranium  $L_3$  edge. The data were fit using the program EXAFSPAK [16] to the theoretical phase and amplitude functions generated by FEFF 7.02 [17].

The results show similar patterns to those observed in each of the other experiments. The third phase is distinctly different from each of the other samples, which are identical to each other regardless of U(VI) loading or TBP concentration. Figure 2 shows the radial distribution of the shells of atoms about the U(VI) center (without phase shift correction). The EXAFS of the samples before phase splitting (Samples 4-6) and the light phase after splitting (Sample 8) are indistinguishable. The two “-yl” oxygen atoms are observed at  $1.765 \pm 0.005$  Å in all of the samples. Two TBP oxygen atoms at  $2.35 \pm 0.02$  Å and 4 oxygen atoms from bidentate nitrate groups at  $2.50 \pm 0.01$  Å can be partially resolved in the equatorial coordination sphere. These results agree well with previous work [18, 19].

None of the uranium-oxygen bond distances change significantly upon formation of the third phase. In addition, the number of inner sphere TBP oxygen atoms (2) observed in the third phase (Sample 7) is exactly the same seen for the other samples. The primary difference in the U(VI) inner coordination sphere of the heavy phase is a significant decrease (from 4.0 to 3.5) in the average number of nitrate oxygen atoms (when the Debye-Waller factor,  $\sigma^2$ , for the equatorial oxygen atoms is held constant). This decrease in the number of coordinated nitrate oxygen atoms with no change in the number of coordinated TBP groups is entirely inconsistent with the formation of even small amounts of  $UO_2(NO_3)_3^-$  in the heavy phase, given the bicoordinate nature of the nitrate groups demonstrated by the IR data. The additional equivalent of  $NO_3^-$  present in the third phase cannot be present in the U(VI) inner coordination sphere.

All of our results are consistent with some of the bidentate nitrate ligands of  $UO_2(NO_3)_2 \cdot 2TBP$  becoming monodentate with respect to a single U(VI) in order to bridge two uranyl centers or possibly to form a strong hydrogen bond with the water or nitric acid present in the heavy phase. Such behavior would lower the symmetry of the complex, accounting for the change in the UV-visible spectrum for the heavy phase without requiring the presence of an inner sphere trinitrato complex. Nevertheless, the changes in the U(VI) inner coordination sphere that induce, or are a result of, third phase formation in the uranyl/nitrate/TBP system are subtle.

## SANS Measurements

SANS measurements on samples similar to those in Table 1, but prepared in deuterated *n*-dodecane, were made using the small-angle neutron diffractometer SAND at the Argonne National Laboratory Intense Pulsed Neutron Source (IPNS) as previously described [4]. Figure 3 shows the neutron scattering data for selected samples together with their fit to an elliptical form factor. Table 2 reports the values of the perpendicular (a) and parallel (b) semiaxis resulting from the elliptical form factor fit for all samples investigated, together with the gyration radius ( $R_g$ ) of the scattering entities present in solution.

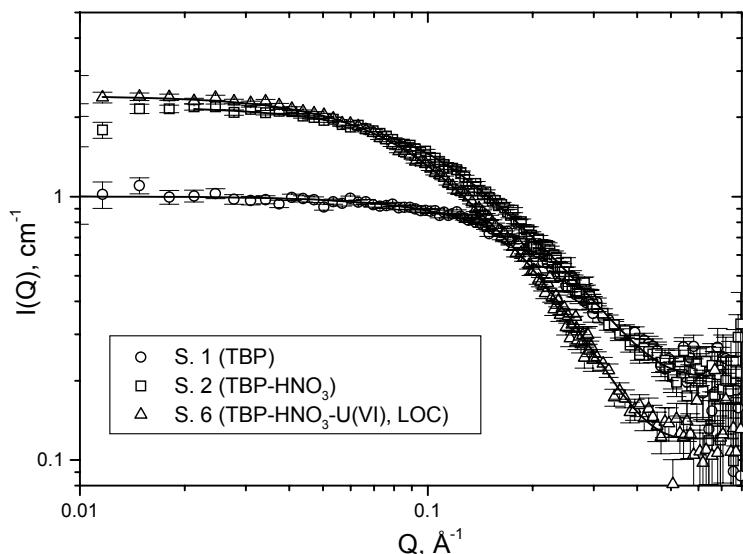

Figure 3. SANS data and fit to elliptical form factor for samples 1, 2 and 6.

Table 2. Elliptical form factor fit for U(VI)-TBP samples.

Sample no.	a Å	b Å	$R_g$ Å
1	$7.0 \pm 0.4$	$12.2 \pm 0.6$	$7.0 \pm 0.5$
2	$6.7 \pm 0.2$	$25.9 \pm 0.3$	$12.3 \pm 0.3$
3	$6.7 \pm 0.1$	$27.1 \pm 0.2$	$12.8 \pm 0.2$
4	$7.4 \pm 0.1$	$28.8 \pm 0.3$	$13.7 \pm 0.3$
6 (LOC)	$7.5 \pm 0.1$	$32.1 \pm 0.3$	$15.1 \pm 0.3$
8 (Light Ph.)	$7.1 \pm 0.2$	$25.2 \pm 0.3$	$12.1 \pm 0.3$

From the data in Table 2 it appears that growth of the solute particles along the parallel axis occurs when  $HNO_3$  is extracted by TBP. When extracted U(VI) progressively replaces  $HNO_3$  in the aggregates, only modest further growth takes place. The largest aggregates exist, as expected, in sample 6 (LOC), with the parallel axis  $b$  equal to approximately 3 times that for the TBP species in sample 1. Somewhat smaller aggregates exist in the light phase after phase splitting. The third phase sample presents a more complex scattering profile. Because the third phase is a highly concentrated sample, interpretation of the SANS data requires a different approach. Attempts to this effect are in progress.

## CONCLUSIONS

Chemical analyses, spectroscopic and EXAFS evidence indicate that, under the experimental conditions of this work, U(VI) is extracted by 20 % TBP in *n*-dodecane as  $\text{UO}_2(\text{NO}_3)_2 \cdot 2\text{TBP}$ , while the third phase species has the composition,  $\text{UO}_2(\text{NO}_3)_2 \cdot 2\text{TBP} \cdot \text{HNO}_3$  where both of the TBP oxygen atoms are in the inner coordination sphere. Aggregation of the organic phase species occurs upon  $\text{HNO}_3$  extraction in the absence of metal. Coextraction of U(VI) promotes only modest additional growth. Based on these results, it seems reasonable to conclude that formation of a third phase in this system is probably not caused by extensive solute aggregation. More likely, a dramatic change in solution leading to phase splitting takes place when one molecule of  $\text{HNO}_3$  becomes part of the U(VI)-adduct. At this point, the solute probably becomes too polar to exist in the alkane diluent and collects in a separate phase.

## SUPERCritical CO<sub>2</sub> FLUID LEACHING (SFL) OF URANIUM FROM SOLID WASTES USING HNO<sub>3</sub>-TBP COMPLEX AS A REACTANT

Osamu Tomioka, Yoshihiro Meguro\*, Shuichi Iso\*, Zenko Yoshida\*, Youichi Enokida\*\*, Ichiro Yamamoto

A new method, which is based on the efficient and selective dissolution of uranium oxides with supercritical CO<sub>2</sub> containing HNO<sub>3</sub>-tributylphosphate (TBP) complex and is referred to as supercritical CO<sub>2</sub> fluid leaching (SFL) method, has been developed for the removal of uranium from the solid waste contaminated by uranium oxides. It was found that uranium oxides, UO<sub>2</sub> or U<sub>3</sub>O<sub>8</sub>, could be dissolved almost completely in supercritical CO<sub>2</sub> phase at 60 °C and 20 MPa. The feasibility of the SFL method for the decontamination of uranium from the solid wastes was demonstrated using a synthetic waste, *i. e.*, a mixture of the standard sea sand (*ca.* 50 g) and UO<sub>2</sub> or U<sub>3</sub>O<sub>8</sub> powders (*ca.* 100 mg of U). The decontamination factor of UO<sub>2</sub> or U<sub>3</sub>O<sub>8</sub> of 10<sup>2</sup> or 10<sup>4</sup>, respectively, were attained by the recommended procedure.

### INTRODUCTION

Removal of radioactive contaminants from various solid wastes such as mine tailings, ash and sludge products from the nuclear processes leads to safe and economical storage and disposal of these wastes. The decontamination treatment of the solid wastes, however, is not commonly conducted because of the following methodological limitations; methods feasible for a large-scale treatment of the wastes are very limited and a large amount of the secondary wastes is often generated from the decontamination process. A method based on a new principle, which can be applied to the contaminated solid of a large amount and generates less process waste, is required to be developed.

Recently, much attention has been paid to a novel method for the separation of metals using the supercritical CO<sub>2</sub> fluid as a medium [1-12]. Supercritical fluid extraction (SFE) with the supercritical CO<sub>2</sub> instead of an organic solvent has several advantages as follows. The extraction efficiency and rate are expected to be enhanced due to rapid mass transfer in the supercritical fluid phase. The rapid and complete recovery of the extracted substances from CO<sub>2</sub> is attained by gasification of CO<sub>2</sub>. The extraction efficiency or selectivity can be optimized by changing optionally the properties of the CO<sub>2</sub> medium by tuning pressure or temperature [3,11]. The use of SFE in the field of nuclear technology exhibits a particular significance for minimizing the amount of the radioactive solvent waste [13]. The authors have developed the SFE of U(VI) and Pu(IV) from nitric acid solution using supercritical CO<sub>2</sub> containing tributylphosphate(TBP) [1-4,13]. An alternative and more attractive method based on the SFE is "direct leaching (extraction)" of the metals from the solid samples. Neither organic solvent nor acid for the pretreatment of the samples are necessary to be used in this method, which leads to a total minimization of the secondary wastes generated from the metal separation process.

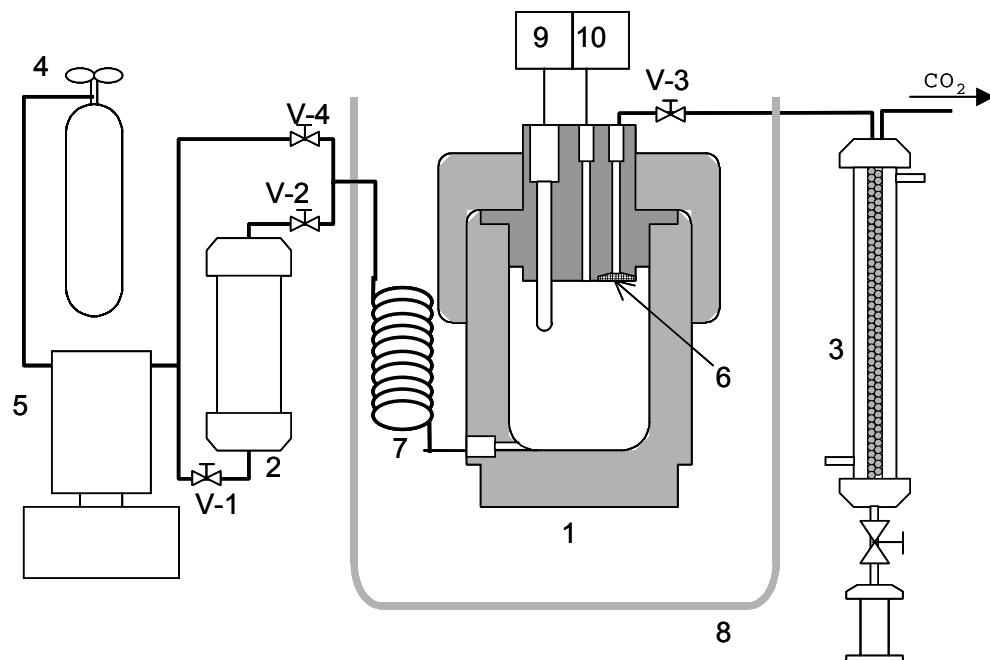

The present study aims at the development of a method, *i.e.*, the supercritical CO<sub>2</sub> fluid leaching (SFL), for the decontamination of uranium from the solid wastes containing uranium oxides, UO<sub>2</sub> or U<sub>3</sub>O<sub>8</sub>. The HNO<sub>3</sub>-TBP complex was employed as a reactant to dissolve the uranium oxides efficiently and selectively into supercritical CO<sub>2</sub> phase.

## EXPERIMENTAL

Apparatus for the SFL, which was essentially identical to that used for the supercritical CO<sub>2</sub> fluid extraction of the metal from an aqueous solution [2], is shown in Figure 1. The main part of the apparatus consisted of a stainless steel reaction vessel (50 ml), which was installed in a thermostat oven (60°C), a reactant mixing vessel and a collector. Stainless balls of 3.2 mm in diameter were packed in the collector which was made of Pyrex glass cylinder of 300 mm in height and 10 mm in diameter with water jacket to keep temperature at 60 °C. A syringe pump was used to flow CO<sub>2</sub>.

The HNO<sub>3</sub>-TBP complex was prepared by mixing vigorously 100 ml of 70% HNO<sub>3</sub> (Wako Pure Chemicals Co.) with 100 ml of TBP (Koso Chemical Co.) in a conventional extraction tube for 30 min. The HNO<sub>3</sub>-TBP complex liquid thus obtained was determined to contain HNO<sub>3</sub> and TBP at mole ratio of 1.4 ~ 1.5 : 1 as the mixture of (HNO<sub>3</sub>)<sub>2</sub>(TBP) and HNO<sub>3</sub>(TBP) complexes[14]. The water content of the HNO<sub>3</sub>-TBP complex was determined to be 1.6 mol/l by Karl-Fischer titration method.

A synthetic solid waste sample was a mixture of ca. 100 ~ 200 mg of UO<sub>2</sub> or U<sub>3</sub>O<sub>8</sub> powders and 50 g of the standard sea sand (Wako, 20-30 mesh). The UO<sub>2</sub> powder was obtained by grinding mechanically the UO<sub>2</sub> nuclear fuel pellet and the U<sub>3</sub>O<sub>8</sub> was prepared by heating the UO<sub>2</sub> powder at 480 °C in air for 2 hrs.

- 10; pressure gauge.

## RECOMMENDED PROCEDURE

Place the solid waste sample (*ca.* 50 g) in the reaction vessel (1) and keep the temperature inside the vessel at 60°C. Take an aliquot of HNO<sub>3</sub>-TBP complex (2.2 ml) in the reactant mixing vessel (2) of 15.7 ml in inner volume which is kept at 25°C. Close all valves V-1 to V-4. Open valve V-1 and introduce the CO<sub>2</sub> into the reactant mixing vessel by means of the syringe pump (5) until the pressure in the vessel becomes 20 MPa. Open V-2 to introduce a mixture of the HNO<sub>3</sub>-TBP complex and the CO<sub>2</sub> into the reaction vessel through the pre-heating coil using the syringe pump until the pressure becomes 20 MPa. Close V-2 and allow the system to stand for an appropriate time (30 to 180 mins) to leach uranium from the solid sample [static SFL procedure]. After the static SFL, open V-4 and V-3 and flow the CO<sub>2</sub> at a given flow rate (3.0 ml/min at the syringe pump and 3.6 ml/min at the outlet of the reaction vessel) for an appropriate time (30 to 180 mins) to transport such CO<sub>2</sub>-soluble contents of the reaction vessel as the uranium-TBP complex and the HNO<sub>3</sub>-TBP complex unreacted into the collection vessel through a restrictor and to wash the solid wastes [washing procedure].

## RESULTS AND DISCUSSION

Fundamental studies have been performed on the dissolution behavior of UO<sub>2</sub> or U<sub>3</sub>O<sub>8</sub> in supercritical CO<sub>2</sub> containing HNO<sub>3</sub>-TBP complex as a reactant. The results obtained are summarized as below, and will be published [15] in more detail.

- (i) The UO<sub>2</sub> and U<sub>3</sub>O<sub>8</sub> powders react with HNO<sub>3</sub>-TBP complex in the supercritical CO<sub>2</sub> medium to form U(VI)-TBP complex, UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>(TBP)<sub>2</sub>, which is soluble in the CO<sub>2</sub> phase. The UO<sub>2</sub> or U<sub>3</sub>O<sub>8</sub> solids can be thus dissolved (leached) in the supercritical CO<sub>2</sub> phase.
- (ii) The rate of the dissolution of UO<sub>2</sub> or U<sub>3</sub>O<sub>8</sub> is high enough when the content of HNO<sub>3</sub> in the HNO<sub>3</sub>-TBP complex is high. In particular, when the ratio of the mole fraction of HNO<sub>3</sub> to that of TBP is larger than unity, *i.e.*, the content of 2 : 1 complex (HNO<sub>3</sub>)<sub>2</sub>TBP becomes large, the dissolution rate increases remarkably.
- (iii) The dissolution of UO<sub>2</sub> or U<sub>3</sub>O<sub>8</sub> is facilitated by the presence of the water which is dissolved in the CO<sub>2</sub> phase at the concentration more than *ca.* 0.2 mol/l.
- (iv) The dissolution rate is not strongly dependent on the temperature in the range of 40 to 60°C, and is dependent on the pressure so that the dissolution rate decreases with an increase of the pressure in the range of 12 to 25 MPa.
- (v) The UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>(TBP)<sub>2</sub> complex dissolved into the supercritical CO<sub>2</sub> can be completely recovered in the collector. The UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>(TBP)<sub>2</sub> is decomposed by mixing with 1 M (NH<sub>4</sub>)<sub>2</sub>CO<sub>3</sub> solution and U(VI) is dissolved into the aqueous solution.

The reactant HNO<sub>3</sub>-TBP complex was found to be enough effective to dissolve UO<sub>2</sub> or U<sub>3</sub>O<sub>8</sub> and to play multi-functions as follows in the dissolution of the uranium oxides. (i) H<sup>+</sup> contained in HNO<sub>3</sub>-TBP complex dissociates the U-O bond, (ii) NO<sub>3</sub><sup>-</sup> in the complex plays roles both as an oxidant to convert U(IV) to U(VI) and as the counter anion to neutralize the uranium ion, and (iii) TBP acts as a complex forming agent to result hydrophobic complex UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>(TBP)<sub>2</sub>, being soluble into supercritical CO<sub>2</sub> phase [2].

The decontamination of the synthetic uranium-containing solid wastes, the mixture of UO<sub>2</sub> or U<sub>3</sub>O<sub>8</sub> and the standard sea sand, was conducted according to the recommended procedure. The sand sample after the decontamination procedure was washed to remove uranium using concentrated nitric acid at boiling point for 30 min. The concentration of uranium in the nitric acid solution was analyzed by an ICP-AES (Shimadzu, ICPS-8000E). The results are shown in Table 1.

*Table 1. Decontamination efficiency of synthetic uranium-containing solid wastes by SFL using the supercritical CO<sub>2</sub> + HNO<sub>3</sub>-TBP complex.*

Synthetic solid wastes	Total amount of U remaining in the solid after the SFL (mg)	Decontamination factor (DF) <sup>1)</sup>
120 mg UO <sub>2</sub> powder + 50 g sea sand	0.3	3.5 × 10 <sup>2</sup>
120 mg U <sub>3</sub> O <sub>8</sub> powder + 50 g sea sand	0.009	1.1 × 10 <sup>4</sup>

SFL condition; 60 °C, 20 MPa, the static SFL for 150 mins and washing for 100 min (flow-rate of CO<sub>2</sub>; 3.5 ml/min).

<sup>1)</sup>DF = (U before SFL) / (U after SFL)

The solid sample after the SFL treatment was in a form of dried solid which contains neither acid and organic solvent nor reactant. It was found also that most of uranium (95-99%) was recovered in the collector. This allows the further treatment or management of the solid waste more easily. Uranium(VI) was quantitatively stripped as U(VI)-carbonate from the UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>(TBP)<sub>2</sub> using (NH<sub>4</sub>)<sub>2</sub>CO<sub>3</sub> aqueous solution and the TBP recovered can be reused.

The synthetic solid waste employed in the present work was the simple physical mixture of uranium oxides and sand. Many real wastes generated from the nuclear-fuel production processes are in the form of the simple mixture of the uranium oxides and a variety of solid substances. The recommended procedure can be applied to these solid wastes. On the other hand, a waste containing uranium which is strongly bound to the solid matrices is also present. Further investigation is now in progress to optimize the SFL condition for the practical use of the method for the treatment of such wastes of more complicated form.

## CONCLUSION

A supercritical CO<sub>2</sub> fluid leaching (SFL) method for the decontamination of uranium oxides from uranium-containing solid wastes has been developed. The UO<sub>2</sub> or U<sub>3</sub>O<sub>8</sub> in the solid wastes can be removed and recovered using the supercritical CO<sub>2</sub> containing HNO<sub>3</sub>-TBP reactant. The most distinguished advantages with the proposed SFL method are that (i) the highly efficient removal of U(VI) is attained, (ii) a generation of the secondary wastes from the decontamination process is totally minimized, and (iii) CO<sub>2</sub> and even HNO<sub>3</sub>-TBP reactant can be easily reused.

## STRUCTURAL STUDIES BY NMR AND MOLECULAR DYNAMIC CALCULATIONS OF LANTHANIDE COMPLEXES WITH ETHOXY MALONAMIDES IN SOLUTION

Claude Berthon, Philippe Guilbaud, Maryline Bousquet and Chantal Gimenez

CEA – Marcoule, Bagnols-sur-Cèze, France

<sup>17</sup>O NMR spectra obtained with TEEEMA (2-(2-ethoxyethyl)-N,N,N',N'-tetraethylmalonamide) in solution are consistent with solid state results: there is a direct carbonyl oxygen interaction with the metal ion that is not observed with the ether oxygen. Structural information such as the ratio of average distance between metal and carbon atoms of the ligand are determined from the <sup>13</sup>C NMR longitudinal relaxation time. The experimental data are used as constraints for molecular dynamic simulations. Calculations performed with the TEEEMA/La<sup>3+</sup>/H<sub>2</sub>O system show that the more water molecules there are in the system, the better the agreement between experimental and calculated results. <sup>1</sup>H NMR spectra of malonamides obtained at low temperatures in a H<sub>2</sub>O/acetone/CBr<sub>2</sub>F<sub>2</sub> mixture show a water molecule in the first coordination sphere of La(III). This water molecule appears able to bind with the metal and the ether oxygen, in good agreement with molecular dynamic simulations.

### INTRODUCTION

In studies related to nuclear fuel reprocessing, malonamides have been proposed as extractants [1] able to separate trivalent actinides from most fission products with the exception of the trivalent lanthanides, which are coextracted with actinides(III). Extensive data have been compiled to understand the extraction mechanisms. A large number of molecules with the general formula RR'N-COCHR"-CO-NRR' have been evaluated. Malonamides with the ethoxy alkyl chain R" are molecules of interest because they lead to higher extraction [2] of both actinides(III) and lanthanides(III) than those with an alkyl chain R". In order to explain this behavior, it was suggested that the ether O atom present in the R" radical participates in complexation. However, it has been established that this potential donor atom is not bound to the metal ion in the solid state [3, 4]. Because there is no straightforward answer concerning such systems in liquid media, the present study attempts to elucidate the structure of a malonamide ligand complexed to a lanthanide nitrate in a liquid phase. NMR experimental data combined with theoretical calculations yielded significant data about the TEEEMA/Nd(NO<sub>3</sub>)<sub>3</sub>/CH<sub>3</sub>CN system.

### EXPERIMENTAL DESCRIPTION

Among the malonamides, TEEEMA (Figure 1) was chosen in this study for <sup>17</sup>O NMR and theoretical calculation purposes. Light molecules yield narrower NMR signals than the conventional malonamide extractant, with long hydrophobic alkyl chains. Moreover, short alkyl or alkyl ethoxy chains make dynamic calculations less time consuming. TEEEMA was provided by Panchim, Lisses (91), France, and used without further purification.

DMDOHEMA (2-[2-(hexyloxy)ethyl]-*N,N'*-dimethyl-*N,N'*-dioctylmalonamide) was also provided by Panchim. Acetonitrile, the liquid medium of the system, and lanthanide nitrates  $\text{La}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$  or  $\text{Nd}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$  (Aldrich) were all at least reagent grade and were used as received. Acetonitrile-d3 and acetone-d6 (Euriso-Top) provided a deuterium lock signal. The  $\text{CBr}_2\text{F}_2$  (Aldrich) was used as received (97% purity) to prepare a mixture with acetone for low-temperature NMR experiments.

The NMR spectra were recorded on a Varian 300 VXR-s spectrometer equipped with a 5 mm broadband probe. Quantum mechanics calculations were carried out with the Gaussian 98 program [5], molecular dynamic (MD) simulations with Amber [6,7] release 5, and programs for imaging or analysis of molecular trajectories in solution with MDS and Draw [8]. All calculations were performed with R12000 Silicon Graphics processors.

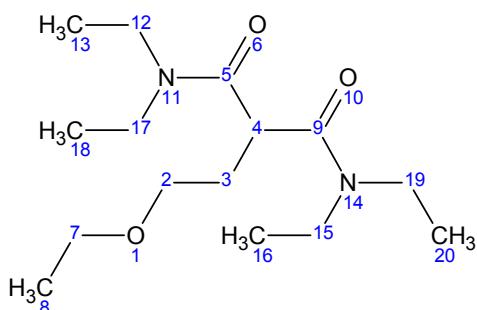

Figure 1. TEEEMA molecule (2-(2-ethoxyethyl)- $N^1,N^1,N^3,N^3$ -tetraethylmalonamide) with atom numbering.

## EXPERIMENTAL RESULTS: $^{17}\text{O}$ NMR SPECTRA

One of the easiest ways to check oxygen binding with lanthanide(III) ion in solution is to examine  $^{17}\text{O}$  NMR spectrum variations due to the presence or absence of a paramagnetic cation. From a TEEEMA solution in  $\text{CD}_3\text{CN}$ , it can be seen (Figure 2A) that the carboxyl O atoms ( $\text{O}_6$  and  $\text{O}_{10}$ ) are 327 ppm and the ether O atom ( $\text{O}_1$ ) is 9 ppm from the  $\text{D}_2\text{O}$  reference signal. When Nd(III) nitrate is added to this solution, only the carboxyl signal is enlarged (590 Hz to 1445 Hz) and shifted up field. There is, in fact, a direct interaction between the carboxyl oxygen atoms and the metal ion, while the ether O atom is not directly bound to the paramagnetic ion.

This straightforward answer is in agreement with solid state results. However, we carried out further NMR and MD structural investigations in solution.

## STRUCTURAL STUDIES

### NMR Investigation

The malonamide:metal ion stoichiometry of the complexes formed is commonly 1:1 and/or 2:1 depending on the lanthanide nitrate and ionic strength of the medium [9-11]. After  $^1\text{H}$  and  $^{13}\text{C}$  NMR assignments of the TEEEMA in  $\text{CD}_3\text{CN}$ , the binding constant and stoichiometry were determined for the TEEEMA/ $\text{Nd}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}/\text{CH}_3\text{CN}$  system by chemical shift analysis. The concentration of neodymium nitrate was kept constant during the experiments, with variable TEEEMA concentrations. From  $^1\text{H}$  and  $^{13}\text{C}$  NMR signal analysis, the best results were obtained for 2:1 stoichiometry and the binding constant corresponding to the following equilibrium was found to be  $K_{21}=1.3 \pm 0.1 \text{ mol} \cdot \text{L}^{-1}$ .

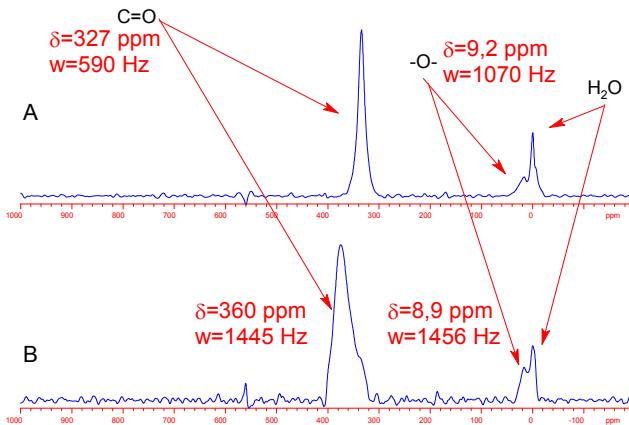

Figure 2.  $^{17}\text{O}$  NMR spectra of TEEEMA  $0.1\text{mol}\cdot\text{L}^{-1}$  in  $\text{CD}_3\text{CN}$  with (bottom) and without (top)  $\text{Nd}(\text{NO}_3)_3$   $0.045\text{mol}\cdot\text{L}^{-1}$ .

At room temperature, it has been established that a fast exchange occurs for this system on the NMR time scale. Because of this fast exchange, the observed relaxation times  $T_{1\text{obs}}$  are the sum of the contributions from each  $T_1$  TEEEMA species: free and bound TEEEMA (respectively  $T_{1f}$  and  $T_{1b}$  in Eq. 1;  $x$  is the molar fraction of the complex). In order to extract the  $\text{TEEEMA}_2\text{Nd}(\text{NO}_3)_3$  complex longitudinal relaxation time from  $^{13}\text{C}$  NMR  $T_1$  measurements, further analysis was performed using the binding constant determined earlier.

$$\frac{1}{T_{1\text{obs}}} = \frac{1}{T_{1f}} + x \frac{1}{T_{1b}} \quad (1)$$

We paid special attention to  $^{13}\text{C}$  atoms 2 and 7, which neighbor on the ether oxygen, and to carbon atom 4, which is in a central position within the malonamide. These three nuclei are far enough from the complex metallic center so that the contact interaction term is negligible. The main contribution to the  $T_1$  relaxation time in the paramagnetic complex ( $T_{1b}$ ) thus comes from dipole-dipole interactions from which structural information can be deduced. The ratio of the induced relaxation rates of the nuclei  $i$  and  $j$  is given as:

$$\frac{T_{1b}(i)}{T_{1b}(j)} = \left( \frac{R_i}{R_j} \right)^6 \quad (2)$$

where  $R_i$  and  $R_j$  are the average distances between the Nd(III) metal ion and the  $^{13}\text{C}$  nuclei  $i$  and  $j$  of the ligand. The experimental ratios obtained from the relaxation time values of the selected carbon atoms were then used for molecular dynamic simulations.

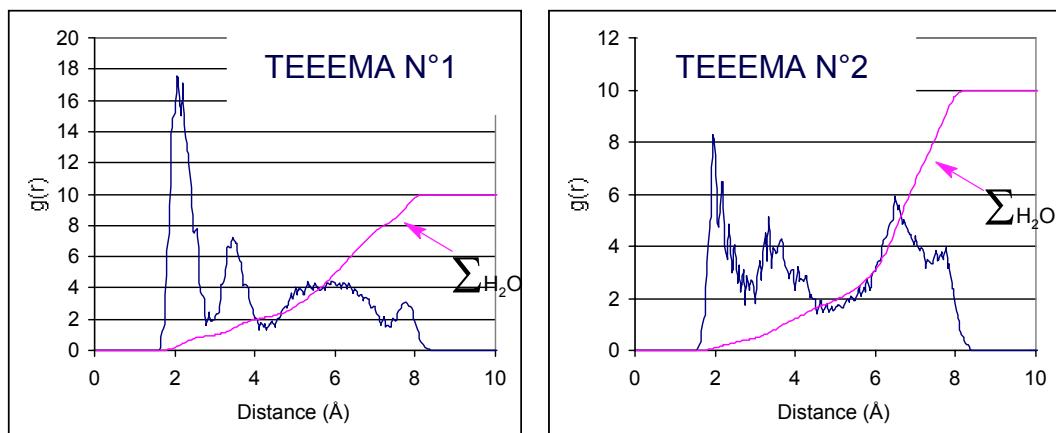

### Theoretical Calculations

After TEEEMA partial charge calculation of the atoms, the structure was optimized by *ab initio* quantum mechanics calculations using the 6-31G<sup>\*\*</sup> basis set. MD studies were performed on a system composed of two TEEEMA molecules and one lanthanum cation with 0 to 5 H<sub>2</sub>O molecules, in a vacuum and in a water box. For convenience, the Nd(III) were replaced by the La(III) metallic ion because a consistent published set of La<sup>3+</sup>, Eu<sup>3+</sup> and Lu<sup>3+</sup> parameters was available [12]. We verified later that the choice of La<sup>3+</sup> instead of Eu<sup>3+</sup> to simulate experimental results with the Nd<sup>3+</sup> did not induce any significant change in our study.

The  $R_4$  distance was determined for various complexes using MD simulations. From the NMR relaxation time ratios determined above,  $R_{2(NMR)}$  and  $R_{7(NMR)}$  distances were obtained and compared with  $R_{2(MD)}$  and  $R_{7(MD)}$  from MD simulations. In the gas phase without  $\text{H}_2\text{O}$  molecules, the O ether atom may or may not be coordinated with the metal, in which case the  $R_{2(MD)}$  and  $R_{7(MD)}$  values are either too short or too long. From MD simulations with 1 to 5 water molecules, we noted that the more  $\text{H}_2\text{O}$  molecules in the first coordination sphere of  $\text{La}^{3+}$ , the closer  $R_{2(MD)}$  and  $R_{7(MD)}$  are to  $R_{2(NMR)}$  and  $R_{7(NMR)}$ . In a water box, at least one TEEEMA molecule is bidentate and the other malonamide may be dissociated or monodentate. The  $\text{La}^{3+}$  ion may also be coordinated with 6 to 7 water molecules.

Another series of MD simulations was performed with  $R_{2(MD)}$  and  $R_{7(MD)}$  constrained to  $R_{2(NMR)}$  and  $R_{7(NMR)}$ . From gas phase simulations with water molecules, the number of hydrogen bonds with the O ether atom was found to increase with the number of  $\text{H}_2\text{O}$  molecules in the system. However, in a water box, one TEEEMA molecule is monodentate.

Thus, for bidentate coordination of TEEEMA ligands, the agreement between the experimental and calculated distance ratios improves as the number of water molecules in the system increases. More interestingly, from the simulated trajectories, the analysis of the Radial Distribution Functions (RDF) of water protons around the O ether (Figure 3) reveals that one water molecule is bound to one malonamide. According to the second malonamide RDFs and visual inspection of the trajectories, it can be seen that the aforementioned water molecule temporarily bridges the TEEEMA ether oxygen. The other molecules are at least 5 Å from the TEEEMA ethoxy chain.

*Figure 3. Water-ether oxygen radial distribution function (RDF) for both malonamides from simulated trajectories in the case of a MD with five water molecules. Pink curves characterize the sum of the  $\text{H}_2\text{O}$  hydrogens ( $\Sigma_{\text{H}_2\text{O}}$ ).*

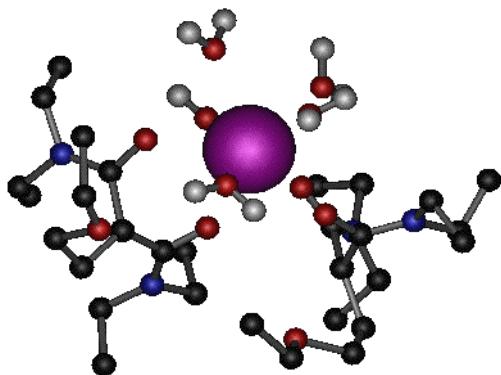

One of the most typical structures during MD simulations with five water molecules in the gas phase is shown in Figure 4. Note that the oxygen atom of the ethoxy chain may be bound to the metal atom via a water molecule.

Further NMR experiments were carried out at low temperatures to check these interesting results.

### LOW-TEMPERATURE $^1\text{H}$ NMR SPECTRA

The low-temperature NMR technique allows the metal-ion solvation shell to be studied directly. Extensive research has been done in this field recently [13]. At temperatures below -100°C, proton and ligand exchange are slow enough to permit direct observation of  $^1\text{H}$

resonance signals for coordinated and free water molecules, leading to an accurate measure of the  $\text{La}(\text{NO}_3)_3$  hydration number. Such temperatures require an acetone/ $\text{CBr}_2\text{F}_2$  mixture to preserve a liquid phase.

*Figure 4. Image of the  $(\text{TEEEMA})_2/\text{La}^{3+}/(\text{H}_2\text{O})_5$  system during the molecular dynamic simulation with  $R_{2(\text{NMR})}$  and  $R_{7(\text{NMR})}$  constraints of 5 kcal·mol<sup>-1</sup>.*

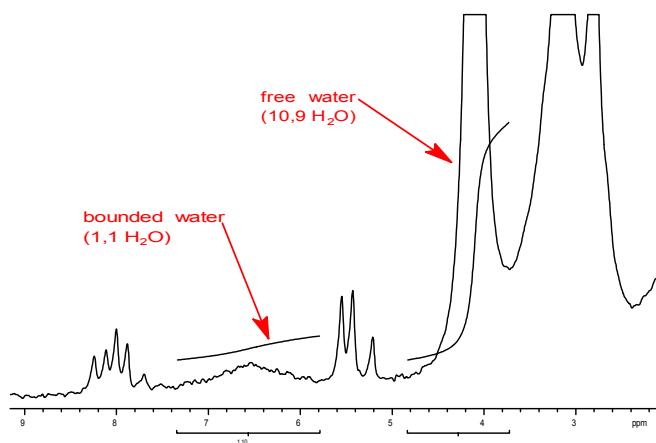

Because of the small amount of TEEEMA available in our laboratory, NMR experiments were carried out with DMDOHEMA. In a way, this hydrophobic malonamide brought us closer to the extraction process. A diamagnetic cation, La(III), was used in preference to a paramagnetic one (Nd(III)) to prevent a broad <sup>1</sup>H signal especially for the bound water.

<sup>1</sup>H NMR spectra were obtained from three kinds of solutions:

- DMDOHEMA/acetone/ $\text{CBr}_2\text{F}_2$
- $\text{La}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ /acetone/ $\text{CBr}_2\text{F}_2$
- $\text{La}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$ /DMDOHEMA/acetone/ $\text{CBr}_2\text{F}_2$

The first one allowed us to determine the amount of free water in the DMDOHEMA sample (3  $\text{H}_2\text{O}$  molecules per malonamide). The second spectrum showed two  $\text{H}_2\text{O}$  signals: coordinated water at low field (2 water molecules per lanthanum cation) and free water (4 water molecules). The La(III) hydration number of two is in agreement with other studies [14]. According to the two previous spectra, Figure 5, showing the third spectrum, suggests that the water molecule is bound to the lanthanum cation.

The first coordination sphere of the metal ion thus comprises two DMDOHEMA molecules directly bonded via the carbonyl groups and one water molecule.

*Figure 5. <sup>1</sup>H NMR spectrum of DMDOHEMA 0.06 mol·L<sup>-1</sup> with  $\text{La}(\text{NO}_3)_3 \cdot 6\text{H}_2\text{O}$  0.03 mol·L<sup>-1</sup> in an acetone: $\text{CBr}_2\text{F}_2$  mixture (molar ratio 2:1) at -112°C.*

## CONCLUSION

MD simulations and experimental distances ( $R_2$  and  $R_7$ ) suggest that a water molecule may be bound to the ether oxygen via a hydrogen bond; a direct ether oxygen bond to the metal would have given short  $R_2$  and  $R_7$  values. Low-temperature NMR experiments clearly validate these results by showing there is only one water molecule in the first coordination sphere of the metal which is in fast exchange with free water.

The enhanced extraction properties of malonamide with an ethoxy chain may be explained, in part, by the ability of a water molecule to be extracted in the organic phase. Consequently, the hydration sphere of the lanthanum does not need to be completely removed to allow extraction of the metal.

One of our future projects will be to check whether water molecules are involved in alkyl malonamide complexed with lanthanide(III) nitrates. The number and the position of the oxygen atoms in the oxyalkyl chain will be studied in solution. In addition, the MD simulations will be improved by adding nitrates.

## EXTRACTION OF Ln(III) AND Am(III) FROM NITRATE MEDIA BY MALONAMIDES AND POLYDENDATE N-BEARING LIGANDS

M.C. Charbonnel, J.L. Flandin, S. Giroux, M.T. Presson, C. Madic and J.P. Morel\*

CEA/Valrho, Marcoule, Bagnols-sur-Cèze, France

\* Université Blaise Pascal, Aubière, France

Malonamides and polydendate N-bearing ligands are promising extractants for the partitioning of actinides from high-level active nuclear wastes. This study focuses on the stoichiometry of their extracted complexes of actinides(III) and lanthanides(III) and on some related thermodynamic properties.

The extraction of Nd(III) from 2.5 M NaNO<sub>3</sub> by the malonamides DMDBTDMA and DMDOHEMA in dodecane has been studied in the range of temperature 10 to 40°C. The stoichiometry of the extracted complexes Nd(NO<sub>3</sub>)<sub>3</sub>L<sub>x</sub> is influenced by temperature for both extractants. Consequently the classical van't Hoff method should be used with care to determine the extraction enthalpy  $\Delta_{ext}H$ ; microcalorimetric titration seems to be more appropriate for such a complex chemical system.

The extraction of Eu(III) and Am(III) from 2.5 M NaNO<sub>3</sub> into *pr*-BTPs in octanol-1 has also been studied. The specie ML<sub>3</sub>(NO<sub>3</sub>)<sub>3</sub> is the dominant extracted complex under all experimental conditions and the extraction enthalpies and entropies have been calculated from the temperature dependence of the metal ion distribution ratios. The driving force for Am(III) or Eu(III) extraction by *pr*-BTPs from aqueous nitrate solution is the enthalpic term of the Gibbs free energy. The extraction is more exothermic for Am(III) than for Eu(III) which is an indication of the enhanced Am-BTP bond strength.

### INTRODUCTION

This study was carried out under the CEA programme for the partitioning of long-lived radionuclides, particularly the minor actinides, contained in high-level radioactive liquid waste (HAW) generated by reprocessing nuclear spent fuel. The first step of the separation strategy is the DIAMEX process, designed to coextract trivalent actinides and lanthanides from the HAW using a diamide extractant. The malonamide DMDBTDMA (N,N'-dimethyl-N,N'-dibutyltetradecylmalonic diamide) was the first reference extractant; extensive data were therefore collected to understand its extraction behaviour and to define a computer model of the DIAMEX process [1]. The extractant has been optimized to improve the extraction properties [2]; since 1997, the reference molecule is DMDOHEMA (N,N'-dimethyl-N,N'-diethyl-hexylethoxymalonic diamide). The second step of the strategy is the SANEX (Selective ActiNide(III) EXtraction) process, designed to separate actinides(III) from lanthanides(III). Among numerous nitrogen polydendate ligands, BTP molecules (2,6-bis(5,6-alkyl-1,2,4-triazin-3-yl)pyridines) were found promising [3,4] because the Am(III)/Ln(III) separation could be performed from highly acidic liquid waste. Counter-current hot tests with genuine high-level liquid waste confirmed the feasibility of the DIAMEX and SANEX concepts [1,3].

Although extraction and structural studies have been performed on both systems [1,3], very few basic data on the complexes present in the organic phases have been published to date. Some results obtained in this field are briefly presented here.

## EXPERIMENTAL

### Materials

The malonamides DMDBTDMA and DMDOHEMA were provided by Panchim, Lisses, 91029 EVRY Cedex, France. Their purity, determined by mass spectrometry, was better than 99%. The diamide DMDBTDMA was further purified on a alumina column to eliminate surface-active compounds [1]. The extractants 2,6-bis(5,6-bis-*iso*-propyl-1,2,4-triazin-3-yl)-pyridine and 2,6-bis(5,6-di-*n*-propyl-1,2,4-triazin-3-yl)-pyridine (designated *iPr*-BTP and *nPr*-BTP, respectively) were synthesized in our laboratory [4]. The purity of the BTP molecules was checked by NMR and mass spectrometry. Lanthanide(III) nitrates, lithium nitrate, sodium nitrate, *n*-dodecane and *n*-octanol-1 were reagent grade with purity better than 99% .

### Procedure and Apparatus

Organic phases were systematically pre-equilibrated with suitable aqueous solutions a few hours before the tests. The rare earth concentration in each phase was determined either by arsenazo III visible spectrophotometric analysis, X-ray fluorescence measurements or Inductive Coupled Plasma analysis. The radionuclides  $^{152}\text{Eu}$  and  $^{241}\text{Am}$  were used as tracers for some experiments and were measured by gamma spectrometry (at 121.8 keV and 59.54 keV, respectively).

For measurements at variable temperatures, a Haake bath was used with a temperature control of  $\pm 0.1^\circ\text{C}$ .

Microcalorimetric titrations were performed with a Thermal Activity Monitor (TAM) microcalorimeter from Thermometric. This modular system with a highly stable temperature-controlled bath ( $\pm 0.2 \text{ mK}$ ) could contain up to four calorimetry vessel units. The aqueous phase was loaded in a 2 mL glass ampoule and the organic phase was delivered through a fine bore cannula. The volume of titrant delivered was controlled by a programmable motor-driven syringe pump.

## RESULTS AND DISCUSSION

### Extraction of Ln(III) Nitrates by Malonamides in Neutral Aqueous Conditions

#### *Stoichiometries of extracted complexes*

Experiments were conducted to determine the enthalpy of Ln(III) and An(III) nitrates extraction by DMDBTDMA noted L hereafter. The extraction of Ln(III) or An(III) proceeds through the formation of solvates according to Equation 1:

Of course, the knowledge of the nature of all species present in the organic phases is a prerequisite condition to allow a correct interpretation of the extraction data and for the determination of the extraction thermodynamic properties.

The first measurements were related to the extraction of Nd(III) from aqueous phases ( $\text{NaNO}_3$ ) without acid. The pH was measured and the concentration of the lanthanide ion was checked before and after extraction. The pH was equal to 5.9 which is sufficient at conditions of  $2.5 \text{ mol.L}^{-1}$  ionic strength to prevent metal ion hydrolysis and precipitation [5].

The experimental conditions were selected to have a constant ionic strength in the aqueous phases and thus to ignore the variation of the aqueous activity coefficients. As a first approximation, we also considered the ratio  $\gamma_{M(NO_3)_3L_x}/\gamma_L^x$  as constant. The apparent equilibrium constant  $K'$  can then be written as follows:

$$K' = \frac{[M(NO_3)_3L_x]}{[M^{3+}][NO_3^-]^3[L]^x} \quad (2)$$

The experimental distribution ratio  $D_M$  is the ratio of the concentrations of the extracted complex to the metal species in the aqueous phase, *i.e.*, the aquo  $M^{3+}$  and the 1/1  $M^{III}$  nitroso complex  $M(NO_3)_{aq}^{2+}$  with  $\beta_1$  stability constant:  $D_{Nd} = [M(NO_3)_3L_x] / [M^{3+}](1+\beta_1[NO_3^-])$ .

This equation combined with equation (2) gives an expression of  $D_M \cdot (1+\beta_1[NO_3^-])$  versus  $[L]$ . The slope of the log-log plot allows the determination of the stoichiometry of the extracted complex.  $[L]$  has been calculated as  $[Diamide]_{tot} \cdot x[Nd]_{org}$ . A first value for  $x$  was selected and then corrected if the slope obtained was not consistent with the hypothesis.

At 25°C, the average slope for the log-log plot was  $5.1 \pm 0.2$ . The involvement of five molecules of diamide in the extracted complex can be explained by the aggregation of diamide in the second sphere of coordination around the inner-sphere complex  $Nd(NO_3)_3L_2$  [6]. Numerous extraction studies by the classical slope method corresponding to aqueous acidic conditions indicate a metal/ligand stoichiometry close to 1/2 for the extracted complex. This result is consistent with most of the crystal structures published related to the complexes formed between Ln(III) nitrates and diamide ligands [4,7]. Nevertheless, some authors mentioned also conditions where  $x > 2$  [8] or  $x = \text{non-integer number}$  [9]. The authors often attributed these results to the existence of molecules of ligand in the second sphere of coordination of the metal ion. Metal/diamide stoichiometries close to five have also been pointed out in our laboratory by recent ESI-MS measurements.

In these experimental conditions, the main extracted complex seems to be  $Nd(NO_3)_3L_5$ .

In order to determine Nd(III) extraction thermodynamic parameters, we measured Nd(III) distribution ratios for different temperatures. The curves of  $\log D_{Nd}(1+\beta_1[NO_3^-])$  against  $\log [L]$  were plotted. The variation of  $\beta_1$  of the Nd(III) mononitroso complex with temperature can be neglected ( $\Delta H = 1.7 \text{ kJ.mol}^{-1}$  [10] at ionic strength 2.0 mol.kg $^{-1}$ ). We obtained surprising results because it was shown that the slopes of the log/log plots depend on the temperature, as presented in Figure 1: at 10 and 15°C, the slope is close to 3; at 20°C, the slope is close to 4, and at 25-30-35 and 40°C, the slope is close to 5.

The number of diamide molecules in the second sphere of co-ordination of Ln(III) increases with the temperature of extraction.

The same behaviour has also been observed for the diamide DMDOHEMA though the slopes are lower in this case: 2 at 10°C and 4 at 40°C, for example. So, one can conclude that the number of diamide molecules involved in the extraction of Ln(III) nitrates decreases for malonamides with a central group containing an ether oxygen.

The crystal structures of Ln(III) nitrate solvate of malonamide with an ethyl ethoxy chain indicated the absence of coordination of the ether oxygen with the metal ion [4,11].

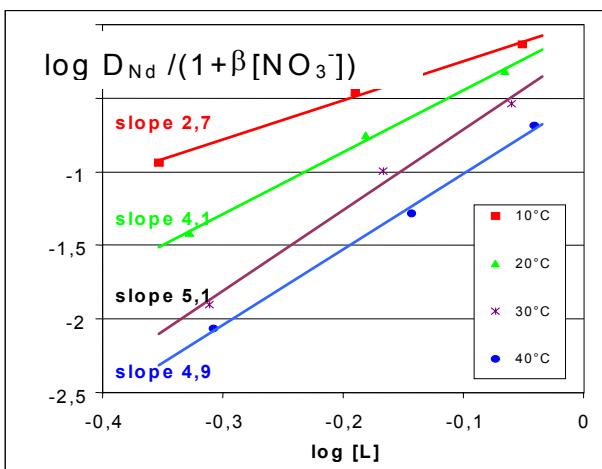

Figure 1. Effect of DMDBTDMA concentration on the extraction of neodymium(III) nitrate from 2.5 M NaNO<sub>3</sub> aqueous solution (pH 5.9-6.0) as a function of temperature.

Previous studies pointed out that the water concentration in the organic phases is higher for malonamides bearing an ethoxy group [1]. Water concentration measurements were done for both diamides DMDBTDMA and DMDOHEMA to compare the number of H<sub>2</sub>O molecules involved in the extraction of neodymium(III) nitrate. When neodymium(III) nitrate is extracted by a diamide, the concentration of water in the organic phase is higher than observed in the absence of Nd(III) (organic phase pre-equilibrated with NaNO<sub>3</sub>). From the data obtained it appears that Nd(III) nitrate is extracted by DMDBTDMA with one molecule of H<sub>2</sub>O and by DMDOHEMA with two molecules of H<sub>2</sub>O. The important role of H<sub>2</sub>O molecules was also pointed out for these systems by molecular modelling and NMR experiments [12] where the presence of a bridging H<sub>2</sub>O molecule between the metal ion and the oxygen ether in the Ln(III) nitrate extracted complex(es) could be an explanation for the better affinity of malonamides possessing an ethoxy group in their central substituent. At a molecular scale, the behaviour of the two diamide extractants seems to present some differences: the presence of more H<sub>2</sub>O molecules can possibly explain the lower number of ligands involved in the extraction of neodymium(III) nitrate by DMDOHEMA.

#### Determination of thermodynamic extraction properties

The Gibbs free energy related to this reaction,  $\Delta_{ext}G' = -RT \cdot \ln K'$  lead to the average value of  $2.4 \pm 0.2 \text{ kJ.mol}^{-1}$  (see some selected values in Table 1).

Table 1. Apparent constant of extraction of Nd(III) nitrate from 2.5 mol.L<sup>-1</sup> aqueous NaNO<sub>3</sub> solution by DMDBTDMA-dodecane solution (25°C ; [Nd]<sub>init</sub> = 0.1 mol.L<sup>-1</sup>).

[diamide] (mol L <sup>-1</sup> )	D <sub>Nd</sub>	K (L <sup>8</sup> .mol <sup>-8</sup> )	$\Delta_{ext}G'$ (kJ.mol <sup>-1</sup> )
0.42 ± 0.01	0.028	0.388	2.34
0.50 ± 0.01	0.056	0.368	2.42
0.66 ± 0.01	0.166	0.391	2.32
1.18 ± 0.05	1.22	0.385	2.36

If we assume that the slopes of the lines presented in Figure 1 are related to a single complex present in the organic phase, we can calculate K<sub>ext</sub> and ΔG'<sub>ext</sub> for each temperature. The corresponding data are presented in Table 2.

*Table 2. Values of  $K'$  and  $\Delta G'$  related to the extraction of Nd(III) nitrate from  $\text{NaNO}_3$  2.5 mol.L<sup>-1</sup> by DMDBTDMA in dodecane (0.5 to 1.1 mol.L<sup>-1</sup>).*

Temperature (°C)	Stoichiometry Nd(III)/diamide	$K'$ (L <sup>8</sup> .mol <sup>-8</sup> )	$\Delta G'$ (kJ.mol <sup>-1</sup> )
10	3	0.48 ± 0.03	+1.7 ± 0.2
15	3	0.35 ± 0.02	+2.5 ± 0.1
20	4	0.34 ± 0.05	+2.6 ± 0.3
25	5	0.37 ± 0.02	+2.4 ± 0.2
30	5	0.22 ± 0.05	+3.8 ± 0.4
35	5	0.21 ± 0.03	+4.0 ± 0.3
40	5	0.11 ± 0.02	+5.6 ± 0.4

The van't Hoff method can be applied only for determinations between 25 and 40°C for which the stoichiometry of complexes is similar: 1/5. The plot  $\log K'$  versus  $1/T$  gives straight lines and the slope gives the value  $\Delta H = -56 \pm 6 \text{ kJ.mol}^{-1}$ .

The microcalorimetric approach is certainly more appropriate here because each determination can be realised for one temperature (here 25°C) and thus for only one stoichiometry of the extracted complex. The quantity of heat measured after each addition of aliquot of organic phase has been divided by the amount of formed complex (*i.e.* organic neodymium transferred to the organic phase) to calculate  $\Delta H$ .

*Table 3. Microcalorimetric determination of enthalpy variations for the extraction of Nd(III) nitrate from  $\text{NaNO}_3$  aqueous solution by DMDBTDMA-dodecane solution.*

(Experimental conditions: 25°C; aqueous phase in vessel: 0.8 mL of  $[\text{Nd}]_{\text{init}} = 0.1 \text{ mol.L}^{-1}$  in 2.5 mol.L<sup>-1</sup>  $[\text{NO}_3^-]$ ; addition of aliquot of DMDBTDMA in dodecane pre-equilibrated with  $\text{NaNO}_3$ .)

[diamide] (mol.L <sup>-1</sup> )	Number and volume of aliquots added	Average heat (mJ)	$n_{\text{Nd}} / \text{each aliquot added (mol)}$	$\Delta_{\text{ext}}H$ (kJ.mol <sup>-1</sup> )
$0.50 \pm 0.01$	9 * 5 $\mu\text{L}$	-1.5 ± 0.1	$2.48.10^{-8}$	-63 ± 5
	20 * 10 $\mu\text{L}$	-3.4 ± 0.1	$5.04.10^{-8}$	-68 ± 5
$0.60 \pm 0.01$	9 * 5 $\mu\text{L}$	-3.3 ± 0.4	$5.0.10^{-8}$	-65 ± 8
$0.82 \pm 0.02$	9 * 5 $\mu\text{L}$	-9.1 ± 0.5	$1.52.10^{-7}$	-58 ± 3
$1.00 \pm 0.03$	9 * 5 $\mu\text{L}$	-12.3 ± 0.5	$3.17.10^{-7}$	-39 ± 3
$1.30 \pm 0.03$	9 * 5 $\mu\text{L}$	-24 ± 0.4	$8.36.10^{-7}$	-29 ± 1
	20 * 10 $\mu\text{L}$	-46.5 ± 1.5	$1.55.10^{-6}$	-30 ± 1

The  $\Delta H_{\text{ext}}$  values presented in Table 3 exhibit important variations with the DMDBTDMA concentration when  $[\text{diamide}] > 0.8 \text{ mol.L}^{-1}$ . This effect may be due to the supramolecular organisation of the Nd(III)-malonamide solvate at high diamide concentrations observed in third phases but also in organic phases in the absence of third phase [4].

In the diamide concentration range 0.5 to 0.9 mol.L<sup>-1</sup>, the results are the following:  $\Delta H = -63 \pm 5 \text{ kJ.mol}^{-1}$  by microcalorimetry and  $\Delta H = -56 \pm 5 \text{ kJ.mol}^{-1}$  by the classical van't Hoff method in the temperature range 25-40°C. The calculated values of  $\Delta H$  obtained by two different approaches give values that are quite similar. We think that microcalorimetry is certainly the best method for such a complex chemical system and we will try to optimize the experimental conditions to reduce the uncertainties. Moreover, we have to check our first assumption since the slopes of the log/log plots (Figure 1) can represent average values of the stoichiometries of different  $\text{Nd}(\text{NO}_3)_3\text{L}_x$  complexes present in the organic solutions.

However, we can estimate, for [diamide] < 0.9 mol.L<sup>-1</sup>, the variation of entropy for Nd(III) nitrate extraction by DMDBTDMA  $\Delta S = (\Delta H - \Delta G)/T$ :  $\Delta S = -220 \pm 20$  J.K<sup>-1</sup>.mol<sup>-1</sup>.

### Extraction of Eu(III) and Am(III) Nitrates by BTPs

Experiments were conducted with *n*- and iso-BTPs, which exhibited promising efficiency for the separation of Am(III) versus Eu(III) [3,4]. For this system, preliminary determinations were conducted to check the stoichiometry of the reaction (no data were published to date in absence of nitric acid and for a diluent of 100 % octanol-1).

We assumed that the extraction of Eu(III) proceeds in neutral conditions through the formation of solvates according to the following equation:

The ratio of the activity coefficients of the organic species is considered constant, and the thermodynamic activities of the aqueous species were calculated using the Mikulin relation:  $a_{M^{3+}(NO_3)_3} = \gamma_{st}^4 [M(III)][NO_3]^3$  [13]. It was necessary to work with different nitrate concentrations in order to avoid precipitation in organic phase. We then obtained the following apparent extraction constant:

$$K'_{ex} = \frac{[M(III)]_{org}}{[BTP]^z \cdot \gamma_{stoch}^4 \cdot [M(III)].[NO_3]^3} \quad (4)$$

The slope analysis method was applied to treat the distribution ratio data. The log/log plots related to the influence of [free BTP] on  $D_{Eu}$  give straight lines and the slopes obtained are closed to 3 (2.97 for the variation of [free *i*Pr-BTP] from  $1.9 \cdot 10^{-3}$  to  $3.10^2$  mol.L<sup>-1</sup>). These results, compared to previous ones, pointed out that the absence of proton has no influence on the stoichiometry of the reaction:  $x = 3$ . This stoichiometry is not influenced by temperature (measurements were realised at 10 and 40°C).

The second step of this study was the determination of the thermodynamic data related to the M(III) extraction reactions:  $K_{ex}$ ;  $\Delta G_{ex} = -RT \ln K_{ex}$ ;  $\Delta H_{ex}$  and  $\Delta S_{ex}$ , using the van't Hoff method, with  $D_{Eu}$  and  $D_{Am}$  determined for several temperatures.

*Table 4. Gibbs free energy, enthalpy and entropy variations for the extraction of Eu(III) and Am(III) nitrate from aqueous NaNO<sub>3</sub> 2.2 ± 0.2 mol/L solution by BTPs in octanol-1 solution.*

Ligand	Aqueous phase	[BTP] (mol.L <sup>-1</sup> )	$D_{M(III)}$	log $K'$	$\Delta G'$ (kJ.mol <sup>-1</sup> )	$\Delta H'$ (kJ.mol <sup>-1</sup> )	$\Delta S'$ (J.mol <sup>-1</sup> .K <sup>-1</sup> )
<i>n</i> Pr-BTP	Eu as traces	0.01	0.078	6.7 ± 0.1	-38.5 ± 1	-31 ± 6	+25 ± 15
	Am as traces		0.101 5.59 6.69	6.8 ± 0.1 8.5 ± 0.2 8.6 ± 0.2	-	-	+6 ± 10
<i>i</i> Pr-BTP	Eu as traces	0.01	50.3 42.6	9.4 ± 0.3 9.4 ± 0.3	-53 ± 2	-	-
	[Eu] <sub>init</sub> = $10^{-2}$ mol.L <sup>-1</sup>		0.286 0.293	8.7 ± 0.3 8.9 ± 0.3	-50 ± 2	-	-
	0.03	3.38 3.29 4.34	8.8 ± 0.2 8.8 ± 0.2 9.1 ± 0.2	-51 ± 1	-53 ± 8	-7 ± 10	

The main results obtained are presented in Table 4. The behaviours of *n*Pr-BTP and *i*Pr-BTP are similar from a thermodynamic point of view: the extraction reaction is governed by the enthalpy for both BTP extractants. The ligand *i*Pr-BTP exhibits a greater affinity for Eu(III) owing to a more favorable entropic term. The reaction is more exothermic for Am(III) extraction, which can be an indication of the formation of stronger M-N bond between BTP molecules and Am(III) compared to those between BTP and Eu(III). But in the same time, the entropic term becomes less favorable. It could be noticed that  $\Delta S$  is very low compared to results related to the extraction by malonamides.

## CONCLUSION

The preliminary results for the determination of thermodynamic parameters of the extraction of trivalent lanthanide and actinide nitrates showed the complexity of the thermodynamic properties, which involve numerous parameters.

The driving force for the M(III) nitrate extraction by malonamides and *pr*-BTPs from aqueous nitrate solution was always the enthalpic term.

## ACKNOWLEDGEMENTS

The authors are grateful for the financial support from the European Communities Research Programme (Contract PARTNEW - FIKW-CT2000-00087). The BTP molecules were synthesised by D. Guillaneux and S. Garcia-Argote (CEA/DEN/DRCP Marcoule). We warmly thank the referee for his remarks and helpful advice.

In the framework of the research of a physical model to predict the occurrence of third-phase formation in liquid-liquid extraction, we investigated the malonamide extractant used in the so-called DIAMEX process for partitioning of minor actinides from high-level liquid radioactive wastes. Third-phase transition was studied from a fundamental point of view. The organisation of the organic phases of the system DMDBTDMA / *n*-dodecane / water / neodymium nitrate / lithium nitrate was studied at three levels: 1/ at a macroscopic scale: the phase transition boundaries were determined and quantified by the LOC (limit organic concentration) of solute; 2/ at a molecular scale: the composition(s) of the extracted complex(es) was determined and this give information about the stoichiometry of the organic phase species; 3/ at a supramolecular scale: the critical micellization concentration was measured and the aggregation number was determined. Small Angle Neutron Scattering (SANS) measurements were used to give qualitative information about the size and interactions between the organic aggregates. The observable macroscopic effect, *i.e.*, the phase split of the organic phase with the formation of the third phase, results from an increase of the aggregation number of the DMDBTDMA in the organic phase and an increase of the interactions of these aggregates with the increase of the concentration of the extracted neodymium(III) nitrate.

## INTRODUCTION

In liquid-liquid solvent extraction, the stability of the organic phase, composed at least of two components, *i.e.*, the solvent (diluent) and the extractant, is fundamental for the definition of industrial processes. For a particular extraction system, the risk that the organic phase splits into two layers - phenomenon known as *third-phase formation* - depends essentially on the concentration of the extractant and solutes and of the temperature. This risk can possibly be reduced, by the optimisation of the extractant formula.

In the frame of the research of a physical model to predict the occurrence of third-phase formation, we investigated the malonamide extractant used in the so-called DIAMEX process for partitioning of minor actinides from high-level liquid radioactive wastes. The feasibility of the DIAMEX process has been demonstrated during counter-current "hot" tests with (*N,N'*-dimethyl *N,N*'-dibutyltetradecyl malonamide, (C<sub>4</sub>H<sub>9</sub>(CH<sub>3</sub>)NCO)<sub>2</sub>CH(C<sub>14</sub>H<sub>29</sub>) (DMDBTDMA), which was the first reference molecule of the process [1, 2]. Since few years, studies have been started to consider third phase transition on a fundamental point of view [3-7]. The objectives of the present investigation were to demonstrate the link between the composition boundaries where third-phase formation occurs and the supramolecular interactions between aggregates in the organic phase.

This paper deals with the organisation of the organic phases of the system DMDBTDMA / *n*-dodecane / water / neodymium (III) nitrate / lithium nitrate at three levels:

- At a macroscopic scale, the phase transition boundaries were determined and quantified by the LOC (limit organic concentration) of solutes, before the third phase formation.
- At a molecular scale, the compositions of the extracted complexes were determined and give information about the stoichiometry of the organic phase species.
- At a supramolecular scale, the critical micellization concentration was measured. It represents a change in the organisation of the organic phase. The aggregation number was quantified by vapour pressure osmometry. The organisation of the species in the organic phases was analysed by Small Angle X-Ray Scattering (SAXS) and Small Angle Neutron Scattering (SANS).

## EXPERIMENTAL

### Reagents

DMDBTDMA was provided by Panchim, Lisses, 91, France. Its purity, determined by mass spectrometry, was better than 99%. The diamide was then purified on a silica column to eliminate traces of surface-active compounds [8]. Neodymium nitrate hexahydrate, lithium nitrate and dodecane were reagent grade with purity better than 99%.

### Procedure and Apparatus

The diamide concentrations in organic solutions were determined by pHmetric titration with  $\text{HClO}_4$  in anhydride acetic media. The water content of the organic phases was determined using a Karl Fischer Metrohm KF737 coulometer. The neodymium concentration in each phase was determined by X-ray Fluorescence (Nd  $\text{K}\alpha$  ray at 35-45 keV).

The organic/aqueous interfacial tension measurements were carried out using the drop-weight technique. The organic phases have been systematically pre-equilibrated before measurement with the appropriate aqueous solutions.

The osmometric measurements were carried out using a Knauer Model K7000 vapour pressure osmometer (VPO). The temperature is fixed at 60°C to obtain accurate vapour pressure osmometry measurements. The calibration of the osmometer was performed using bromotetradecane diluted in dodecane because it does not aggregate and using myristic acid because this compound is present as dimers in the dodecane diluent. A period of 20 min was sufficient to reach equilibrium. The organic phases have been systematically pre-equilibrated with the appropriate aqueous solutions. The aggregation of the DMDBTDMA (noted E) can be represented by the general equation :  $n \cdot E = E_n$ , where E corresponds to the momomeric species and  $E_n$  corresponds to the *n*-mere. The average number of aggregation  $N_{\text{average}}$  was determined by the procedure proposed by Buch [9], defined as follows :

$$N_{\text{average}} = \sum (n \cdot [E_n]) / \sum [E_n].$$

Small Angle X-ray Scattering (SAXS) experiments were performed on the Huxley-Holmes, High Flux camera of the small-angle X-ray laboratory in the Service de Chimie Moléculaire, at CEA Saclay. Small Angle Neutron Scattering (SANS) experiments were carried out in the Laboratoire Léon Brillouin, at CEA Saclay. The characteristics of these instruments and the procedure to place the data in a two-dimensional spectra have been reported in previous studies [4, 5, 10].

## RESULTS AND DISCUSSION

### Macroscopic Scale

The phase transition boundaries during neodymium(III) nitrate extraction were determined. Figure 1 shows the phase transition line between the single organic phase (2 phases: *i. e.*, one aqueous and one organic) and the biphasic system (3 phases) issued from its split into a intermediate phase (third phase) and an upper one. Figure 2 presents the LOC (limiting organic concentration) of neodymium nitrate as a function of the DMDBTDMA concentration in the initial organic phase. The LOC value increases strongly with the diamide concentration.

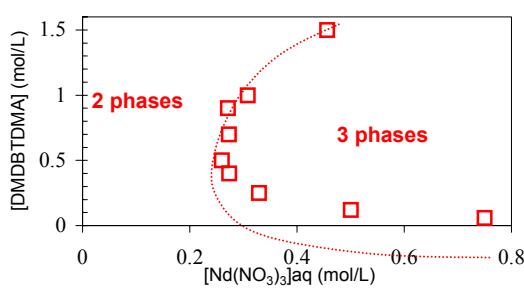

Figure 1. Third phase boundary for neodymium(III) nitrate extraction by DMDBTDMA diluted in dodecane. Aqueous phase: neodymium nitrate in lithium nitrate 1 mol/L, pH=2. Temperature: 23°C.

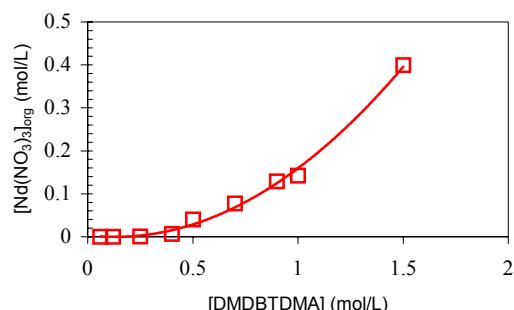

Figure 2. Limiting organic concentration (LOC) of neodymium(III) nitrate as a function of DMDBTDMA concentration in dodecane contacted with neodymium (III) nitrate in lithium nitrate 1 mol/L pH=2. Temperature: 23°C.

### Molecular Scale

Macroscopic variations (splitting of the organic phase into two layers) may have an explanation at molecular scale. Indeed, a modification in the neodymium(III) nitrate extraction mechanism when the apparition of the third phase could account for changes of organic solutes concentrations and thus for third phase formation.

Figure 3 represents the ratio R and R' of neodymium(III) ion *per* DMDBTDMA molecule and water molecule *per* DMDBTDMA molecule corresponding to the LOC values in the organic phases. Thus, it can be concluded that the splitting of the organic phase does not appear for a fixed value of the ratio R or R' of neodymium(III) ion or water molecule *per* extractant molecule. These ratios related to the LOC are dependent on the DMDBTDMA concentration: the slopes of the straight lines  $[\text{Nd}]_{\text{org}}/[\text{DMDBTDMA}]$  and  $[\text{H}_2\text{O}]_{\text{org}}/[\text{DMDBTDMA}]$  as a function of the DMDBTDMA concentration are respectively equal to 0.19 and 0.38. From these data, it is evident that water molecules are co-extracted with neodymium nitrate.

To study the transition between the biphasic and triphasic systems, an organic solution of DMDBTDMA was contacted with several aqueous phase containing increasing neodymium(III) nitrate concentration. Each organic and aqueous phase was analysed and its composition was determined for the two-phase system as well as the three-phase system. Figure 4 represents the ratio of neodymium(III) ion or water molecule (R and R') *per* extractant molecule during the extraction of neodymium(III) nitrate in the organic phase (two-phase system) or in the middle phase (three-phase system). In the upper phase, the concentration of diamide, water and neodymium are not represented because they are very low.

Before third-phase formation, water molecules are coextracted with neodymium(III) nitrate. The ratios  $[Nd]_{org}/[DMDBTDMA]$  R and  $[H_2O]_{org}/[DMDBTDMA]$  R', increase strongly just before the splitting of the organic phase, and after the splitting the ratio  $[Nd]_{org}/[DMDBTDMA]$  R in the third phase continues to increase while the  $[H_2O]_{org}/[DMDBTDMA]$  ratio R' decreases. Thus, one can conclude that the neodymium(III) nitrate extracted species are reorganized in the third phase with the elimination of water.

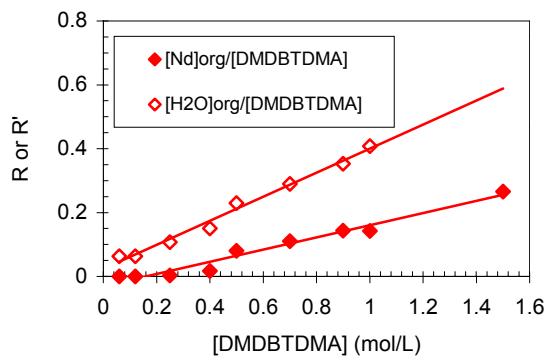

Figure 3.  $[Nd(NO_3)_3]_{org}/[DMDBTDMA]$  and  $[Nd(NO_3)_3]_{org}/[H_2O]$  ratios, R and R', corresponding to the LOC values as a function of DMDBTDMA concentration. Organic phase: DMDBTDMA in solution in dodecane contacted with neodymium(III) nitrate in lithium nitrate 1 mol/L, pH=2. T: 23°C.

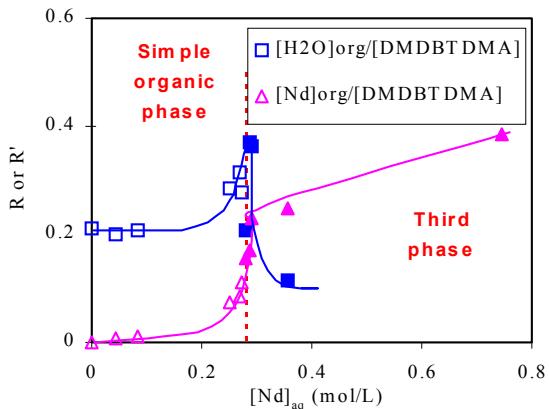

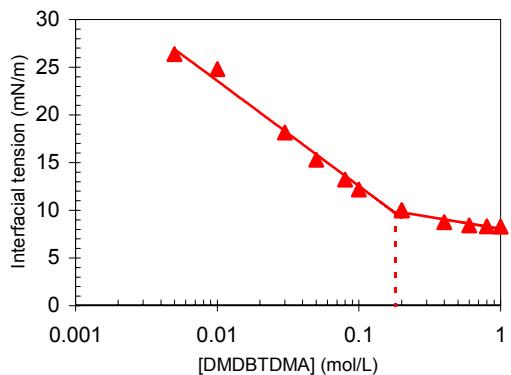

Figure 4.  $[Nd(NO_3)_3]_{org}/[DMDBTDMA]$ ;  $[H_2O]_{org}/[DMDBTDMA]$  ratios, R and R', as functions of  $[Nd(NO_3)_3]_{aq}$ . Organic phase :  $[DMDBTDMA]_{initial}$  0.7 mol/L in dodecane. Aqueous phase: neodymium(III) nitrate in lithium nitrate 1 mol/L pH = 2. T: 23°C.

### Supramolecular Scale: Formation, Size and Interactions of Aggregates

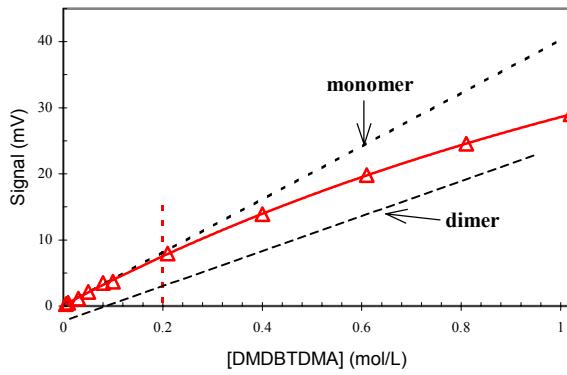

Supramolecular organisation (aggregates formation), if present, could also possibly explain the macroscopic variations of the third phase boundary. Formation of aggregates is characterised by the critical micellization concentration (cmc), above which extractant molecules coexist as monomers and aggregates. Figure 5 represents the interfacial tension at the aqueous / organic interface as a function of the DMDBTDMA concentration for a given aqueous phase containing neodymium(III) and lithium nitrate. The slope rupture indicates the presence of aggregates with a cmc value equal to 0.18 mol/L.

The average aggregation number  $N_{average}$  was determined by VPO. Figure 6 represents the VPO measured signal as a function of the DMDBTDMA concentration for organic solution equilibrated with a given aqueous phase : neodymium nitrate 0.2 mol/L in lithium nitrate 1 mol/L, pH = 2. This signal is compared with those measured for bromotetradecane (monomeric solute) and for myristic acid (dimeric solute). For total DMDBTDMA concentration lower than 0.2 mol/L, the DMDBTDMA does not form aggregates and for total diamide concentration larger than 0.2 mol/L, the average aggregation number is lower than 2: few aggregates are probably present in organic phases.

To understand the role of the neodymium(III) concentration in organic phase on the observed phenomena, we determined by VPO the average aggregation number of different organic solutions of diamide issued from a two-phase system as well as from a three-phase system (Table 1). Figure 7 represents these average aggregation number as a function of the organic neodymium concentration. The aggregation number is slightly dependent on the amide concentration, but it depends of the organic neodymium concentration whatever the amide concentration.

**Figure 5.** Organic / aqueous interfacial tension as a function of [DMDBTDMA].

**Figure 6.** Measured signal by vapour pressure osmometry as a function of [DMDBTDMA] at 60°C. Organic phase: DMDBTDMA in solution in dodecane contacted at 23°C with an aqueous phase with the composition: neodymium nitrate 0.2 mol/L, lithium nitrate 1 mol/L, pH=2.

**Table 1.** Average aggregation number determined by vapour pressure osmometry at 60°C.

	[DMDBTDMA] (mol/L)	[Nd] <sub>org</sub> (mol/L)	N <sub>average</sub>
Organic phase	0.1	0.013	1.2
	0.4	0.013	1.2
	0.61	0.015	1.2
	0.81	0.021	1.3
	1.02	0.025	1.4
	0.7	0.003	1.4
	0.7	0.04	1.5
Third phase	0.227	0.02	1.1
	0.93	0.14	2.7
	1.1	0.25	2.9
	1.3	0.4	6.5

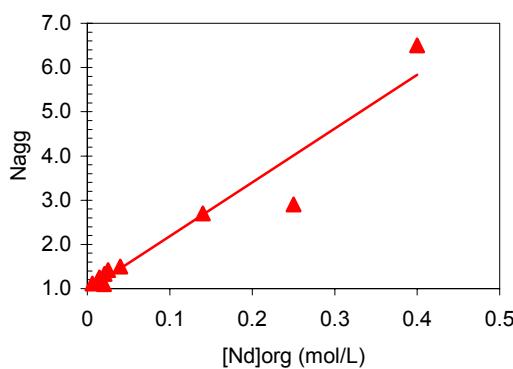

Organic phase : DMDBTDMA in solution in dodecane contacted with an aqueous solution containing neodymium nitrate and lithium nitrate 1mol/L, pH=2.

The aggregates were then characterised by SANS experiments to determine interactions and the size of aggregates in the organic phases. The scattered intensity  $I(q)$  of organic phase samples was registered as a function of the scattering vector  $q = (4\pi/\lambda) * \sin\theta$ , where  $2\theta$  is the scattered angle. The scattered intensity  $I(q)$  is relative to the interactions between aggregates for low values of  $q$  [0.001 to 0.1 Å<sup>-1</sup>] and to the shape and size of aggregates for high values of  $q$  [0.1 to 1 Å<sup>-1</sup>].

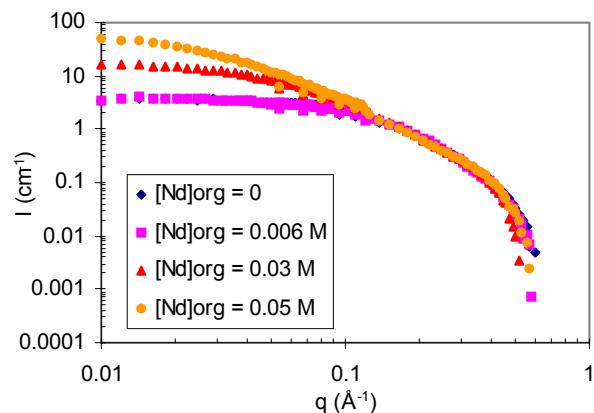

Qualitative information about the size and their interactions can already be deduced from experimental data. Experimental scattered intensities  $I(Q)$  are represented for [DMDBTDMA] 0.7 mol/L in dodecane contacted with various neodymium(III) aqueous solutions on Figure 8. For high values of  $q$  (from 0.1 to 1 Å<sup>-1</sup>), the intensities spectra are converging towards the same curve. Without even numerical evaluation of models, we know that it is the consequence of constant surface/volume ratio of aggregates. Considering these aggregates

in the first approximation as spheres, we can conclude that the aggregation number is independent on neodymium(III) concentration. This is agreement with the osmometry measurements because the corresponding average aggregation number is about 1.5 for the whole SANS curve.

For low values of  $q$  (0.001 to 0.1  $\text{\AA}^{-1}$ ), the intensities, relative to interactions between aggregates, are increasing with the neodymium(III) concentration. It can thus be concluded that an increase in neodymium concentration induces an increase of attractive interactions between aggregates.

*Figure 7. Average aggregation number determined by vapour pressure osmometry at 60°C as a function of neodymium (III) concentration in organic phase. Organic phase: DMDBTDMA in solution in dodecane contacted with an aqueous solutions of neodymium nitrate and lithium nitrate 1 mol/L, pH=2 at 23°C.*

*Figure 8. SANS spectra: experimental scattered intensity  $I(q)$  of organic solutions of DMDBTDMA 0.7 M in dodecane contacted with an aqueous solution of neodymium (III) nitrate and lithium nitrate 1 mol/L, pH=2. Room temperature. The neodymium organic concentrations are reported in the legend.*

## CONCLUSION

This study shows that DMDBTDMA in solution in dodecane does not form aggregates when its concentration is lower than 0.2 mol/L. When the DMDBTDMA concentration is higher than 0.2 mol/L, small aggregates can be formed, the aggregation number being dependent of the concentration of the neodymium(III) nitrate in the organic phase. The increase of the neodymium(III) concentration in the organic phase leads also to an increase of the interactions between aggregates. A thermodynamic model of attractive spheres at short distances (Baxter's model) will be used to quantify aggregate interactions. This model is based on the use of an attractive interaction potential  $U$  that can account for three known interactions that come into play: 1/ the destabilising van der Waals interaction, 2/ the stabilising hard sphere repulsion, and 3/ a repulsive steric contribution from the aliphatic chains of the extractant molecules.

The observable macroscopic effect, namely the phase split of the organic phase with the formation of the third phase, results from an increase of the neodymium(III) concentration in the organic phase which induces an increase of the aggregation number of the DMDBTDMA and an increase of the interactions between these aggregates.

# EXTRACTION OF TRIVALENT ACTINIDES AND LONG-LIVED FISSION PRODUCTS BY DIFFERENT CLASSES OF FUNCTIONALIZED CALIXARENES

Jean François Dozol, Alejandro Garcia-Carrera, Véronique Lamare  
and Hélène Rouquette

CEA Cadarache, Saint Paul Lez Durance, France

High and medium level activity liquid wastes arising from nuclear fuel reprocessing contain important concentrations of transplutonium elements (Am, Cm) and fission products including cationic species, such as cesium and strontium, and anionic species, such as pertechnetate or selenate. A strategy developed by CEA is the separation of these long-lived nuclides from these highly acidic solutions. Calixarenes represent a class of cyclic oligomers, offering nearly unlimited possibilities of chemical modification. Several new classes of functionalized calixarenes were synthesised. These compounds, diluted in nitrophenylalkylether, at concentrations ranging from  $10^{-3}$  to  $10^{-2} M$ , display distribution coefficients comparable to those of their podand counterparts used at a hundredfold higher concentration. This improvement of extraction strength is essential to remove the targeted element among many other elements arising from fission.

## INTRODUCTION

Nuclear spent fuels contain both fissile and fertile residues of significant energy value and radioactive products, alpha, beta, gamma and neutron emitters, which make them very irradiant and which release an important amount of heat (mainly due to  $^{90}\text{Sr}$  and  $^{137}\text{Cs}$ , after a five years of cooling process). The radio-toxicity of these fuels can last for millions of years. Reprocessing is of great interest to recover uranium and plutonium, which can be recycled in the form of new nuclear fuels, and to optimise the conditioning of waste.

Acidic solutions arising from the PUREX process contain minor actinides (neptunium, americium, curium) and 99 % of the non-gaseous fission products. Some of these radionuclides have long half-lives:  $^{93}\text{Zr}$  ( $1.5 \times 10^6$  y),  $^{107}\text{Pd}$  ( $7 \times 10^6$  y),  $^{129}\text{I}$  ( $1.7 \times 10^7$  y),  $^{135}\text{Cs}$  ( $3 \times 10^6$  y),  $^{237}\text{Np}$  ( $2.14 \times 10^6$  y). The present strategy is to vitrify these high level activity wastes for disposal or long-term storage. An alternative strategy, studied in France, Japan and Russia, is to separate the minor actinides and the long-lived fission products from these wastes and destroy them by transmutation or dispose of them in specific matrixes. This would also involve the recovery of other fission products,  $^{90}\text{Sr}$  (27.7 y) and  $^{137}\text{Cs}$  (30 y), which would remove about 90 % of the heat released by high activity wastes, allowing their volume to be reduced and thereby facilitating their disposal or their intermediate storage.

## CALIXARENES

Calix[*n*]arenes, cyclic compounds constituted by *n* phenolic units linked by methylene groups, are conformationally mobile. Calix[4]arenes which display four conformations: cone, partial cone, 1-3 alternate, 1-2 alternate, can be tailored for the removal of the different long-lived elements (Figure 1). On this structure, different functions can be substituted for the hydrogen of the phenolic units (narrow rim) or to *p* *tert* butyl groups (wide rim). The different calixarenes studied were synthesised by the Universities of Parma (calix[4]arenes-crown-6, calix[*n*]arenes amides) and Mainz (calixarenes CMPO) within the framework of projects granted by Commission of European Communities.

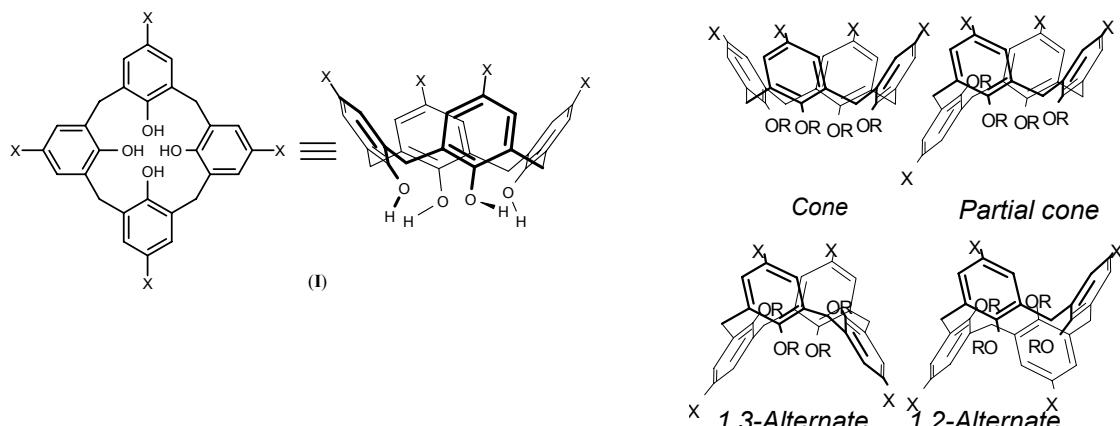

Figure 1. Calix[4]arene and its four conformations.

These calixarenes are exceptionally efficient for the extraction of cesium, specially from high concentration soda media. They allow a quantitative extraction of cesium ( $10^{-3} M$ ) from near saturated soda solutions (NaOH 15 M) (Table 1).

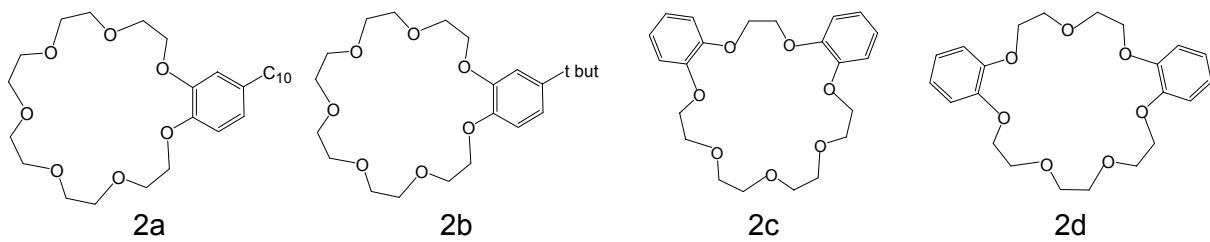

Table 1. Sodium and cesium distribution (*D*) coefficients of *t*-butyl-calix[4]arene,  $10^{-2} M$  in NPHE.

## DI ALKOXY CALIXARENES CROWN 6

Crown ethers or cyclic polyethylene glycol being the most efficient extractants of cesium, it seemed interesting to graft this polyethylene glycol moiety on calix[4]arene (Figure 2). Calix[4]arene-crown-*n* compounds consist of a calix[4]arene frame, maintained in the 1-3 alternate conformation by a polyethylene glycol bridge containing *n* oxygen atoms. The two remaining phenolic units are derived with alkyl chains (Figure 3).

Distribution coefficient values and extraction of efficiency of the different compounds are summarized in Table 2. To be efficient, the calixarene crown 6 must adopt the 1-3 alternate conformation; dihydroxy- and diethoxy-calix[4]arenes which are conformationally mobile are less efficient than calix[4]arenes bearing alkyl groups bulkier than ethoxy (such as dipropoxy, diiso-propoxy, dioctyloxy). The latter are much more efficient than benzo or dibenzo 21-crown-7-ethers.

*Figure 2. a: Decyl-benzo-21-crown-7, b: t-butyl-benzo-21-crown-7, c: 2,5-benzo-21-crown-7, d: 3,4-benzo-21-crown-7.*

*Figure 3. a: Di-alkoxy-calix[4]arene-crown-6, b: di-alkoxy-calix[4]arene-benzocrown-6, c: di-alkoxy-calix[4]arene-di-benzo-crown-6, d: di-alkoxy-calix[4]arene-propylene-crown-6.*

*Table 2. Cesium distribution (D) coefficients and extraction efficiency (E) for different di-alkoxy-calix[4]arene-crown-6 and 21-crown-7. Aqueous solution :  $MNO_3 5 \times 10^{-4} M$ ,  $HNO_3 1 M$ . Organic solution :  $1 \times 10^{-2} M$  calixarene or crown ether in NPHE.*

Compounds	DCs	E (%)
Di-hydroxy-calix[4]arene-crown-6	$1.2 \times 10^{-2}$	1.2
Di-methoxy-calix[4]arene-crown-6	$4 \times 10^{-2}$	3.8
Di-ethyleneglyco-calix[4]arene-crown-6	4.2	80.8
Di-propoxy-calix[4]arene-crown-6	19.5	95.1
Di-iso-propoxy-calix[4]arene-crown-6	28.5	96.6
Di-iso-propoxy-calix[4]arene-(propylene crown-6)	2.5	71.4
Di-n-octyloxy-calix[4]arene-crown-6	33	97.0
Di-n-octyloxy-calix[4]arene-benzo-crown-6	24	96.0
Di-iso-propoxy-calix[4]arene-(t-oct benzo crown-6)	34	97.1
Di-n-octyloxy-calix[4]arene-dibenzo-crown-6	31	96.9
Di-iso-propoxy-calix[4]arene-(dibenzo-propylene-crown-6)	0.78	43.8
Di-iso-propoxy-calix[4]arene-(di-t-butyl dibenzo-crown-6)	$1.7 \times 10^{-2}$	1.7
Di-methoxy-calix[4]arene-crown-7	$7 \times 10^{-3}$	0.7
n-decylbenzo-21-crown 7	0.3	23
t-butylbenzo-21-crown 7	0.3	23
2,5-dibenzo-21-crown 7	0.52	34.2
3,4-benzo-21-crown 7	0.3	23

Calix[4]arene-crown-4 and calix[4]arene-crown-5 are selective respectively for sodium [1] and for potassium [2], whereas calix[4]arene-crown-6 [3] is selective for cesium, while the size of calix[4]arene-crown-7 is too large for this cation. Increasing the size of the crown by adding one carbon in the polyethylene glycol chain of the crown leads to an important decrease of extracting ability of calixarene-propylene-crown-6. All these trends can be explained by molecular modeling [4].

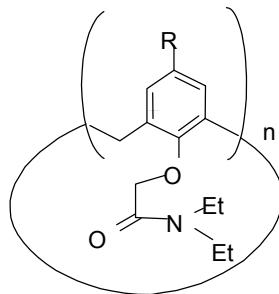

Like crown ethers, the crowns of calixarenes can include one or two benzene units. Introduction of these units in the crown strongly increases the cesium extraction and reduces that of nitric acid. The very low distribution coefficients displayed by di-iso-propoxy-calix[4]arene-(di-*t*-butyl dibenzo-crown-6) are explained by the presence of four bulky *t*-butyl groups which lead to strains on the crown, which are detrimental to the preorganization of the crown. For all the calixarenes-crowns, extraction of cesium is enhanced as the nitrate concentration increases and reaches a maximum (for a nitric acid concentration ranging between 2 and 3 M) then decreases due to a competitive extraction of nitric acid. For a nitric concentration of 3 M, the distribution coefficients values are respectively for di-octyloxy-calix[4]arene-crown-6, di-octyloxy-calix[4]arene-benzo-crown-6 and di-octyloxy-calix[4]arene-dibenzo-crown-6, 24, 105 and 200 whereas they are 2.2 for the best crown ether (2,5-dibenzo-21-crown 7).

### CALIX[n]ARENES AMIDES

Starting from the observation that Sr<sup>2+</sup>/ Na<sup>+</sup> selectivity in calixarene-amides increases going from calix[4] to calix[6]arenes (Table 3), Parma University prepared a series of calix[6]arene-hexamides and calix[8]arene-octamides which present different substituents at the wide rim (Figure 4).

*Table 3. Sodium and strontium distribution (D) coefficients for different *t*-butyl calix[n]arene-amides. Aqueous solution: MnO<sub>3</sub> 5 × 10<sup>-4</sup> M, HNO<sub>3</sub> 1 M. Organic solution: 10<sup>-2</sup> M for calix[n]arene (n = 4, 5), 5 × 10<sup>-3</sup> calix[6]arene in NPHE.*

Compounds	D <sub>Na</sub>	D <sub>Sr</sub>	D <sub>Sr</sub> /D <sub>Na</sub>
p- <i>t</i> -butyl-calix[4]arene-tetra-di-N-ethyl-amine	12.3	0.11	0.089
p- <i>t</i> -butyl-calix[5]arene-penta-di-N-butyl-amine	0.82	2.3	2.8
p- <i>t</i> -butyl-calix[6]arene-hexa-di-N-ethyl-amine	510 <sup>-3</sup>	3.8	760

*Figure 4. Calix[n]arene-di-N-ethyl-amine.*

Trends observed when the size of calixarenes increases from tetramer to hexamer are confirmed by the larger calix[8]arene-octa-di-N-ethyl-amine. Some bearing benzyloxy, pentyloxy, octyloxy functionality display an efficiency towards strontium much higher than its counterpart hexamer or than usual extractants of strontium: di-cyclohexano-18-crown-6 or the more lipophilic di-*t*-butyl-di-cyclohexano-18-crown-6. The distribution coefficients depend on the para substituent of calix[8]arene-octa-di-N-ethyl-amine (Table 4). Crowns have to be used at a concentration higher than 10<sup>-2</sup> M in NPHE to be able to remove strontium from

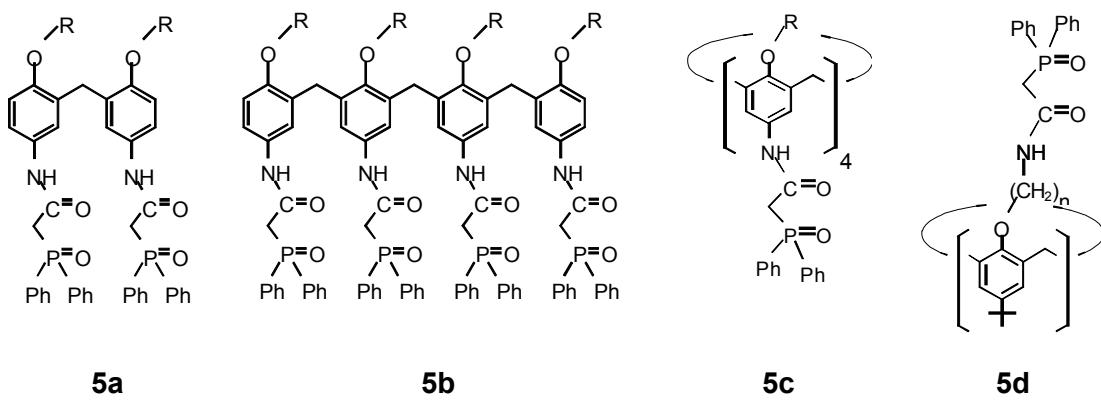

acidic solutions. One has to point out that this efficiency observed for pentyloxy calix[8]arene-octa-di-N-ethyl-amine for a nitric acid concentration of 1 M is maintained for acidities ranging between 1 and 3 M.

*Table 4. Strontium distribution (*D*) coefficients for different calix[8]arene-di-N-ethyl-amide. Aqueous solution:  $MNO_3$   $5 \times 10^{-4}$  M,  $HNO_3$  1 M. Organic solution:  $10^{-2}$  M for calix[n]arenes amide and DC18-crown 6 in NPHE.*

Extractants	$D_{Sr}$

entyloxy calix[8]arene-octa-di-N-ethyl-amide	30
octyloxy calix[8]arene-octa-di-N-ethyl-amide	24
octyloxy calix[6]arene-hexa-di-N-ethyl-amide	0.80
di-cyclohexano-18-crown-6	0.28
di-t-butyl- di-cyclohexano-18-crown-6	0.43

### CALIX[4]ARENES CMPO

The TRUEX process was developed in the United States for the extraction of actinides and lanthanides, whatever their valence, from high salinity or acidic media. The process uses CMPO or octylphenyl N,N diisobutyl carbamoyl methyl phosphine oxide. It was decided to synthesize calixarenes CMPO in order to combine the extracting ability of CMPO and the preorganization of calixarene (Figure 5). Various compounds were synthesized. All the "CMPO-like" calixarenes were soluble at a very low concentration in NPHE ( $10^{-3}$  M). None of the classical extractants are able to remove actinides from acidic media at this concentration, whereas the dimer extracts plutonium and the trimer extracts americium, in agreement with the stoichiometries of the corresponding CMPO complexes [5].

*Figure 5. a: Dimer, b: tetramer, c: wide rim calixarenes CMPO, d: narrow rim calixarenes CMPO.*

Measurements carried out in acidic medium with CMPO, wide rim calixarenes CMPO and the tetramer, acyclic counterpart of the latter show that to obtain comparable distribution coefficients for lanthanides or trivalent actinides (americium, curium), CMPO has to be used at a concentration of 0.25 M while calixarene and tetramer were applied at a concentration of  $10^{-3}$  M. Whereas CMPO and tetramer display a low selectivity among lanthanides, a marked decrease of the distribution coefficients along the lanthanide series is observed for calixarene CMPO. Many other fission products are present in raffinate arising from Purex process (Zr, Nb, Mo, Ru, Rh, Pd...). Some of these elements are significantly extracted by CMPO. Extraction kinetics of some of these elements being slow, organic and aqueous phases were put in contact for three days. On the contrary, except for palladium, where distribution was comparable for CMPO and calixarene CMPO, distribution coefficients for these elements are

very low (Table 5). Calixarenes CMPO are much more selective and enable minor actinides to be separated from most of the fission products except palladium and lightest lanthanides.

One has to also emphasize that calixarenes bearing CMPO on the narrow rim display a different behaviour: distribution coefficients are lower and selectivity is not so marked as for wide rim calixarene CMPO [6]. An other important factor is the length of the arm linking CMPO moieties and calixarene cavity. Increasing the length of the arm ( $n$  varying from 2 to 5) leads to inversion of the order of selectivity among lanthanides.

*Table 5. Zr, Nb, Mo, Ru, Rh, Pd distribution coefficients for CMPO and wide rim calixarene CMPO. Aqueous solution: HNO<sub>3</sub> 1 M, MnO<sub>3</sub> 10<sup>-5</sup> M. Organic solution: 0.25 M for CMPO, 10<sup>-3</sup> M for calix[n]arenes CMPO in NPHE.*

Extractants	Zr	Nb	Mo	Ru	Rh	Pd
CMPO	85	5.5	6	0.09	0.03	185
Calixarene CMPO	0.2	0.1	0.08	0.02	0.03	170

## CONCLUSIONS

Synthesis of many calixarenes demonstrates the interest of this very lipophilic structure, well adapted to liquid-liquid extraction. The comparison of different calixarenes (di-alkoxy-calixa[4]rene-crown-6, calixarene-CMPO ...) with their non-calixarene counterparts (crown-ether, CMPO...) shows an enhancement of extracting abilities and, above all, an exacerbation of selectivity—indispensable properties to remove specific nuclides from solutions containing large amounts of nitric acid and many ionic species often present at higher concentrations. Examples given show that there are many possibilities of synthesis and that in some cases minor changes (size, conformation, rigidification of calixarenes, grafting on one or other rim...) in the structure of calixarenes induce large modifications of extraction properties and selectivity. Moreover, dialkoxy calixarenes crown 6 display good chemical and radiochemical stability. A process was defined for the removal of cesium from acidic high liquid waste and tested on genuine waste arising from PUREX and DIAMEX (actinide removal) processes.

## ACKNOWLEDGEMENTS

CMPO-like calixarenes are potential alternative extractants for the trivalent actinide/lanthanide separation in nuclear fuel reprocessing. Extraction mechanisms of HNO<sub>3</sub> and actinide/lanthanide cations (Am(III), Cm (III), Eu(III) and Ce(III)) from nitric acid media are investigated for the calix[4]arenes-CMPO. Spectrometric techniques (infrared spectroscopy and mass spectrometry / electrospray ionisation) give information about the way extraction is carried out (chemical groups implied in complexation, complexes formed during cation extraction). Using this information and liquid-liquid extraction results, the extraction of nitric acid and cations have been modelled.

### INTRODUCTION

Nuclear fuel reprocessing is important to reduce the toxicity and volume of waste for disposal. Following PUREX processing, the acidic effluent contains numerous long-lived radionuclides, such as transplutonium elements. Selective extraction of the actinides from lanthanides is a critical step in order to transmute them into short lived or non-radioactive radionuclides. Calix[4]arenes substituted by acetamidophosphine oxide groups (CMPOs) are powerful extractants for trivalent actinides and lanthanides from aqueous nitric acid media. They could be used for the treatment of PUREX effluent.

The substitution of calixarenes on their wide or narrow rim modifies extraction efficiency and separation factors between actinides and lanthanides. Wide rim calixarenes are more efficient extractants than narrow rim congeners for actinides and lanthanides. However the stripping and acid hydrolysis behaviour of calixarenes substituted on their narrow rim make them interesting molecules for study.

### EXPERIMENTAL

Calix[4]arenes-CMPO were synthesised by V. Böhmer's group (University of Mainz, Germany). These extractants (Figure 1) were diluted in NPHE (1,2-nitrophenylhexylether). Extraction experiments were performed by shaking equal volumes of aqueous solutions and organic solvents for one hour at 20°C (equilibrium was reached in a few minutes). Samples were taken for analysis after centrifugation. Acidities were measured by titration with NaOH in aqueous media for respectively aqueous and organic solutions. <sup>241</sup>Am(III), <sup>152</sup>Eu(III), <sup>144</sup>Ce(III) concentration were analysed by  $\gamma$  counting ( $\gamma$  spectrometry). <sup>244</sup>Cm(III) concentration was measured by  $\alpha$  counting (liquid scintillation).

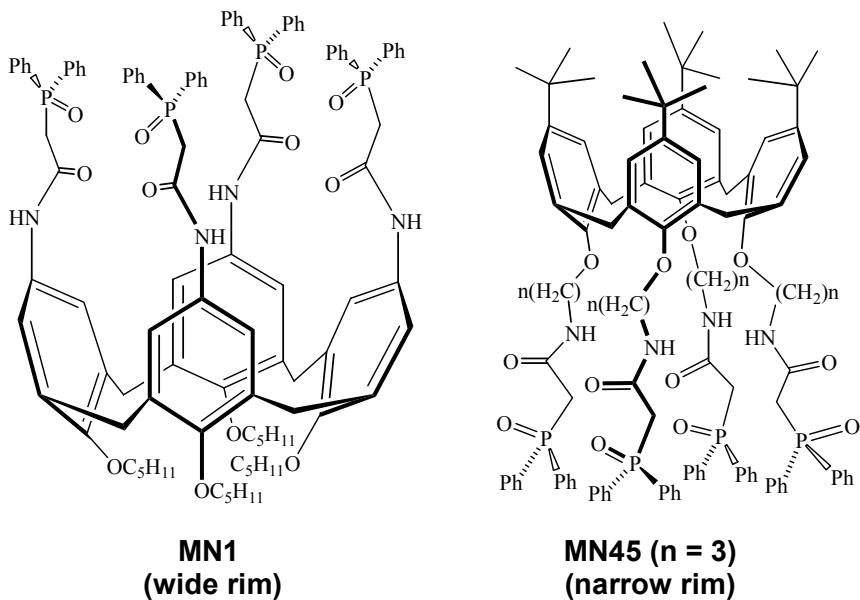

Figure 1. Wide and narrow rim calix[4]arenes-CMPO.

## RESULTS AND DISCUSSION

### Nitric Acid Extraction

The  $\text{HNO}_3$  extraction isotherms for MN1 and MN45 are plotted in Figure 2. This feature shows the presence of species such as  $[(\text{HNO}_3)_n \cdot \text{Calix}]_{\text{org}}$  ( $n = 1 - 6$ ) since the  $\text{HNO}_3$  concentration extracted by the calixarene is  $n$  times higher than that of the extractant, (the nitric acid extraction by the diluent (NPHE) is subtracted).

MN45 extracts more acid than MN1 at high nitric acid concentrations, due to the higher mobility of the structure (alkyl chains linking calixarene platform with the CMPO moieties).

To gain insight into the  $[\text{calix}-\text{HNO}_3]_{\text{org}}$  bonds, the infrared (IR) spectra of  $[\text{calix}(\text{HNO}_3)_n]$  adducts in the organic phase were investigated. Diluents other than NPHE were used to carry out the acid extractions to avoid interferences between diluent and adducts IR bands. Trichlorethane, octanol and chloroform were selected.

For the free calixarene MN1, two main C=O stretching bands at  $1680$  and  $1603 \text{ cm}^{-1}$  were identified (Table 1). A new band was observed ( $\sim 1675 \text{ cm}^{-1}$ ) for the samples after  $\text{HNO}_3$  extraction ( $[\text{HNO}_3] > 1 \text{ M}$ ). In the same way, P=O functions are involved in the nitric acid complexation at high nitric acid concentration. New bands (at lower wave numbers than those of free calixarene) are well defined for  $[\text{HNO}_3] > 4 \text{ M}$ .

The band at  $1550 \text{ cm}^{-1}$  belongs to the aromatic groups (calixarene platform). For nitric acid concentrations ( $[\text{HNO}_3]_{\text{aq},\text{init}}$ ) higher than  $4 \text{ M}$ , a shoulder at lower wave numbers ( $1535 \text{ cm}^{-1}$ ) appeared, becoming a new band at  $[\text{HNO}_3]_{\text{aq},\text{init}} 7 \text{ M}$ . This drift could indicate that aromatic units are involved in the nitric acid extraction at high acid concentration.

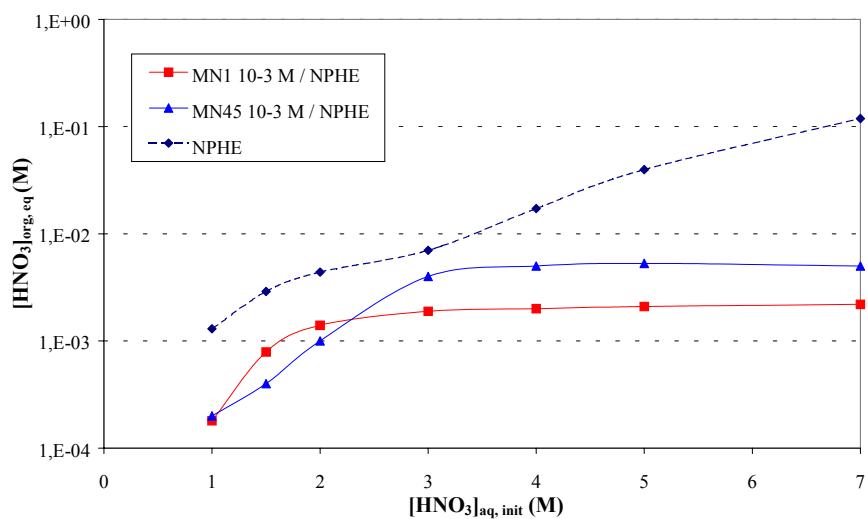

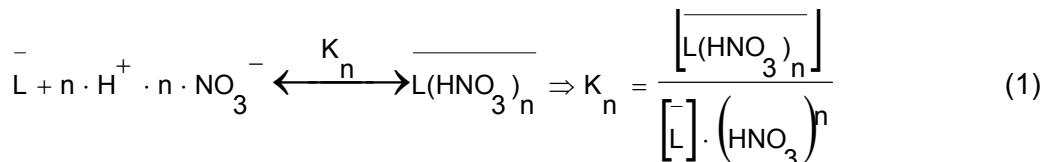

Figure 2. Nitric acid extraction by MN1, MN45 and NPHE.  
[MN1] = [MN45] = 10<sup>-3</sup> M in NPHE (T = 20°C).

Taking into account the IR results (C=O (mainly), P=O and aromatic groups involved in the acid extraction at high nitric acid concentration), numerous complexes [calix(HNO<sub>3</sub>)<sub>n</sub>]<sub>org</sub> are formed in the organic phase during extraction (Table 1).

$\nu_{Ph}$	1552	1552	1552	1552	1552 (1533)	1532

The general extraction equilibrium can be written in which bars indicate organic species (assuming that the activity coefficients are constant in the organic phase),

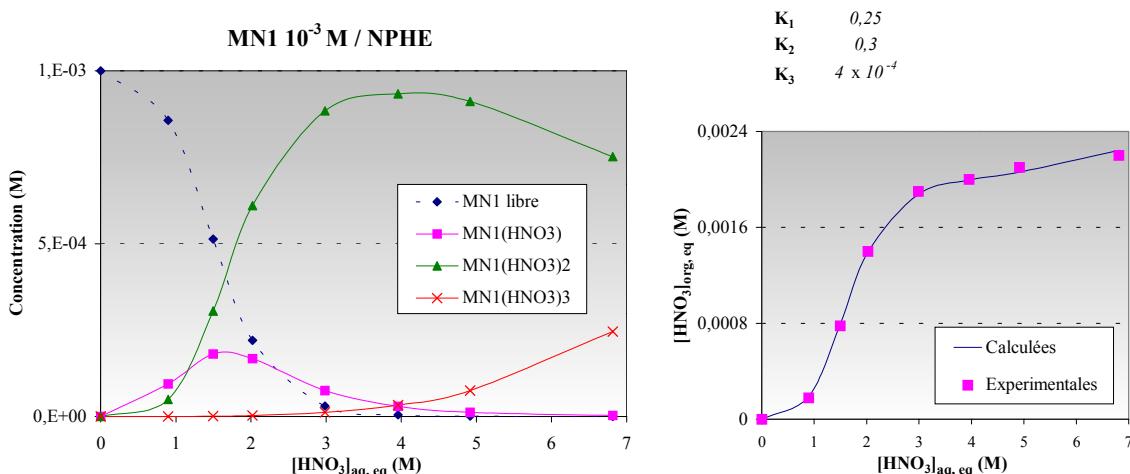

where parenthesis indicate activities and brackets concentrations. Activity coefficients for aqueous HNO<sub>3</sub> solutions were taken from [1]. Assuming constant activity coefficients in the organic phase. Total extractant concentration is constant. The organic acid concentration is very low compared with the “diluent concentration”, so, all the organic species were mainly surrounded with diluent molecules.

The free extractant concentration can be written,

$$[\bar{L}] = \frac{[L]_0}{1 + K_1 \cdot (HNO_3) + K_2 \cdot (HNO_3)^2 + \dots + K_n \cdot (HNO_3)^n} \quad (2)$$

Introducing values of the effective constants,  $K_n$ , we obtain the free calixarene concentration, which may be used to calculate the organic  $HNO_3$  concentration. This calculated concentration is compared with the experimental value.

**Figure 3. Extraction of  $HNO_3$  by  $[MN1] = 10^{-3} M$  in NPHE ( $T = 20^\circ C$ ).**  
*Distribution of organic species with respect to the aqueous acidity.*  
*Calculated and experimental  $HNO_3$  extraction isotherms.*

The concentration of each species, for MN1, as a function of  $[HNO_3]_{aq, eq}$ , and the fit of calculated and experimental values, are illustrated in Figure 3. It can be seen that free MN1 was the main species for nitric acid concentration lower than 1.5 M, but for higher  $HNO_3$  concentrations,  $[MN1(HNO_3)_2]_{org}$  predominated.

In the case of MN45, for low nitric acid concentrations, results were similar to those for MN1, but for  $HNO_3$  concentrations higher than 2.5 M, the main species was  $[MN45(HNO_3)_5]_{org}$ , and  $[MN45(HNO_3)_6]_{org}$  was not negligible for high acidities. A good fit of the model to the experimental data was obtained.

### Cation Extraction

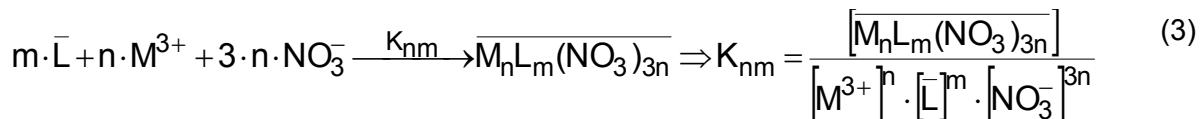

The study of the extraction of the different lanthanides from a highly acidic medium by CMPO like calixarenes demonstrates the ability of these compounds to extract these cations. A sensible discrimination occurs between trivalent actinides and lanthanides and among the trivalent lanthanides [2,3,4].

The IR spectra results illustrated that calixarene coordination sites were the oxygen of P=O (mainly) and C=O groups. Table 2 shows the changes of the C=O and P=O vibration bands as a function of the lanthanide. For the best extracted (i.e. the lightest) cations, a shift of the C=O and P=O IR bands, towards lower wave numbers, appears in comparison with the free calixarene IR spectrum.

*Table 2. IR Spectra of MN1. Lanthanide extraction.*  
 $[MN1] = 10^{-2} M$  in  $CHCl_3 // [Ln(NO_3)_3] = 10^{-2} M // [HNO_3] = 1M$  ( $T = 20^\circ C$ ).  
 Solid sample (evaporation of  $CHCl_3$ ) / KBr pellet.

	MN1	La	Ce	Nd	Sm	Eu	Gd	Dy	Er	Lu
$\nu_{PO}$ ( $cm^{-1}$ )	1183		1162	1163	1164	1163	1164	1162	1182	1184
$\nu_{CO}$ ( $cm^{-1}$ )	1678	1675	1676	1677	1678	1678	1678	1679	1676	1679
		1617	1617	1614	1612	1611	1610	1606	1605	1606
		1653	1653	1653	1653	1653				

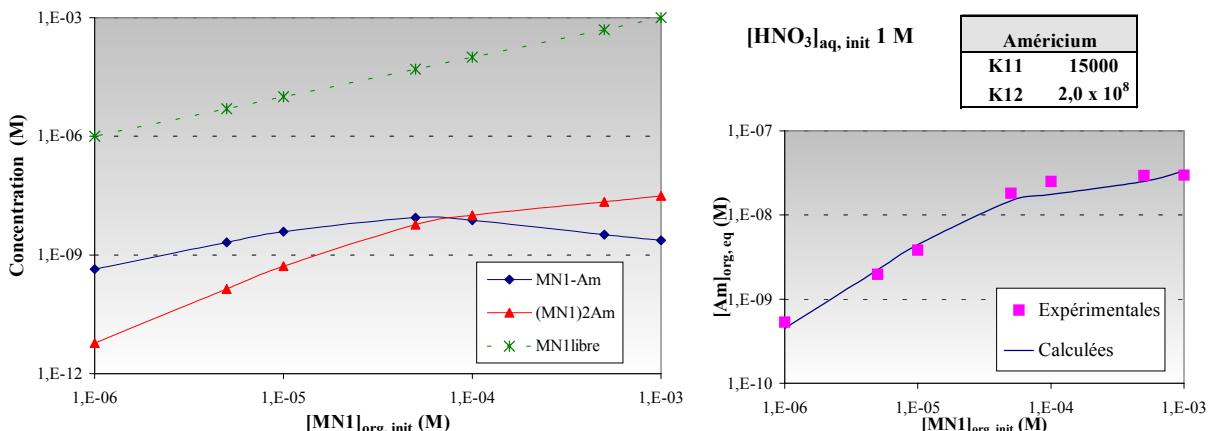

The extraction of a metallic cation,  $M^{3+}$ , by a calixarene, L, is described by the equilibrium,

Taking into account the ES/MS spectra, three different stoichiometries, 1:1, 1:2 and 2:1, (calixarene : cation) can be considered. So, the equilibrium extractant concentration can be written,

$$[L]_{eq} = [L]_0 - [L]_{acid} - \left\{ K_{11} \cdot [M^{3+}] \cdot [L]_{eq} \cdot [NO_3^-]^3 + 2 \cdot K_{12} \cdot [M^{3+}] \cdot [L]_{eq}^2 \cdot [NO_3^-]^3 + K_{12} \cdot [M^{3+}]^2 \cdot [L]_{eq} \cdot [NO_3^-]^6 \right\} \quad (4)$$

We consider that certain acid species,  $[(HNO_3)_n \text{ Calix}]$  (with  $n < 5$ ), extract cations in the same way that free calixarene. After protonation of the four carbonyl functions, phosphoryl groups can be protonated. We assume that phosphoryl protonation prevents cation extraction.

*Figure 4. Extraction of Am by  $[MN1] = 10^{-3} M$  in NPHE ( $T = 20^\circ C$ ).*  
*Distribution of organic species with respect to calixarene concentration.*  
*Calculated and experimental americium extraction values.*

When the cation concentration is very low in comparison with the calixarene concentration, two main species are involved in the extraction  $[(\text{calix})_n M]_{\text{org}}$  ( $n=1,2$ ), for every cation (lanthanide or actinide) and calixarene (MN1 or MN45). The proportion of  $[(MN1)_2 M]_{\text{org}}$  increased with the calixarene concentration. A good fit of the model with the experimental data was obtained (Figure 4).

When the cation concentration is comparable to or higher than that of calixarene, the species  $[MN1(M)_2]_{\text{org}}$  can dominate. Also, when the aqueous solution contains two different cations, the species  $[MN1(M_1)(M_2)]_{\text{org}}$  were taken into account to fit the model to the experimental data. These species were identified by ES/MS.

On the other hand, for high cation and nitric acid concentration, nitric acid extraction can compete with that of the cation. Figure 5 illustrates the fit of the model to the experimental data for the joint extraction of  $\text{Eu}^{3+}$  and  $\text{Ce}^{3+}$  by MN45 taking into account the following three hypotheses in relation to the ability of the acid species  $[\text{MN45}(\text{HNO}_3)_n]$  to extract cations: (1) All the acid species  $[\text{MN45}(\text{HNO}_3)_n]$  behave like free MN45, (2)  $[\text{MN45}(\text{HNO}_3)_n]$  ( $n = 1 - 4$ ) behave like free MN45, but not for  $n = 5, 6$  and (3) No acid species  $[\text{MN45}(\text{HNO}_3)_n]$  behaves like free MN45.

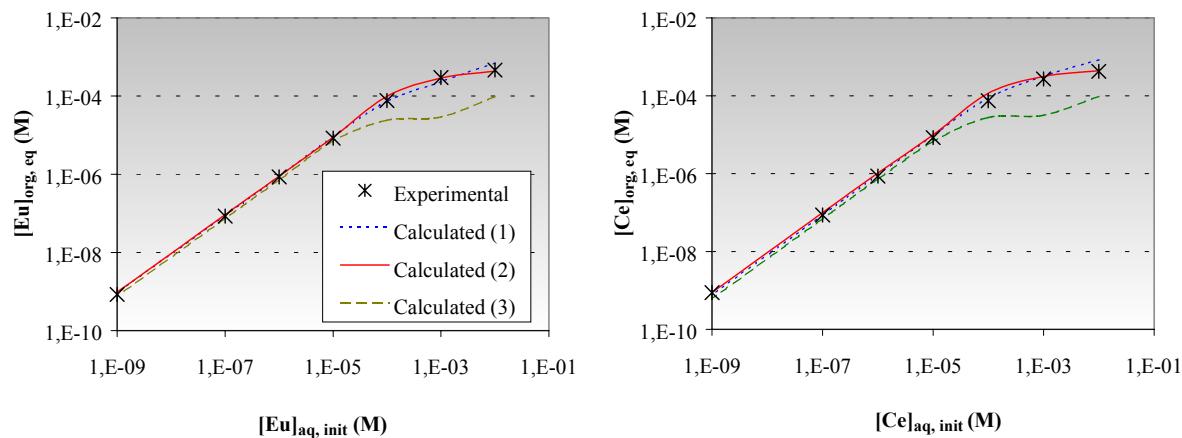

Figure 5. Extraction of  $\text{Eu}^{3+}$  and  $\text{Ce}^{3+}$  by MN45.  
 $[\text{MN45}] = 10^{-3} \text{ M}$  in NPHE /  $[\text{Eu}^{3+}] = [\text{Ce}^{3+}]$  variable /  $[\text{HNO}_3] = 3 \text{ M}$  ( $T = 20^\circ\text{C}$ ).  
 Calculated and experimental Eu and Ce extraction isotherms.

Model (1) performs better than Model (2), but for the highest cation concentration, it overestimates the calculated concentration. Modelling of cation extraction at higher nitric acid concentration could help to elucidate if only certain acid species,  $[\text{MN45}(\text{HNO}_3)_n]$ ,  $n < 5$  can extract cations like free MN45 – assuming that carbonyl groups are protonated but the phosphoryl groups are available for cation complexation.

## CONCLUSIONS

The extraction of  $\text{HNO}_3$  by CMPO-like calixarenes occurs through the formation of numerous organic species. Nitric acid is linked by hydrogen bonds to the carbonyl functions. Moreover, phosphoryl and phenyl groups seem to be implicated in the complexation of  $\text{HNO}_3$  at high nitric acid concentrations.

On the other hand, the extraction of the trivalent lanthanides and actinides by the wide rim calixarenes is more efficient than that of the narrow rim ones. Nitric acid complexation prevents cation extraction, when coordination sites, mainly phosphoryl groups, are “taken up” by  $\text{HNO}_3$  molecules.

A good fit of the model with the experimental data was obtained for  $\text{HNO}_3$  and cation extraction by CMPO-like calixarenes.

## **EXTRACTION OF ACTINIDES AND LANTHANIDES WITH DIPHENYL[DIBUTYLCARBAMOYLMETHYL]PHOSPHINE OXIDE IN THE ABSENCE OF A SOLVENT**

**B. F. Myasoedov, Yu. M. Kulyako, D. A. Malikov, T. I. Trofimov and M. K. Chmutova**

V. I. Vernadsky Institute of Geochemistry and Analytical Chemistry,  
Russian Academy of Sciences, Moscow, Russia

It is established for the first time that solid diphenyl[dibutylcarbamoylmethyl]phosphine oxide (DPBCMPO) forms liquid phases ("liquid reagent") non-miscible with acid solutions on contact with mineral acids. It is found that the compositions of liquid reagent correspond to DPBCMPO· $\text{HNO}_3 \cdot n\text{H}_2\text{O}$  and 2DPBCMPO· $\text{HAn} \cdot n\text{H}_2\text{O}$ , where HAn is  $\text{HClO}_4$  or HCl. The compositions of nitrate and perchloric complexes of liquid reagent with U(VI) and Nd(III) are found. Extraction of a number of actinides in various oxidation states as well as extraction of some lanthanides by liquid reagent in the absence of organic solvent is studied. It is shown that in case of extraction by liquid reagent, distribution ratios increase in comparison with usual solvent extraction. It is established that the complex of the reagent with nitric acid has redox properties resulting in a change of valence states of some actinides in the process of extraction. The use of inert matrices containing DPBCMPO is suggested for isolation and immobilization of actinide and rare-earth elements by vitrification.

### **INTRODUCTION**

Solvent extraction is a simple, effective, express and selective method of isolation and separation of the elements. Nevertheless, the most serious deficiency in this method is the necessity to use large volumes of organic solvents, many of which are volatile, combustible, flammable, toxic and explosive liquids. A number of untraditional systems were developed to avoid the use of organic solvents. Two-phase aqueous systems based on polyethylene glycol, where the second aqueous phase enriched by the polymer is formed as a result of influence of salts on water structure, are such systems [1]. Aqueous systems, aliquation of which is conditioned by chemical interaction of the constituents of aqueous solution being in definite molar ratios, were suggested [2, 3]. The systems "water–antipyrine-pyrocatechol" [2], "water-antipyrine-monochloracetic acid" [3] and others are examples. Solvent-free extraction systems using liquid reagent (for example, 100% tributylphosphate [4]) as an extracting phase are known.

Earlier [5] the study on solubility of such bidentate neutral organophosphorus compounds (BNOC) such as diphenyl[dibutylcarbamoylmethyl]phosphine oxide (DPBCMPO) in nitric acid solutions has shown that the solid like-powder reagent changed its aggregative state from solid to liquid on contacting with the acid. The liquid phase formed, which is immiscible with water ("liquid reagent"), was a complex of the reagent with the acid, and it had high extraction capability with respect to Am(III), Cm(III) and Pr(III) [6, 7]. In further works [8-11] we studied an influence of various factors on both changes of aggregative state of the reagent and its extraction capability with respect to lanthanides and actinides in various valence states. The results of these works, as well as new data regarding the systems DPBCMPO –  $\text{HClO}_4$  and DPBCMPO – HCl are presented in this work.

## RESULTS

### Interaction of DPBCMPO with Mineral Acids

Visual examination of the processes occurring in the system solid DPBCMPO–mineral acid has shown that an irregular lump covered by an oily layer is formed immediately after mixing the components. On subsequent stirring the lump becomes gel-like and develops into a drop on centrifuging. The formation of a "liquid reagent" is observed at acid concentrations  $\geq 0.8$  M  $\text{HClO}_4$ ,  $\geq 2$  M  $\text{HNO}_3$  [6] and  $\geq 4$  M HCl. Transformation of the solid reagent into a liquid one is accompanied by an increase of its weight. The correlation coefficient, which takes into account this increase, is equal to  $1.266 \pm 0.015$ . The density of nitrate "liquid reagent" is equal to  $1.163 \pm 0.012$  g/cm<sup>3</sup> [7]. Thus, for nitric acid solutions one can determine the weight of liquid reagent and its volume, knowing the weighed portion of dry reagent.

The compositions of liquid reagent formed on contacting DPBCMPO with  $\text{HNO}_3$ ,  $\text{HClO}_4$  and HCl solutions were determined (Table 1). The results show that the average molar ratio of the reagent to bound acid is close to 1 in the case of nitrate liquid reagent. Therefore, composition of nitrate liquid reagent corresponds to the formula  $\text{DPBCMPO} \cdot \text{HNO}_3 \cdot n\text{H}_2\text{O}$  [7, 8]. For perchloric and hydrochloric acids, the reagent/acid ratio is close to 2 and compositions of liquid reagents in this case are expressed as  $2\text{DPBCMPO} \cdot \text{HAn} \cdot n\text{H}_2\text{O}$ , where An is the acid anion. The formation of bi-solvate was noticed earlier during extraction of perchloric acid by the solutions of carbamoylmethylphosphine oxides [12], dioxides [13] and carbamoylmethylphosphonates [14] in organic solvents.

*Table 1. Composition of "liquid reagent" formed on contacting DPBCMPO with  $\text{HNO}_3$ ,  $\text{HClO}_4$  and HCl solutions.*

HAn (acid)	Initial concen- tration of HAn, M	Weighed portion of DPBCMPO, mole	Quantity of absorbed HAn, mole	Ratio DPBCMPO:HAn
$\text{HNO}_3$	3.947	$8.11 \times 10^{-4}$	$6.99 \times 10^{-4}$	1
	6.464	$8.54 \times 10^{-4}$	$8.82 \times 10^{-4}$	
	8.143	$10.98 \times 10^{-4}$	$11.69 \times 10^{-4}$	
$\text{HClO}_4$	0.868	$2.79 \times 10^{-4}$	$1.37 \times 10^{-4}$	2
	1.742	$2.77 \times 10^{-4}$	$1.38 \times 10^{-4}$	
	3.012	$2.85 \times 10^{-4}$	$1.30 \times 10^{-4}$	
HCl	4.685	$6.16 \times 10^{-4}$	$2.93 \times 10^{-4}$	2
	6.130	$7.77 \times 10^{-4}$	$3.91 \times 10^{-4}$	
	7.124	$8.85 \times 10^{-4}$	$4.35 \times 10^{-4}$	

The solubility of  $\text{DPBCMPO} \cdot \text{HNO}_3 \cdot n\text{H}_2\text{O}$  in 3 M nitric acid solution, where  $n = 2-3$ , is 1.76 g/L [5, 7]. The solubility of perchloric DPBCMPO as liquid reagent in 3 M  $\text{HClO}_4$  solution ( $2.5 \pm 0.5$  g/L) is higher than it is in 3 M  $\text{HNO}_3$  solution.

### Solvent-free Extraction of Np, Pu and Am in Various Oxidation States by "Liquid Reagent" (LR) from $\text{HNO}_3$ Solutions

Solvent-free extraction of the actinides in various oxidation states by liquid reagent (LR) from nitric acid solutions was studied. In all the cases, a weighed portion of dry reagent (DPBCMPO) was introduced into the solution containing the actinides. The heterogeneous system was stirred for 3 minutes followed by centrifuging for 10 minutes to separate the phases. Time of contact of the reagent with acid solution was sufficient for its transformation into a liquid. The data obtained are presented in Table 2. It is seen, that the efficiency of actinides extraction depends on their valence state and decreases in the following order: IV > VI > III > V. The concentration factor of actinides varies from 20 to 66.

*Table 2. Solvent-free extraction of the actinides in various oxidation states by “liquid reagent” from 4 M HNO<sub>3</sub> solutions.*

M <sup>n+</sup>	[M <sup>n+</sup> ], M		V, mL (aq. ph.)	DPDPCMPO, mole	V, mL (org. ph.)	D*	E*, %

U(VI)	1.50×10 <sup>-3</sup>	9.10×10 <sup>-6</sup>	1.0	1.0×10 <sup>-4</sup>	0.050	3.3×10 <sup>3</sup>	99.40

(\*) – distribution ratio (D) and extraction efficiency (E) were calculated according to the formulas: D = C<sub>org.</sub>/C<sub>aq.</sub>; E = [D/(D+V<sub>aq.</sub>/V<sub>org.</sub>)].100.

Np(IV), Np(VI), Pu(IV) and Pu(VI) do not change valence state during extraction by the liquid reagent. At the same time Pu(III), Np(V) and Am(VI) change valence state to Pu(IV), Np(VI) and Am(III), Am(V), respectively. Therefore, the reagent has redox properties. Taking into account the values of formal redox potentials of Pu(IV)/Pu(III), Np(VI)/Np(V) and Am(VI)/Am(V) pairs equal to +0.982 V, +1.37 V and +1.60 V, respectively [15], its redox potential may be evaluated as about +1.5 V.

### Solvent-free Extraction and Solvent Extraction of Actinides and Lanthanides by DPDPCMPO from Nitric Acid Solutions

It was of interest to compare efficiency of extraction of the elements from nitric acid solutions by DPDPCMPO as LR with the efficiency of extraction with the same quantity of DPDPCMPO in organic solvent (liquid-phase extraction – “LPE”). In the case of Pr(III) extraction, the concentration of DPDPCMPO is less than is required for maximum extraction of the metal ([Pr(III)] = 8·10<sup>-3</sup> M, [HNO<sub>3</sub>] = 5.8 M, V<sub>(aq. phase)</sub> = 2 mL, quantity of DPDPCMPO was equal to 18.5 mg for both types of extraction). Dichloroethane and fluoropol (“ftoropol”), in which DPDPCMPO has a maximum extraction capability [16], were used as a solvent for solvent extraction. In case of extraction of Np(IV) and Np(VI) the quantity of DPDPCMPO was sufficient for maximum extraction of the metal ([Np(IV)] = 1.51·10<sup>-3</sup> M, [Np(VI)] = 1.72·10<sup>-3</sup> M, [HNO<sub>3</sub>] = 4 M, V<sub>(aq. phase)</sub> = 1.2 mL, quantity of DPDPCMPO was equal to 16.3 mg for both types of extraction, dichloroethane was used for solvent extraction as a solvent). The data obtained are presented in Table 3. It is seen that the use of DPDPCMPO as liquid reagent for extraction of the metals from nitric acid solutions is more effective than extraction by the solutions of DPDPCMPO in organic solvents.

**Table 3. Extraction of Pr(III), Np(IV) and Np(VI) by DPBCMPO as “liquid reagent” (LR) and by the solution of the same quantity of DPBCMPO in organic solvent (liquid-phase extraction – “LPE”).**

Type of extraction	Element	D*	E*, %
LR	Pr(III)	1.61	62
LPE (dichloroethane)		0.11	10.4
LPE (fluoropol)		0.48	32.5
LR	Np(VI)	242	99.6
LPE (dichloroethane)		20	95.2
LR		81	98.8
LPE (dichloroethane)		8	88.4

(\*) – distribution ratio (D) and extraction efficiency (E) were calculated according to the formulas:

$$D = C_{\text{org}} / C_{\text{aq}}, E = [D/(D+1)] \cdot 100$$

### **Compositions of U(VI) and Nd(III) Complexes with Nitrate and Perchloric “Liquid Reagent”**

It is known, that americium (III) is extracted by organic solutions of diaryl[dialkylcarbamoylmethyl]phosphine oxides from perchloric acid solutions as tri- and tetra-solvates [17] and from nitric acid solutions as bi-solvates[18, 19].

We determined the molar ratio of the reagent to metal cation belonging to the complex formed as a result of extraction of U(VI) and Nd(III) by nitrate LR. The composition of extracted compounds of Nd(III) with perchloric LR was determined as well. The data obtained are presented in Table 4. In all cases, the extraction of cations of the metals by LR from acid solutions was complicated by solidification (cementing) of formed complexes of U(VI) and Nd(III) with liquid reagents. Increasing the temperature of heterogeneous systems to about 80°C allowed us to carry out the extraction processes further. Heated phases were separated by centrifugation. Analysis of residual contents of U(VI) and Nd(III) was carried out at room temperature. The extraction process was completed, when the content of metal cations in the aqueous solution was constant after the next extraction. The quantity of the extracted element was determined and a ratio between constituents in formed complex was calculated. Melting points of complex compounds of Nd(III) with nitrate and perchloric liquid reagent were evaluated as 65-70C and 110-120C, respectively.

The composition of Nd(III) complexes with LR under study was determined at room temperature as well. In this case, LRs were deposited onto the matrix of silicon oxide (Chromatron, 100-150 µm, DMSC, weight content of DPBCMPO in matrix is equal to 6.06%). Thus, Nd(III) is extracted by LR as tetra-solvate from 3- 7 M HNO<sub>3</sub> solutions and it is extracted as tri-solvate from 0.87 – 3.01 M HClO<sub>4</sub> solutions. Uranium (VI) is extracted by nitrate LR as bi-solvate. A comparison of compositions of extracted complexes obtained by us in the absence of organic solvents with the results reported in literature [17-19] shows, that the compositions of extracted compounds of actinide and lanthanide elements with DPBCMPO depend on composition of both organic (solvent-free or solvent extraction) and aqueous (acid nature) phases.

**Table 4.** The compositions of complexes formed as a result of U(VI) and Nd(III) extraction by “liquid reagent” from nitric acid and perchloric acid solutions.

HAn (acid)	[HAn], (initial) M	Element (M <sup>n+</sup> )	Quantity of DPDBCMPO in “LR”, mole	Quantity of extracted M <sup>n+</sup> , mole	Ratio DPDBCMPO : M <sup>n+</sup>
HNO <sub>3</sub>	2.82	Nd(III)	1.68×10 <sup>-4</sup>	0.429×10 <sup>-4</sup>	3.9
	7.22		1.97×10 <sup>-4</sup>	0.500×10 <sup>-4</sup>	
	3.23	U(VI)	2.75×10 <sup>-4</sup>	1.46×10 <sup>-4</sup>	1.9
HClO <sub>4</sub>	0.87	Nd(III)	8.21×10 <sup>-5</sup>	2.73×10 <sup>-5</sup>	3.0
	3.01		8.29×10 <sup>-5</sup>	2.80×10 <sup>-5</sup>	

The composition of Nd(III) complexes with LR under study was determined at room temperature as well. In this case, LRs were deposited onto the matrix of silicon oxide (Chromatron, 100-150 μm, DMSC, weight content of DPDBCMPO in matrix is equal to 6.06%). Thus, Nd(III) is extracted by LR as tetra-solvate from 3- 7 M HNO<sub>3</sub> solutions and it is extracted as tri-solvate from 0.87 – 3.01 M HClO<sub>4</sub> solutions. Uranium (VI) is extracted by nitrate LR as bi-solvate. A comparison of compositions of extracted complexes obtained by us in the absence of organic solvents with the results reported in literature [17-19] shows, that the compositions of extracted compounds of actinide and lanthanide elements with DPDBCMPO depend on composition of both organic (solvent-free or solvent extraction) and aqueous (acid nature) phases.

#### Recovery and Separation of Uranium and Lanthanides by DPDBCMPO Immobilized on an Inert Matrix from Acid Solutions.

The use of DPDBCMPO immobilized on inert matrices is one of the alternatives for separation of actinide and lanthanide elements and for isolation of those from radioactive waste for their subsequent underground disposal.

#### Separation of uranium and lanthanides by DPDBCMPO immobilized on SiO<sub>2</sub>

A certain quantity of DPDBCMPO (about 10% by weight with respect to SiO<sub>2</sub>) was dissolved in CHCl<sub>3</sub> and mixed with SiO<sub>2</sub> (30-60 mesh) with simultaneous evaporation of the solvent. The mixture obtained was thoroughly stirred until the solvent was evaporated. The necessary quantity of SiO<sub>2</sub> with DPDBCMPO immobilized on its surface and 1.5-2.0 mL of aqueous nitric acid solution containing the element under study were used in the each experiment. Extraction was carried out for 3 minutes at room temperature for achievement of equilibrium. After centrifugation and phase separation, concentrations of the elements involved were determined by spectrophotometry. The data obtained were used for calculation of distribution ratios and extraction percentages. The results obtained are presented in Table 5.

**Table 5.** Extraction of U(VI) and lanthanides by DPDBCMPO immobilized onto SiO<sub>2</sub> from 3 M HNO<sub>3</sub> solution. [Me] = 0.01 M, V<sub>ag. phase</sub> = 2.0 mL, [Me] : [DPDBCMPO] = 1 : 2.

Ion	λ, nm	A <sub>0</sub>	A <sub>1</sub>	E, %	D*, mL/g	S <sub>U/Ln</sub>

Er(III)	379	0.102	0.072	29.4	4.9	47.1

\* - D = c<sub>s</sub> × V / (c<sub>aq</sub> × m) (mL/g), where c<sub>s</sub> and c<sub>aq</sub> denote equilibrium concentrations of the element in phases of SiO<sub>2</sub> (DPDBCMPO) and aqueous solution, respectively, V is the volume (mL) of the aqueous phase, m is the amount (g) of SiO<sub>2</sub>(DPDBCMPO). The concentrations c<sub>s</sub> and c<sub>aq</sub> were calculated, using the expressions: c<sub>s</sub> = (A<sub>0</sub> - A<sub>1</sub>) / εl and c<sub>aq</sub> = A<sub>1</sub> / εl, where A<sub>0</sub> and A<sub>1</sub> are optical absorbances of aqueous phase before and after the extraction, respectively.

As seen in Table 5, the distribution ratio of U(VI) considerably exceeds the distribution ratios of the lanthanides. The separation factor,  $S_{U/Ln}$ , achieves a value of 40. The separation factor,  $S_{U/Ln}$ , was found to be higher in case of heavy lanthanides than that of light ones. Quantitative isolation of the lanthanides from the solid phase of the reagent can be performed by twice repeated re-extraction with 2 mL of water. Unlike lanthanides, very little uranium is stripped with  $H_2O$ . However, it can be easily stripped with 0.01 M sodium carbonate.

#### ***Isolation of Pr(III) with DPDBCIM immobilized on powder-like matrix of aluminum phosphate glass for subsequent vitrification of the product obtained***

A 0.01 M solution of Pr(III) in 3 M  $HNO_3$  was used in the experiment. A sample of molten aluminum phosphate glass was powdered. Immobilization of the reagent onto a glass powder was done as follows. A measured amount of DPDBCIMPO was dissolved in acetone and this solution was mixed with a weighed portion of a glass powder. Acetone was then evaporated carefully, while stirring, and the product was dried at ambient temperature. The matrix of aluminum phosphate glass (2.5 g) contained 0.3 g of DPDBCIMPO. The prepared powder-like mass (1.73 g) containing  $5.0 \times 10^{-4}$  moles of the reagent was placed into a chromatographic column (5 mm i.d. and 40 mm h). Initially, 1 mL of 3 M  $HNO_3$  solution was passed through the column to transform DPDBCIMPO into LR. Next, 5 mL of  $HNO_3$  solution containing  $5 \times 10^{-5}$  moles of praseodymium were passed through the column, followed by washing with 2 mL of 1 M  $HNO_3$  solution at the rate of about 0.18 mL/min. The concentration of Pr(III) was measured by spectrophotometry. The residual concentration of Pr(III) in the solution collected after sorption and washing was equal to  $3 \times 10^{-4}$  M. Thus, more than 96% of the initial amount of Pr was isolated from the solution. The column content was transferred quantitatively into a glass-graphite test-tube and dried. This test-tube was placed into a muffle, where praseodymium-containing glass powder was melted at  $1100^{\circ}C$  for 4-5 hours. The final weight of the vitrified matrix was 1.3 g. Weight loss compared to the initial matrix weight (1.73 g) can be explained by partial dissolution of the matrix in  $HNO_3$  solution.

## **CONCLUSIONS**

The data obtained show that on contact with mineral acid solutions DPDBCIMPO powder changes its aggregative state, being transformed into a liquid colorless viscous substance immiscible with aqueous solutions. Acidity of the solution and interaction of the reagent with mineral acid are the factors determining both physical state of the product of their interaction and extraction capacity of the compound formed. The use of "liquid reagent" allows extracting the metals in question more effectively in comparison with extraction by the DPDBCIMPO solutions in organic solvents. It is promising for the processing of acidic high-level wastes because the use of toxic and environmentally hazardous organic solvents can be avoided.

The dissolution of actinide oxides in supercritical fluid carbon dioxide containing a complex of tri-*n*-butyl phosphate with nitric acid was investigated. It was shown for the first time that milligram amounts of uranium dioxide can be quantitatively dissolved in supercritical carbon dioxide containing this reagent and efficiently separated from plutonium, neptunium, and thorium on its supercritical fluid extraction from a mixture of their oxides. The quantitative dissolution of milligram amounts of uranium trioxide in supercritical carbon dioxide containing thenoyltrifluoroacetone and tri-*n*-butyl phosphate was first performed using ultrasonication. The separation of uranium (VI) and cerium (IV) in the system involved was demonstrated.

## INTRODUCTION

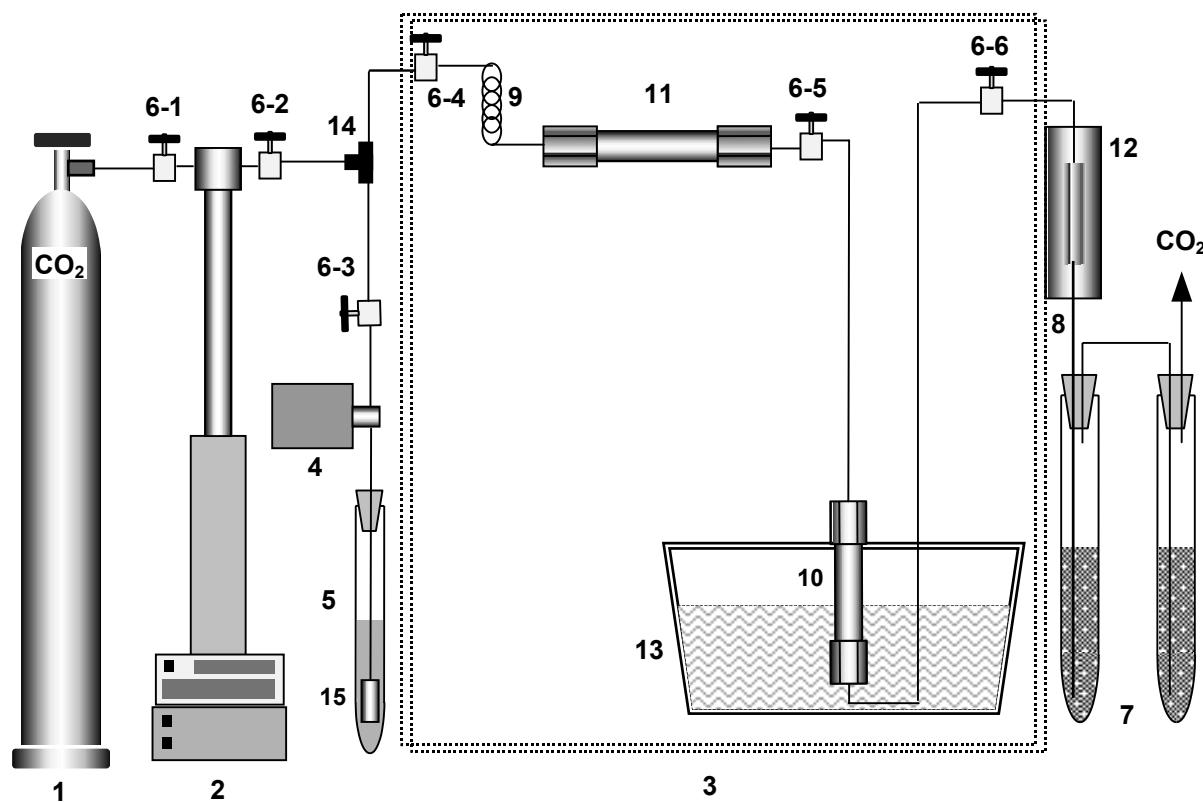

A key chemical process in the nuclear industry is the extraction and purification of uranium and plutonium in the initial production of fuel for nuclear reactors and in reprocessing of spent nuclear fuel. The most widely used commercial process to achieve this objective is the PUREX (Plutonium Uranium Reduction Extraction) process, which involves the dissolution of spent nuclear fuel in strong nitric acid followed by solvent extraction of uranium from the acid solution using tri-*n*-butyl phosphate (TBP) as an extractant [1,2]. The extracted uranium and plutonium nitrate-TBP complexes are further separated by chemical steps to yield pure uranium and plutonium dioxides. The PUREX process, though highly efficient, has the inherited drawbacks of liquid-liquid extraction including generation of large volumes aqueous and organic high-level radioactive wastes. So a search for new alternative techniques for reprocessing of spent nuclear fuels, which will allow minimizing waste generation, is a major task challenging the future of the nuclear industry.

The possibility of using supercritical fluid carbon dioxide as a solvent for reprocessing of spent nuclear fuels was suggested recently in the literature [3]. Of particular interest is the idea of direct dissolution of the spent nuclear fuel in supercritical carbon dioxide utilizing a suitable complexing agent. Supercritical CO<sub>2</sub> is considered a green solvent because it is non-toxic and environmentally benign. Carbon dioxide is also cheap, readily available in relatively pure form, and has moderate critical constants ( $T_c = 31.3^\circ\text{C}$ ,  $P_c = 72.8$  atm, and  $\rho_c = 0.47 \text{ g/cm}^{-3}$ ) [4]. A major advantage of using supercritical CO<sub>2</sub> for reprocessing spent nuclear fuels is elimination of the acid and organic solvent required in the conventional PUREX process. A major problem of developing this new process is to identify a complexing agent that will form a supercritical CO<sub>2</sub>-soluble complex with the main component of the spent nuclear fuel, basically uranium dioxide.

The hexavalent uranyl ion ( $\text{UO}_2^{2+}$ ) is known to form  $\text{CO}_2$ -soluble complexes with a number of complexing agents including TBP and  $\beta$ -diketones [5,6]. It has been demonstrated that uranium trioxide  $\text{UO}_3$  can be dissolved in supercritical  $\text{CO}_2$  with thenoyltrifluoroacetone (HTTA) and TBP [7,8]. Recent studies have also demonstrated the possibility of lanthanide extraction from their oxides using supercritical  $\text{CO}_2$  containing TBP- $\text{HNO}_3$  complex [2]. However the extraction efficiency of all elements involved did not exceed 40%. Thus it was of interest to develop a procedure for the quantitative extraction of uranium from its oxides simultaneously with its separation from other actinides, such as Pu, Np, and Th. The results obtained are presented below.

## PROCESS DESCRIPTION

Figure 1 shows a schematic diagram of the set-up employed for SFE is shown. A syringe pump was used to deliver liquid  $\text{CO}_2$  through a pre-heating coil to the extraction system placed in a chromatographic oven for heating the system to the required temperature. A known amount of either an actinide oxide sample or a mixture of those were put into a glass tube and plugged at both ends with glass wool. After weighing, the tube was placed in a 3.5 mL extraction cell.

*Figure 1. Schematic diagram of the experimental system for uranium oxides dissolution in supercritical carbon dioxide. 1,  $\text{CO}_2$  cylinder; 2, syringe pump; 3, oven; 4, HPLC pump; 5, test-tube with TBP; 6-1 – 6-6, volumeless valves; 7, collection system; 8, restrictor; 9, fluid preheating coil; 10, extraction cell; 11, ligand cell; 12, restrictor heater; 13, ultrasonic cleaner; 14, T-joint; 15, filter.*

The saturation of supercritical CO<sub>2</sub> with the ligands (TTA or TBP-HNO<sub>3</sub> complex) was performed in a 10.4 mL ligand cell connected upstream of the extraction. Pure TBP was injected into the system through a T-end joint using a HPLC pump. The flow rate of TBP injected into the system was about 0.02 mL/min, which corresponded to its concentration in supercritical CO<sub>2</sub> of about 5% v/v. The extractions were performed in static (a sample and supercritical CO<sub>2</sub> are allowed to interact for a given amount of time), dynamic (supercritical CO<sub>2</sub> is allowed to flow continuously through the extraction cell containing the sample), and combined modes (a static mode followed by dynamic mode). The time of the static mode was about 10 min in all runs, and that of dynamic one was varied from 15 to 60 min. Supercritical CO<sub>2</sub> flow rates through the system were maintained at 0.2-0.6 mL/min. Faster flow rates tend to decrease the extraction efficiency of uranium thanks to incompleteness of the interaction of the TBP-HNO<sub>3</sub> complex with an oxide involved. After extraction, the system was allowed to depressurize for about 1 hour. Extracted actinide complexes were collected in a trap solution (chloroform) through the restrictors made of deactivated fused silica, about 25 cm in length and 50 μm in internal diameter. Actinides were back extracted from the trap solutions with 50% nitric acid in the case of using TTA and TBP as the ligands or with 0.1 M (NH<sub>4</sub>)<sub>2</sub>CO<sub>3</sub> in the case of the TBP-HNO<sub>3</sub> complex. The actinide content in the solutions obtained was determined by alpha-radiometry (Pu, Np, and U), luminescence (U), and ICP-MS (Th, Ce). The extraction efficiency E (%) was calculated according to the formula (1).

$$E = \frac{m_1}{m_0} \times 100\% \quad (1)$$

where  $m_1$  and  $m_0$  are the amounts of actinides found in the trap solution and taken in to the run correspondingly (mg). The powder-like oxides of ThO<sub>2</sub>, UO<sub>3</sub>, U<sub>3</sub>O<sub>8</sub>, NpO<sub>2</sub>, and PuO<sub>2</sub> were used as supplied. UO<sub>2</sub> sample was prepared by milling a real, nonirradiated, uranium fuel pellet.

### DISSOLUTION OF THE ACTINIDE OXIDES USING SUPERCRITICAL CO<sub>2</sub> CONTAINING THE TBP-HNO<sub>3</sub> COMPLEX

It is known that uranyl ions in strong nitric acid solutions can be extracted by supercritical CO<sub>2</sub> containing TBP [10]. The extracted uranyl complex UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>•2TBP has an unusually high solubility in supercritical CO<sub>2</sub>, of the order of 4.2×10<sup>-1</sup> mol/L at 40°C and 200 atm [11]. HNO<sub>3</sub> is known to be extracted with TBP forming a complex  $n$ HNO<sub>3</sub>•TBP, where  $n$  = 1, 2, 3, depending on HNO<sub>3</sub> concentration [12]. It was found that this complex is very soluble in the supercritical CO<sub>2</sub> phase [9]. In addition, the TBP-HNO<sub>3</sub> complex may be an effective reagent for dissolution of UO<sub>2</sub> because HNO<sub>3</sub> is an oxidizing agent.

To obtain the TBP-HNO<sub>3</sub> complex, a 100% TBP was treated with concentrated nitric acid (13.8 M, density 1.37 g/cm<sup>3</sup>). After separating phases by centrifuging, the necessary amount of the complex obtained was placed in the ligand cell, where supercritical CO<sub>2</sub> was saturated with the TBP-HNO<sub>3</sub> complex for 15 min.

The results on SFE of actinides from their individual oxides and from a mixture of those using supercritical CO<sub>2</sub> modified with the TBP-HNO<sub>3</sub> complex are presented in Tables 1 and 2, respectively. The chosen SFE conditions were found previously to be optimal for this system. As is seen from the data presented, uranium can be quantitatively extracted from all its oxides tested. It was shown by spectrophotometry, that uranium is present only in the +6 valent state in the trap solution. Thus, as one would expect, it was demonstrated that on interaction of the TBP-HNO<sub>3</sub> complex with UO<sub>2</sub>, oxidation of tetravalent uranium to the hexavalent state proceeds, leading to the formation of the highly soluble UO<sub>2</sub>(NO<sub>3</sub>)<sub>2</sub>•2TBP

complex in the supercritical CO<sub>2</sub> phase. At the same time, the extraction efficiencies of Pu, Np, and Th are extremely poor from both the individual oxides and the mixture with uranium dioxide (Table 2). Of course, the common mixture of oxides is not identical to the real nuclear fuel which is a solid solution of uranium and plutonium dioxides. Nevertheless, the demonstration of effective dissolution of uranium in supercritical CO<sub>2</sub> modified with the TBP-HNO<sub>3</sub> complex and its separation from the actinides tested is very promising for further development of a supercritical CO<sub>2</sub>-based process for reprocessing spent nuclear fuel.

*Table 1. SFE of actinides from their individual oxides using supercritical CO<sub>2</sub> modified with the TBP-HNO<sub>3</sub> complex. T = 65°C, P = 250 atm. SFE mode – thrice-repeated alternation of static (10 min) and dynamic (15 min) modes. \* - not milled uranium fuel pellet.*

## DISSOLUTION OF URANIUM OXIDES IN SUPERCRITICAL CO<sub>2</sub> CONTAINING HTTA AND TBP USING ULTRASONICATION

The hexavalent uranyl ion (UO<sub>2</sub>)<sup>2+</sup> is known to form supercritical CO<sub>2</sub>-soluble complexes with a number of complexing agents including TBP and HTTA [7,10,13]. It has been demonstrated that uranium trioxide can be dissolved in supercritical CO<sub>2</sub> with a fluorinated β-diketone thenoyltrifluoroacetylacetone (HTTA) and TBP according to the following reaction:

However, the extraction efficiency of uranium did not exceed 40% [8].

It is well known that ultrasonication can accelerate many heterogeneous processes. We used an ultrasonic cleaner with a heater (model FS30, Fisher scientific, PA, USA) with working frequency 44-48 kHz (Figure 1). The SFE conditions applied were found previously [8] to be optimal for the UO<sub>3</sub>-HTTA-TBP system. Table 3 shows the effect of ultrasonication on the SFE of uranium from its oxides with supercritical CO<sub>2</sub> containing TTA and TBP.

*Table 3. Dissolution of uranium oxides in supercritical CO<sub>2</sub>, containing HTTA and TBP using ultrasonication. SFE conditions is P = 150 atm and T = 60°C. SFE mode – thrice-repeated alternation of static (10 min) and dynamic (15 min) modes. \* without ultrasonication.*

Oxide	Uranium added, m <sub>0</sub> (mg)	Uranium trapped	
		m <sub>1</sub> (mg)	E (%)
UO <sub>3</sub>	22.9	8.5 ± 0.3	37.0*
UO <sub>3</sub>	25.2	24.3 ± 0.6	96.4
U <sub>3</sub> O <sub>8</sub>	30.9	0.7 ± 0.1	2.3
UO <sub>2</sub>	23.9	1.2 ± 0.2	5.0

As can be seen from the data obtained, ultrasound allows uranium to be quantitatively extracted from UO<sub>3</sub> with the above system. Unfortunately its application does not result in an essential increase of both UO<sub>2</sub> and U<sub>3</sub>O<sub>8</sub> dissolution in supercritical CO<sub>2</sub> containing TTA and TBP. This fact may be explained by structural differences between UO<sub>2</sub>, U<sub>3</sub>O<sub>8</sub>, and UO<sub>3</sub> (UO<sub>2</sub> – face-centered, U<sub>3</sub>O<sub>8</sub> orthorhombic and UO<sub>3</sub> – octahedral), as well as by steric hindrances in the U(IV) complexation with TTA and TBP. The effect of ultrasound can be attributed to the cleaning of the oxide surface by removing the complex formed. As a result, the reaction with TTA takes place more effectively.

The data in Table 4 show that the suggested system can be successfully applied to the separation of uranium and cerium in the SFE from a mixture of UO<sub>3</sub> and CeO<sub>2</sub>. The molar ration [U]:[Ce] in the trap solution is about 30 times higher than that in the starting mixture.

*Table 4. Separation of the U(VI) and Ce(IV) using supercritical CO<sub>2</sub>, containing TTA and TBP under ultrasonication. SFE conditions is P = 150 atm and T = 60°C. SFE mode – thrice-repeated alternation of static (10 min) and dynamic (15 min) mode.*

Oxide	Metal added, $m_0$ , (mg)	Metal trapped	
		$m_1$ (mg)	E (%)
UO <sub>3</sub>	23.0	21.3±0.4	92.7
CeO <sub>2</sub>	13.6	0.4±0.1	3.1

## CONCLUSIONS

The study conducted has demonstrated that milligram amounts of uranium can be quantitatively extracted from UO<sub>2</sub>, UO<sub>3</sub>, and U<sub>3</sub>O<sub>8</sub> with supercritical CO<sub>2</sub> containing the TBP-HNO<sub>3</sub> complex, and efficiently separated from plutonium, neptunium, and thorium in the SFE from the mixture of their oxides. Also milligram amounts of uranium can be quantitatively extracted from UO<sub>3</sub> with supercritical CO<sub>2</sub> containing HTTA and TBP under ultrasonication. The enhanced dissolution of UO<sub>3</sub> by means of ultrasound is, probably, caused by removing the UO<sub>2</sub>(TTA)<sub>2</sub>•H<sub>2</sub>O complex from the oxide surface, hence facilitating the complexation process. Demonstration of effective dissolution of uranium oxides in supercritical CO<sub>2</sub> is of great importance for developing a new alternative environmentally benign process for reprocessing spent nuclear fuel. Application of the SFE technique may be very promising for spent nuclear fuel reprocessing thanks to minimizing of environmentally hazardous liquid radioactive waste generation associated with the currently used PUREX process.

## MODELLING THE INFLUENCE OF ORGANIC PHASE COMPOSITION ON THE EXTRACTION OF TRIVALENT ACTINIDES

M. Nilsson, J-O. Liljenzin, C. Ekberg and S. Wingefors\*

Department of Nuclear Chemistry, Chalmers University of Technology, Göteborg, Sweden

\* Swedish Nuclear Power Inspectorate, Stockholm, Sweden

A model for description of solvent influence on extraction of Am, Cm and Pm is proposed. The model comprises an extension of the Scatchard-Hildebrand theory for regular solutions employing Hansen's 3-D solubility parameters to describe interactions in the organic phase. The model was tested by performing a number of extraction experiments with 2,2':6',2''-terpyridine and 2-bromodecanoic acid as complexing agents in different combinations of organic solvents. The results obtained were used for fitting the parameters in the model and another set of experiments was performed to validate the model. The model shows good agreement between experimental and calculated distribution ratios for most of the extraction cases tested. From this analysis it can be concluded that the choice of solvent has a negligible effect on the selectivity of the studied extraction system.

### INTRODUCTION

One major concern regarding nuclear power production is management of the long-lived radioactive nuclear waste. Through transmutation by neutron irradiation, long-lived waste can be converted into short-lived or stable nuclides. This means that the long-lived waste from the nuclear fuel cycle has to be isolated from the biosphere only for a couple of hundred years instead of, as in the case of direct disposal of spent nuclear fuel, for hundreds of thousands of years. Another benefit from this process is that the released energy may be utilised. This means that the nuclear fuel is more efficiently used, which is a step towards a more sustainable society. A transmutation process must be connected to a partitioning process, where transmutable elements, e.g., Am, Cm and Np, are separated from other elements that will reduce the transmutation efficiency. Sufficient separation of the different elements can be achieved with solvent extraction using a selective extraction system. In order to find a suitable extraction system, a large number of different combinations of organic solvents and extracting reagents must be studied. In an attempt to reduce the time needed for this investigation, a model that can predict the extraction of some trivalent actinides and lanthanides is being developed. The model is based on the Scatchard-Hildebrand solubility parameter theory and its extension to describe dispersion, polar and hydrogen bonding interactions according to Hansen's 3-D solubility parameter concept.

## THEORY

### Solubility Parameters

The relation between intermolecular attraction forces and solubility is reflected in the Hildebrand solubility parameter,  $\delta$ , defined approximately as [1]

$$\delta = \left[ \frac{\Delta H_m - RT}{v} \right]^{\frac{1}{2}} \quad (1)$$

where  $\Delta H_m$  and  $v$  are the molar heat of vaporisation and molar volume respectively. The heat of vaporisation is the energy required to separate the molecules in a liquid from each other, turning the liquid into a gas. This energy can be referred to the amount of energy that holds the molecules together. Thus the Hildebrand solubility parameter is based on the assumption that the same intermolecular attractive forces have to be overcome to vaporise a liquid as to dissolve it. Similar to the miscibility problems with components of different intermolecular attraction forces, immiscibility will occur if the solubility parameters of the compounds differ too much.

The original Scatchard-Hildebrand model was based on the assumption of only weak molecular attraction, dominated by dispersion forces. Higher accuracy in describing non-ideal solutions can be achieved if the total attraction between molecules in a solution is considered as a sum of dispersion, polar and hydrogen bonding forces. The most widely used three-parameter system has been developed by Hansen 1967 [2]. Hansen split the Hildebrand parameter into three parts according to

$$\delta_t^2 = \delta_d^2 + \delta_p^2 + \delta_h^2 \quad (2)$$

$\delta_t^2$  = total Hildebrand parameter

$\delta_d^2$  = dispersion parameter

$\delta_p^2$  = polar parameter

$\delta_h^2$  = hydrogen bonding parameter

### Applications of Solubility Parameters

The extraction is assumed to follow the reaction

$M^{3+}$  is the metal ion that is to be extracted ( $Am^{3+}$ ,  $Cm^{3+}$  or  $Pm^{3+}$ ). HA is the dimerised form of 2-bromodecanoic acid and B is 2,2':6',2''-terpyridine. The bars denote quantities relevant to the organic phase. The thermodynamic equilibrium constant for the extraction reaction in terms of activities is expressed as:

$$K_D = \frac{\overline{M} \overline{H^+}^3}{\overline{M}^{3+} \overline{HA}^3 \overline{B}^2} \quad (4)$$

In equation 4 and subsequently, the extracted complex,  $\overline{MA_3B_2}$ , is written as  $\overline{M}$ . It is assumed that this equilibrium is applicable for all organic solvents. The metal is present in tracer amounts so the concentrations of HA, B and  $H^+$  are assumed constant and equal to starting concentrations,  $\overline{C}_{HA}$ ,  $\overline{C}_B$  and  $C_H$ . With the assumption that the dominating species are trivalent metal ion and non-charged metal complex in the aqueous and organic phase respectively, equation 4 can be transformed into:

$$D \cdot \frac{\left(\frac{x_M}{C_M}\right)}{\left(\frac{x_{HA}}{C_{HA}}\right)^3 \left(\frac{x_B}{C_B}\right)^2} \frac{C_H^3}{C_{HA}^3 \cdot C_B^2} = K_D' \frac{\gamma_{HA}^{-3} \cdot \gamma_B^{-2}}{\gamma_M} \quad (5)$$

where  $x$  is molar fraction and  $K_D'$  the thermodynamic equilibrium constant,  $K_D$ , referred to a standard state of infinite dilution of the organic solvent. The activity factors,  $\gamma$ , are found using the Scatchard-Hildebrand equation

$$RT \ln \gamma_i = v_i [(\delta_{d,i} - \delta_{d,tot})^2 + (\delta_{p,i} - \delta_{p,tot})^2 + (\delta_{h,i} - \delta_{h,tot})^2] \quad (6)$$

If the solubility parameters and molar volume of the extracted complex are known as well as  $K_D'$ , equation 5 together with equation 6 can be used for estimating the distribution ratio.

## EXPERIMENTAL

### Materials

The organic solvents used, 2,2':6,2''-terpyridine (terpy) and 2-bromodecanoic acid along with their solubility parameters are listed in Table 1.

*Table 1. A list of substances used in the experiments.  
All parameter values were found in [3], if not stated otherwise.*

### Procedure and Apparatus

Solvent extraction of Am, Cm and Pm was investigated. The aqueous phase was the same during all experiments and consisted of about 1.7 kBq per cm<sup>3</sup> each of <sup>241</sup>Am, <sup>244</sup>Cm and <sup>147</sup>Pm in 0.05 M HNO<sub>3</sub>. The organic phase was made up of one or more organic solvents with 1 M 2-bromodecanoic acid and 0.1 M terpy. If more than one organic solvent were

present in the organic phase the volume ratio between the solvents was 1. 2.5 ml of each phase was added to a test tube, which was vigorously shaken for 5 minutes and then the phases were allowed to settle. Aliquots from each phase were taken for radiometric analysis. This process was repeated five times to minimise fluctuations. The  $\gamma$ -energy at 59.5 keV for  $^{241}\text{Am}$  was measured using an Intertechnique Gamma Counter 4000 NaI(Tl) detector. For detection of  $\alpha$ - and  $\beta$ -radiation a LKB Wallac 1219 Rackbeta liquid scintillator was used.

## RESULTS AND DISCUSSION

The experimental data show that there is a distinct difference in the distribution of the metals when different organic solvents are used. Am and Cm have higher distribution ratios than Pm, about ten times as high in most extraction cases tested. This actinide-lanthanide separation has been observed in earlier experiments [7]. No specific separation between Am and Cm could be observed.

### Fitting a Model to the Experiments

Experimental distribution ratios (D-values) obtained for a number of pure solvents employed for fitting of the proposed model to find the 5 unknown parameters in equation 5 and 6 (*i.e.*,  $K_D$ ,  $\bar{v}_M$ ,  $\bar{\delta}_{d,M}$ ,  $\bar{\delta}_{p,M}$ ,  $\bar{\delta}_{h,M}$ ). In order to make the model work, the number of unknown parameters must be minimized. Thus, the molar volume of the extracted complex,  $\bar{v}_M$ , can be expressed as a sum of the molar volumes of its components [8].

$$\bar{v}_M = 3 \cdot \bar{v}_{HA} + 2 \cdot \bar{v}_B \quad (7)$$

Also the dispersion parameter of the complex,  $\bar{\delta}_{d,M}$ , can be derived from the dispersion parameters of the organic ligands.

$$\bar{\delta}_{d,M} = \sqrt{\frac{3 \cdot \bar{v}_{HA} \cdot \bar{\delta}_{d,HA}^2 + 2 \cdot \bar{v}_B \cdot \bar{\delta}_{d,B}^2}{3 \cdot \bar{v}_{HA} + 2 \cdot \bar{v}_B}} \quad (8)$$

Hence only three unknown parameters must be found. Data from extraction experiments with solvent mixtures was used for testing the model. The solvent mixtures are displayed in Table 2. Hansen solubility parameters for the total organic phases were calculated using the formula [9]

$$\delta_{i,tot} = \frac{\delta_{i,1} \cdot V_1 + \delta_{i,2} \cdot V_2 + \dots + \delta_{i,n} \cdot V_n}{V_1 + V_2 + \dots + V_n} \quad (9)$$

$i = d, p$  or  $h$

$n =$  number of components

$V =$  volume of each component in the mixture

*Table 2. Combinations of organic solvents used in the experiments where more than one solvent was present in the organic phase.*

Combinations of organic solvents tested
Chloroform / <i>tert</i> -Butylbenzene
Chlorobenzene / Xylene
Ethyl benzene / Chlorobenzene
Cyclohexane / Toluene
Nitrobenzene / <i>n</i> -Hexane
Benzene / Carbon tetrachloride
Benzene / Carbon tetrachloride / Toluene
Cyclohexane / Chloroform / Chlorobenzene

Comparison between experimental and calculated distribution ratios are plotted in graphs, see Figure 1. Parameters obtained by fitting equation 5 are shown in Table 3. Statistical uncertainties in Table 3 were estimated using the chi-square method [10]. The standard deviations presented in Figure 1 were based on five replicate measurements on different samples.

Table 3. Constants used in equation 5 and 6, obtained from fitting and calculations.

Constant parameters for equation 5 and 6	M = Am-complex	M = Cm-complex	M = Pm-complex
$\bar{v}_M$ (cm <sup>3</sup> /mole)	1597.18	1597.18	1597.18
$\bar{\delta}_{d,M}$ (cal/cm <sup>3</sup> ) <sup>1/2</sup>	9.78	9.78	9.78
$\bar{\delta}_{p,M}$ (cal/cm <sup>3</sup> ) <sup>1/2</sup>	2.83 ± 0.06	2.81 ± 0.05	2.75 ± 0.07
$\bar{\delta}_{h,M}$ (cal/cm <sup>3</sup> ) <sup>1/2</sup>	1.99 ± 0.10	1.95 ± 0.09	1.99 ± 0.11
$K_D'$ (mole/dm <sup>3</sup> ) <sup>2</sup>	1.10 ± 0.84	0.83 ± 0.50	0.053 ± 0.05

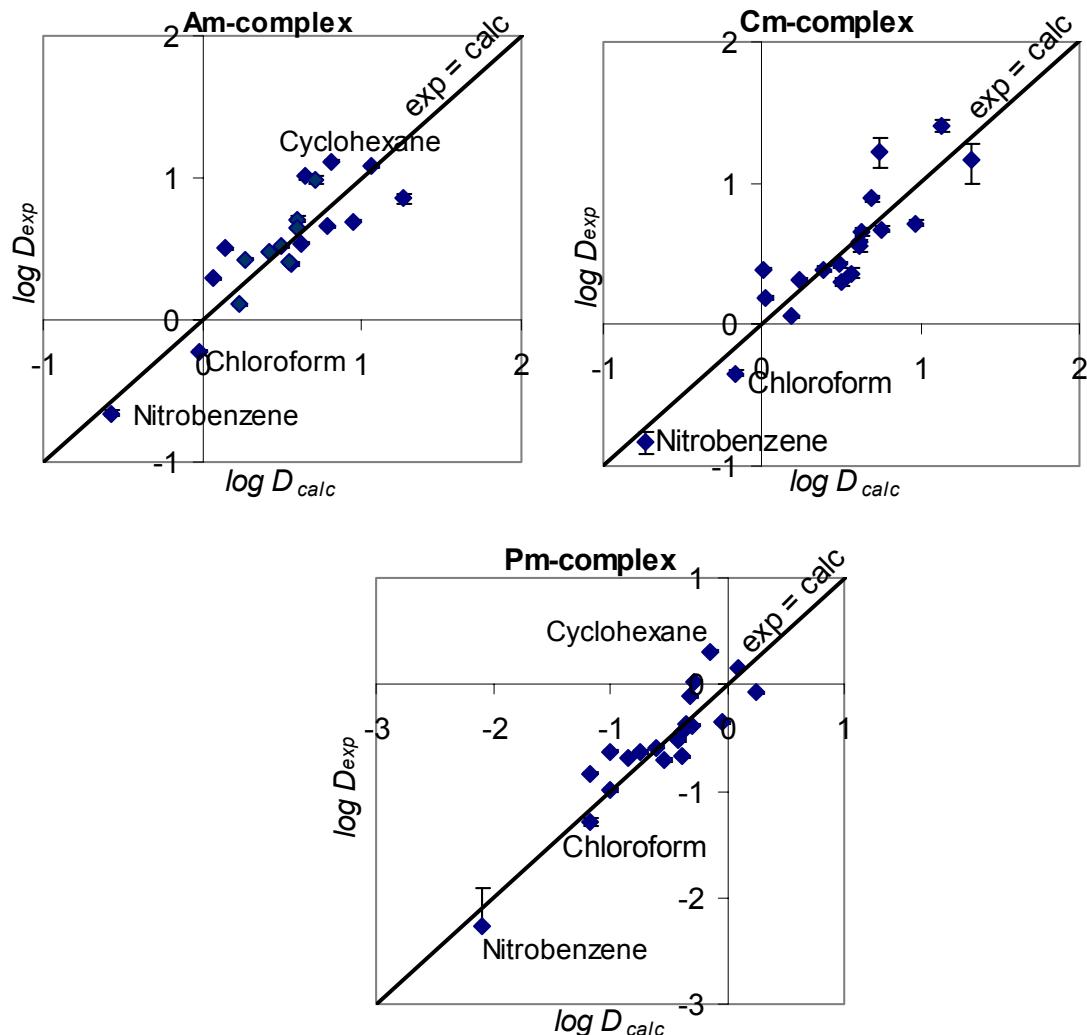

Figure 1. Comparison between experimental and calculated  $D$ -values, with one standard deviation included for the experimental values. A few interesting points are indicated. For most of the experimental  $D$ -values the standard deviation is so small that it is covered completely by the dots.

## CONCLUSIONS

The model gives reasonably good agreement with experiments in most of the extraction cases tested. However, the real merit of this analysis lies more in the possibilities to draw conclusions about the effects of different solvents. Inspection of the fitted polar and hydrogen bonding solubility parameters strongly indicates that there is no significant difference between the three metal complexes in their solvent interactions. This confirms and provides an explanation of why the choice of solvent is of no significance to the selectivity. The separation between lanthanides and actinides is most likely dominated by the complex formation as indicated by the big difference in  $K_D$ -values.

Nevertheless, a careful selection of solvent is still necessary, e.g., with respect to phase flows in a multistage process, chemical and radiolytical stability, ease of phase separation and kinetics.

In future work the viability of still more refined extensions of the Scatchard-Hildebrand theory will be tested, e.g., by inclusion of induced dipole interactions. Similar concepts of this kind have been applied at this department quite some time ago [11].

## ACKNOWLEDGEMENTS

We wish to thank the Swedish Nuclear and Waste Management Co., SKB and the European Union (PARTNEW FIKW-CT2000-00087) for financial support.

SISAK (Short-lived Isotopes Studied by the AKUFVE technique) enables on-line studies of exotic nuclides chemically separated from complex nuclear reaction product mixtures. The technique applies multistage liquid-liquid extraction steps, where rapid phase separation is achieved by using specially designed centrifuges with short hold-up times. The technique has been successfully applied to nuclear spectroscopic investigations of short-lived fission products, but in the recent years focused on studies of the chemical properties of the heaviest elements, the transactinides. The chemical properties that can be investigated with the SISAK system include distribution coefficients and complex formation, as well as the kinetics of solvent extraction processes and redox reactions.

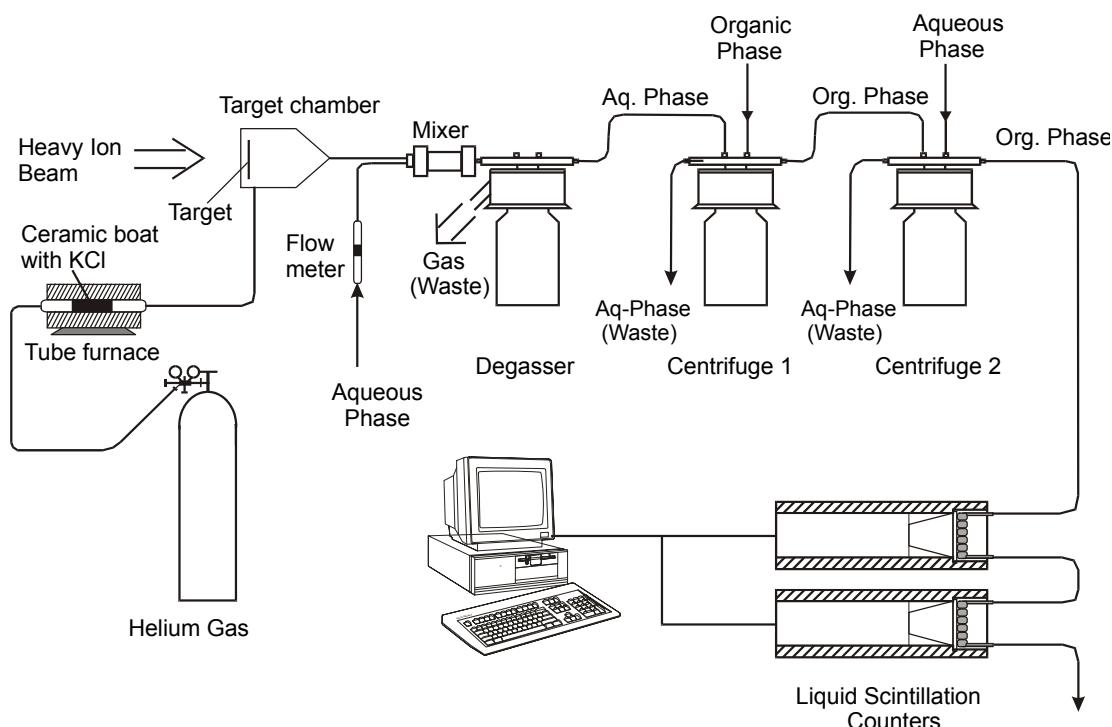

### INTRODUCTION

During the last decades there has been a growing interest in studying chemical properties of the heaviest elements, the transactinides (atomic number  $\geq 104$ ). These investigations are of great interest, because the comparison of the chemical properties of the transactinides with the behavior of their lighter group homologs allows the examination of trends within the periodic table and an assessment of the influence of relativistic effects. The transactinides are synthetic, radioactive elements with short half-lives, usually in the range of seconds. They can be produced at suitable accelerators only in extremely small amounts, typically less than a few atoms per hour. The nuclear reaction products, from which they are to be isolated, comprise a very complex mixture of more or less the rest of the elements of the periodic table. This makes the chemical separation a difficult task. The technique used must be fast, selective and also suitable for one-atom-at-a-time chemistry. The latter statement indicates that the transactinide atoms are likely to arrive at the chemical separation system one at a time, which means that many of the normal chemistry laws are not valid. Examples are that polynuclear complexes cannot be formed, and with only one atom present normal chemical equilibrium does not exist. Instead of concentrations, the probability that the atom exists in a certain chemical state must be used.

The fast chemical separation technique SISAK [1-3] has been developed for studies of exotic nuclides. In this paper, "exotic" refers to nuclides with half-life shorter than a few seconds or nuclides which can only be produced on a one-atom-at-a-time scale. SISAK was originally used for on-line nuclear spectroscopy studies of short-lived  $\gamma$ -emitters. Recently the technique has been successfully adopted to studies of transactinides [4,5]. Below, the method is described together with the application to studies of short-lived isotopes of protactinium and rutherfordium ( $^{104}\text{Rf}$ ).

## EQUIPMENT

In a typical SISAK experiment, see Figure 1, radionuclides are continuously transported from the production site in an accelerator or a research reactor to the SISAK equipment attached to aerosol particles ("clusters") in a gas-jet transport system [6,7]. The nuclides carried by the gas-jet are dissolved in an aqueous phase in a static mixer, and then a specially designed degassing centrifuge [3,8] is used to separate the carrier gas and volatile products from the liquid. The solution is usually heated to  $\sim 70$  °C to enhance the dissolution of the aerosol particles delivered by the gas-jet, to increase the efficiency of the degassing centrifuge and to speed up the solvent extraction kinetics in the subsequent separation steps.

*Figure 1. A typical SISAK set-up for transactinide studies.*

The effluent from the degasser is fed into a battery with a number of H-centrifuges [3,9]. The centrifuges used in the third version of SISAK, the equipment presently in use, are made of PEEK (polyetheretherketone), a material that withstands organic solvents and all common acids except concentrated sulfuric acid. The rest of the equipment is made of Kel-F, PTFE (polytetrafluoroethylene), PVDF (polyvinylidenefluoride) and PEEK. The centrifuges have been thoroughly described elsewhere [3,9], and the technical details will not be further discussed here.

Monitoring the purity of the phases leaving the centrifuges is performed by measuring the optical transmittance through the liquid. In a phase containing entrainment of the opposite phase light will be refracted at the boundaries between the two phases. The measuring devices, which consist of a small light emitting diode (LED) and a photo transistor, are connected to a personal computer. There, the phase purity and its fluctuations with time can be easily displayed. It is also possible to let the computer intervene if the phase purity falls below a selected value, e.g., by switching the valve between the SISAK equipment and the nuclear detection system to a bypass position. The phase purity is adjusted manually by valves affecting the counter-pressure on the phases leaving the centrifuge. Usually the system runs very steadily when pure phases have been achieved, and there has been no urgent need to computerize the valve operation.

The feed pumps used in the equipment are cog-wheel pumps with a flow capacity that can be continuously varied up to ~3 ml/s. Several types of pumps are used: all PEEK pumps, pumps with a house of titanium and cog-wheels of Kel-F and pumps with a house of stainless steel and cog-wheels of carbon. The flowrates of the pumps are measured with mass flow meters, and the flow-rates are displayed on the same computer screen as the phase purity. The computer is also used to regulate the speed of the pumps.

## SOLVENT EXTRACTION PROCEDURES

Rapid SISAK solvent extraction procedures have so far been developed for 20 elements: copper, arsenic, bromine, zirconium, niobium, technetium, ruthenium, palladium, iodine, lanthanum, cerium, praseodymium, hafnium, tantalum, tungsten, neptunium, rutherfordium, dubnium, seaborgium, and bohrium, see Table 1. These procedures are described in detail in [10-23].

One of the most important issues when designing chemical separation procedures for SISAK is the need for fast solvent extraction kinetics. The flow-rates are typically ~1 ml/s, and under these circumstances the contact time of the two phases is ~40 ms. Under ideal conditions solvent extraction is a fast process. An example is the transfer of nitric acid from water to tributylphosphate (TBP) which is complete in about 12 ms [24]. This time is, however, close to the contact time available in the SISAK 3 system. Thus it is necessary to choose separation procedures with rapid chemical kinetics or with a distribution ratio that is high enough to extract a sufficient amount of the element to be investigated, even if the extraction is terminated under non-equilibrium conditions. The first type of procedures can be exemplified by the extraction of inorganic species like Br<sub>2</sub>, AsI<sub>3</sub> or RuO<sub>4</sub> into a pure organic solvent [10,11] and by extraction of ion pairs [11,18]. The second type of systems can be illustrated by the extraction of zirconium or hafnium from 6 M nitric acid into 0.25 M HDBP (dibutyl phosphoric acid) in toluene. In this system the distribution coefficient has been measured to be 10 in SISAK experiments, while the corresponding value in test tube experiments with 5 s contact time is ~1.5·10<sup>4</sup> [20]. A chelate extraction with β-diketones is usually too slow to be used in SISAK experiments, but there are exceptions, e.g. the extraction of short-lived palladium isotopes that is made possible by a fast isotopic exchange with a pre-formed palladium complex [15].

## APPLICATIONS TO STUDIES OF EXOTIC NUCLIDES

The application of SISAK to nuclear spectroscopic studies of short-lived fission products has been described elsewhere [13,14,23,25], and will not be further discussed here. Instead, the application to studies of <sup>224</sup>Pa ( $T_{1/2} = 0.85$  s) and <sup>257</sup>Rf ( $T_{1/2} = 4.0$  s) will be described.

*Table 1. SISAK separation systems available 2001.*

Element	Procedure	References
Cu	Cu extracted from 6 M ZnCl <sub>2</sub> at pH = 3-3.5 into LIX64 in kerosene. Backextraction into 0.5 M HCl	1

<sup>107</sup> Bh	Extraction from 0.05 M HNO <sub>3</sub> and 0.05 M KBrO <sub>3</sub> into 0.05 M TOA in toluene	22

<sup>224</sup>Pa was studied in an experiment to verify that the SISAK technique can be used to identify short-lived  $\alpha$ -decaying radionuclides on a one-atom-at-a-time basis [26]. The protactinium isotope was produced by bombarding a bismuth target with oxygen ions. The production rate was about 60 atoms/s, *i.e.* much higher than in an experiment on a transactinide but nevertheless so low that the protactinium atoms arrived one at a time in the chemical separation equipment. The nuclear reaction products were transported to the SISAK equipment by the gas-jet system, and dissolved in 1 M lactic acid (HLac). Since considerable amounts of polonium were formed in the nuclear reaction, the aqueous phase was put in contact with 1 M Cyanex 471X (tri-isobutylphosphine sulfide) in toluene in the first solvent extraction step. Otherwise polonium would be co-extracted with protactinium in the following step.

In the second step, the aqueous phase was put in contact with 0.047 M tri-n-octyl amine (TOA) in toluene. The organic phase also contained a scintillator, and the solution was fed straight into a liquid scintillation detection system [27] where the radioactivity was measured. In order to make the identification of  $^{224}\text{Pa}$  unambiguous, the entire  $\alpha$ -decay chain  $^{224}\text{Pa} - ^{220}\text{Ac} - ^{216}\text{Fr} - ^{208}\text{Bi}$  was measured. The result of the experiment showed that  $^{224}\text{Pa}$  could be extracted and identified [26], *i.e.* it proved that SISAK can be applied to one-atom-at-a-time separations of short-lived  $\alpha$ -emitters.

Recently, an experiment to study chemical properties of rutherfordium was performed [5]. A lead target was bombarded with titanium ions to produce  $^{257}\text{Rf}$ . The production rate of rutherfordium was a few atoms per hour. To improve the chemical purity of the measured solution, the Berkeley Gas-filled Separator (BGS) [28] was used as a pre-separator to remove polonium and other potential contaminants prior to the chemical separation. The separated rutherfordium was then transferred to the SISAK equipment via a specially designed gas-jet system [29].

The radionuclides were then dissolved in 6 M nitric acid. The acid solution was then contacted with 0.25 M dibutyl phosphoric acid (HDBP) to extract rutherfordium. The organic phase was then washed with 2 M sodium nitrate to back-extract nitric acid that would otherwise disturb the subsequent liquid scintillation measurement. After washing, scintillation chemicals were added and the solution was purged with argon before being pumped into the liquid scintillation system.

So far the experiment, however not fully evaluated, showed that rutherfordium was extracted and the estimated distribution ratio is comparable to those of the homologs zirconium and hafnium, *i.e.*, it shows the expected behavior of a group 4 element.

A general conclusion from the experiment is that rapid on-line liquid-liquid extraction can be used for one-atom-at-a-time separations. Thus it should be possible to obtain distribution curves for transactinides and to deduce information about complex formation. By applying more specific chemical separation systems, it should also be possible to distinguish between different valency states and thus investigate redox properties of the heaviest elements.

## SANEX-BTP PROCESS DEVELOPMENT STUDIES

Clément Hill, Denis Guillaneux and Laurence Berthon

Commissariat à l'Energie Atomique, Marcoule, France

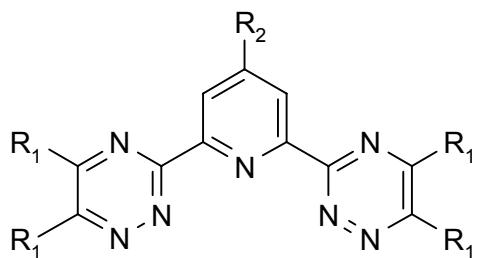

*Bis*-triazinyl-pyridines have been developed at CEA-Marcoule to separate actinides(III) from lanthanides(III). Although high separation performances were observed in the counter-current hot test carried out in 1999 on a highly active effluent, the extraction and back-extraction yields of actinides(III) were lower than expected from calculation. A strong sensitivity of the extractant towards air oxidation and acidic hydrolysis was actually pointed out. Therefore, the hydrolysis of *bis*-triazinyl-pyridines has been thoroughly investigated (qualitative determination of the degradation products) under different experimental conditions. It appeared that the branching of the alkyl groups on the  $\alpha$  position of the triazine rings hindered the hydrolysis of the extractant. The formulation of the solvent was thus optimized and tested again during year 2001 on a genuine DIAMEX back-extraction solution in the ATALANTE facility.

### INTRODUCTION

The separation of trivalent minor actinides ( $An(III) = Am(III)$  and  $Cm(III)$ ) from trivalent lanthanides ( $Ln(III)$ ), accounting for about one third of the total amount of fission products), is a key step for the partitioning of long-lived radionuclides from the highly active effluents issuing from the reprocessing of nuclear spent fuels. However, this separation is very difficult because  $An(III)$  and  $Ln(III)$  exhibit similar chemical properties.

Several studies in media of low acidity have shown already that nitrogen-containing polydendate ligands were able to separate  $An(III)$  from  $Ln(III)$  when mixed with lipophilic anions [1,2]. However, a new family of extractants -*bis*-triazinyl-pyridines- (Btp, Figure 1) has been developed by Dr. Z. Kolarik [3] in the framework of the European contract NEWPART led by CEA-Marcoule. These molecules appeared to be very efficient extracting agents: they remained selective towards  $An(III)$  even in very acidic conditions ( $[HNO_3] \geq 2 \text{ mol/L}$ ).

Various BTP molecules were synthesized and studied at CEA-Marcoule. Among them, the 2,6-bis(5,6-*n*-propyl-1,2,4-triazin-3-yl)-pyridine (*nPr*-Btp) was chosen in 1999 to perform a counter-current hot test in the ATALANTE facility on a genuine radioactive effluent. The performances of the flowsheet were very satisfactory ( $1,400 < DF_{Ln(III)} < 450,000$ ), but the extraction and back-extraction yields of  $Am(III)$  and  $Cm(III)$  were lower than expected from calculation. *nPr*-Btp showed up to be sensitive to air oxidation and to acidic hydrolysis.

with R<sub>1</sub> = H, Methyl, *n*-Propyl,  
*i*-Propyl, *n*-Butyl, *i*-Butyl  
and R<sub>2</sub> = H, *i*-Nonyl

*Figure 1. General formula of Btp.*

## DEGRADATION OF nPr-BTP UNDER OXIDATIVE AND HYDROLYZING CONDITIONS

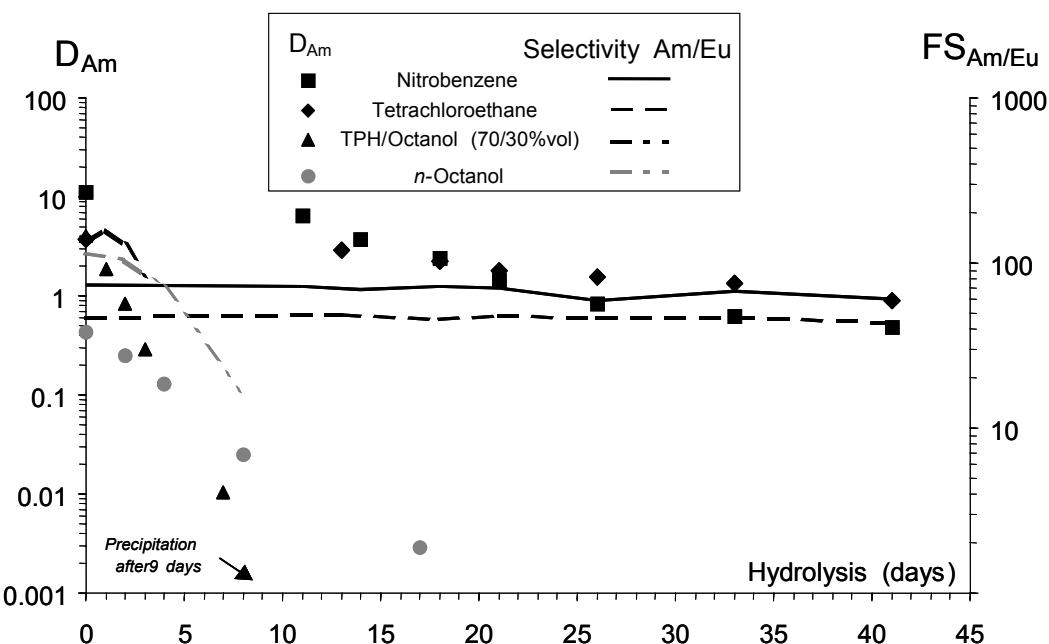

A systematic measurement of the distribution ratios of Am(III) and Eu(III), when hydrolyzing *n*Pr-Btp with nitric acid (with or without nitrous acid), revealed that its extraction properties steadily decreased when the atmosphere was rich in oxygen or when [HNO<sub>3</sub>] exceeded 0.5 mol/L (D<sub>Am</sub> decreased by 80% after 2 days when [HNO<sub>3</sub>] = 1 mol/L). Furthermore, the extraction properties of *n*Pr-Btp quickly decreased when [HNO<sub>2</sub>] exceeded 0.005 mol/L (D<sub>Am</sub> decreased by 50% after 2 hours when [HNO<sub>3</sub>] = 1 mol/L + [HNO<sub>2</sub>] = 0.01 mol/L).

Gas Phase Chromatography and/or Electro-spray Ionization Mass Spectrometry qualified the main degradation products of *n*Pr-Btp. The influence of several parameters such as: (i) the nature of the atmosphere above the Btp solution (e.g.: air or inert argon), (ii) the nature of the diluent (e.g.: dodecane/octanol (70/30%<sub>vol</sub>) mixture or chloroform), (iii) the presence or absence of an acidic aqueous phase, has been studied on the degradation of *n*Pr-Btp. It appeared that the degradation products of *n*Pr-Btp were the same whatever the experimental conditions, only their quantities varied. From these studies, the first step of *n*Pr-Btp degradation was assumed to be the attack of one CH<sub>2</sub> group, on the  $\alpha$  position of the triazinyl rings, resulting in the formation of a nitro compound (observed by <sup>15</sup>N NMR). Thereafter, the compound would degrade into an alcohol (which was the main degradation product observed in the absence of an hydrolyzing aqueous phase) or into a ketone (which was the main degradation product after the hydrolysis of *n*Pr-Btp by nitric acid). In the same way, the attack of a second CH<sub>2</sub> group would result in the formation of bifunctional compounds (dialcohols and diketones). The alcohol compounds could also loose one propyl chain. Another reaction was the breaking of the triazinyl ring leading to cyano compounds.

The nature of the organic diluent affected the stability of *n*Pr-Btp: as compared to aliphatic, alcoholic or aromatic diluents, nitrobenzene and chlorinated diluents seemed to prevent *n*Pr-Btp from degrading (Figure 2). However, since these organic diluents were not acceptable for an industrial separation process development, further investigations were carried out to strengthen *n*Pr-Btp towards hydrolysis. Thus, the formulation of the solvent has been improved and optimized.

## OPTIMIZATION OF THE BTP SOLVENT FORMULATION

Other substituted Btp molecules, especially those bearing branched groups on the  $\alpha$  position of the triazinyl rings (such as Cy-Btp-Me and *i*Pr-Btp), proved to be much more stable in acidic conditions than *n*Pr-Btp or *n*Bu-Btp, bearing linear alkyl groups. Although Cy-Btp-Me and *i*Pr-Btp were not chosen for the implementation of the hot test in 1999, because of several practical reasons (*i.e.*: tedious synthesis, low solubility in organic diluent, slow kinetics of extraction), they actually showed a favorable stability over 30 days of acidic hydrolysis (Figure 3).

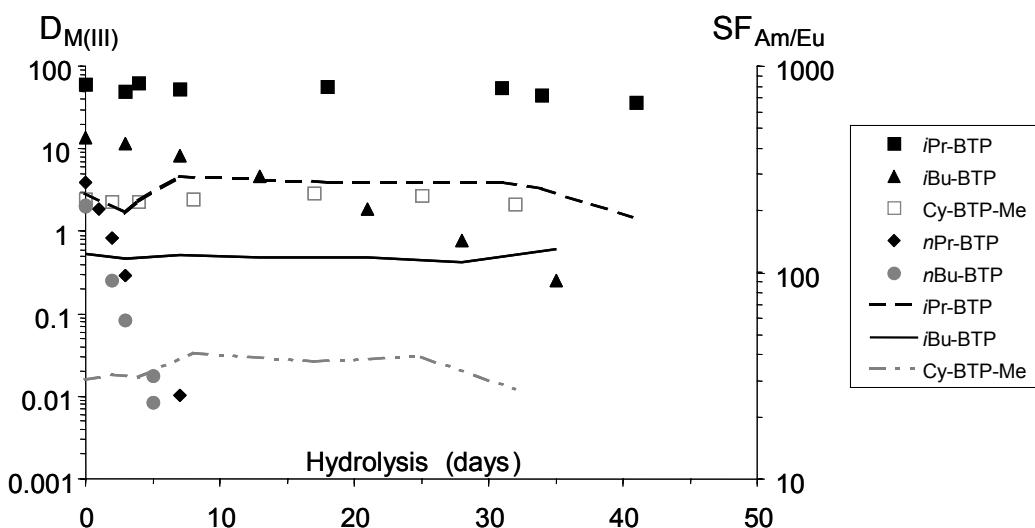

Hydrolysis cycles: 1 hour mixing followed by 2 hours settling (24 hours/day);  $\theta = 25^\circ\text{C}$ .

Hydrolyzing aqueous solution:  $[\text{HNO}_3] = 1 \text{ mol/L}$ .

Hydrolyzed organic solutions:  $[\text{nPr-Btp}] = 0.02 \text{ mol/L}$  in various organic diluents.

Extraction tests:  $[\text{HNO}_3] = 1 \text{ mol/L}$ , spiked with  $^{152}\text{Eu}$  and  $^{241}\text{Am}$ ;  $\theta = 25^\circ\text{C}$ .

Figure 2. Influence of the nature of the organic diluent on the stability of nPr-Btp under acidic hydrolysis/oxidation.

Hydrolysis cycles: 1 hour mixing, followed by 2 hours settling (24 hours/day);  $\theta = 25^\circ\text{C}$ .

Hydrolyzing aqueous solution:  $[\text{HNO}_3] = 1 \text{ mol/L}$ .

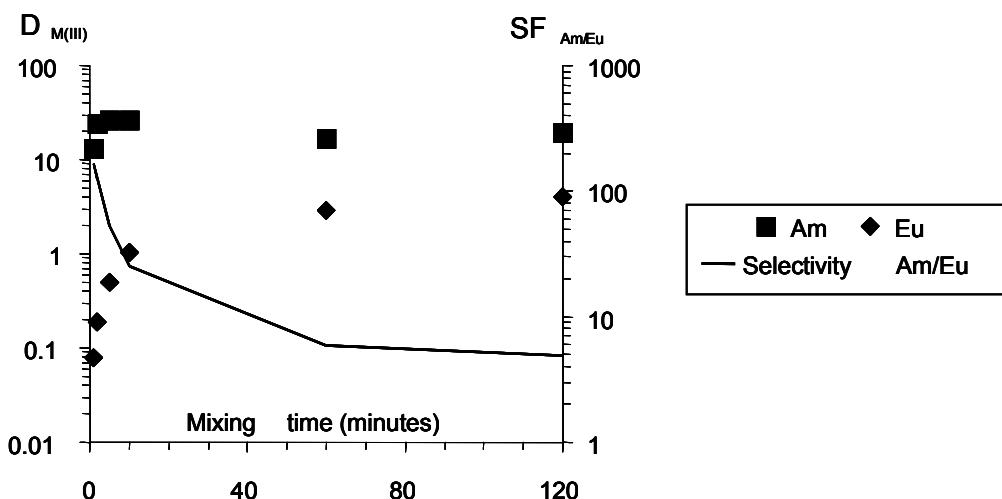

Hydrolyzed organic sol.:  $[\text{Btp}] = 0.005$  or  $0.01 \text{ mol/L}$  in n-octanol or "n-octanol /TPH" mixture.

Extraction tests:  $[\text{HNO}_3] = 1 \text{ mol/L}$ , spiked with  $^{152}\text{Eu}$  and  $^{241}\text{Am}$ ;  $\theta = 25^\circ\text{C}$ .

Figure 3. Comparison of the stability of different Btps under acidic hydrolysis.

Several attempts were made to accelerate the kinetics of extraction of these Btps, by mixing them with other co-extractants, such as: TBP, monoamides or diamides. In some cases, the latter modifiers increased the kinetics of extraction of the Btps, and in other cases, they enhanced their extraction performances or their stability under acidic hydrolysis, but lowered their selectivity towards An(III).

For instance, the case of *i*Pr-Btp was rather peculiar. As compared to *n*Pr-Btp, when *i*Pr-Btp was diluted in a mixture of *n*-octanol and TPH and when the feed solution was only spiked with radio-tracers  $^{241}\text{Am}$  and  $^{152}\text{Eu}$ , the observed extraction kinetics were fast for Am(III) and very slow for Eu(III) (Figure 4a). When concentrated solutions simulating genuine DIAMEX back-extraction effluents were used, a precipitate occurred with the "*n*-octanol/TPH" mixtures. However, no precipitate was observed when dissolving *i*Pr-Btp in pure *n*-octanol, tetrachloroethane or nitrobenzene, but the extraction kinetics became very slow both for Am(III) and Eu(III).

(a) Aqueous solution:  $[\text{HNO}_3] = 1 \text{ mol/L}$ , spiked with  $^{152}\text{Eu}$  and  $^{241}\text{Am}$ .  
Organic solution:  $[\text{iPr-Btp}] = 0.01 \text{ mol/L}$  in an "*n*-octanol / TPH" mixture;  $\theta = 25^\circ\text{C}$ .  
(b) Aqueous solution: synthetic solution simulating a DIAMEX back-extraction effluent.

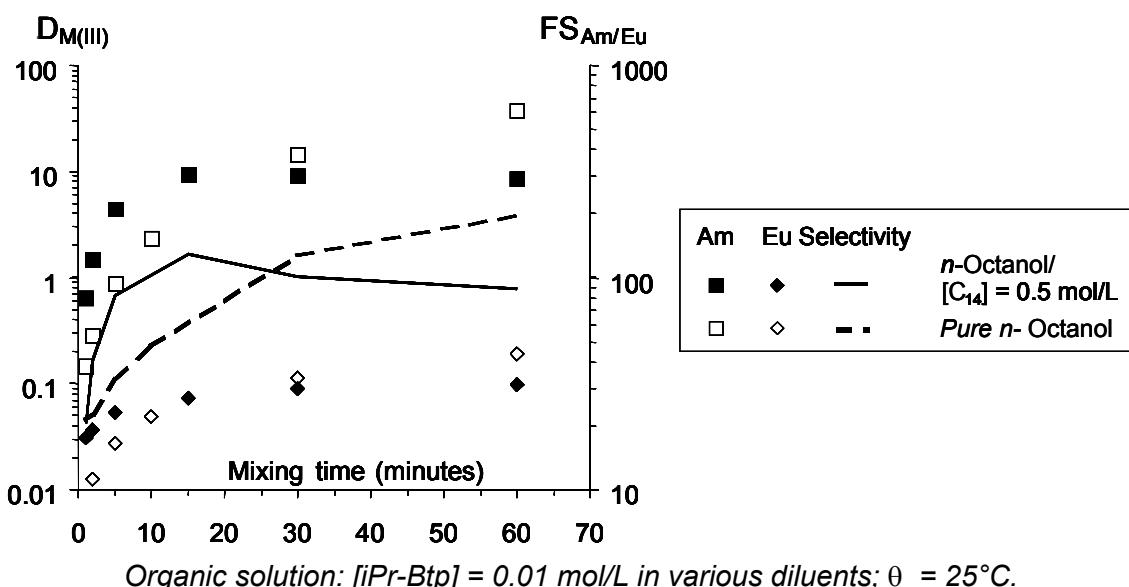

Figure 4. Comparison of the kinetics of extraction of *i*Pr-Btp in various diluents and experimental conditions.

Therefore, a phase transfer catalyst, such as a diamide ( $C_{14}$  = dimethyl-dibutyl-tetradecyl-malonamide) had to be mixed with *i*Pr-Btp to increase the kinetics of extraction and decrease the time required to reach equilibrium (Figure 4b). Other diamides have been tested as co-extractants of *i*Pr-Btp in *n*-octanol. Very good results were observed with dimethyl-diethyl-hexylethoxy-malonamide ( $C_2OC_6$ ). However, although the kinetics of extraction of An(III) and Ln(III) were fast with these binary mixtures, the kinetics of back-extraction of the latter two cations appeared to be easy but too slow in diluted nitric acid to develop a process flowsheet (the equilibrium was only reached after 2 hours of mixing). That is why, hydrophilic complexing agents, such as citric acid or glycolic acid, have been tried to enable and increase An(III) and Ln(III) back-extraction.

Prior to the hot test, numerous series of experiments have been carried out in micro-tubes on synthetic aqueous solutions simulating DIAMEX back-extraction solutions. The influence of the composition of the organic solvent (concentration of *i*Pr-BTP or  $C_2OC_6$  in *n*-octanol) on the extraction yields and extraction kinetics of Ln(III) and An(III) was assessed. A process flowsheet has been designed and first tested on a battery of eight centrifugal-contactors, using a synthetic nitric acid solution containing Nd(III) and Eu(III) at 2 g/L and 100 mg/L, respectively. The hydrodynamic behavior of the solvent was very satisfactory.

A 32-stage process flowsheet should be tested in the ATALANTE facility on a genuine highly active effluent at the end of June 2001. The results of this hot test will be discussed later on.

## CONCLUSION

The SANEX hot test carried out at CEA-Marcoule in 1999 with the 2,6-bis(5,6-*n*-propyl-1,2,4-triazin-3-yl)-pyridine pointed out the strong sensitivity of this extractant towards air oxidation and acidic hydrolysis. Qualitative determination of the degradation compounds of *n*Pr-Btp allowed a better understanding of its degradation mechanism: *n*Pr-Btp mainly degraded into alcoholic derivatives through the oxidation of its propyl substituents (probably through radical reactions). Therefore, many efforts were put forward to strengthen the stability of *n*Pr-Btp under hydrolysis and to optimize the formulation of the solvent. 2,6-bis(5,6-*i*-propyl-1,2,4-triazin-3-yl)-pyridine (*i*Pr-Btp), mixed with dimethyl-diethyl-hexylethoxy-malonamide ( $C_2OC_6$ ) in *n*-octanol, has been chosen to carry out the hot test on a genuine DIAMEX back-extraction solution at the end of June 2001.

UAMyCN, Centro Atómico Ezeiza, Comisión Nacional de Energía Atómica,  
Buenos Aires, República Argentina

A modified IMPUREX process for the co-decontamination of uranium and plutonium from spent nuclear fuel has been developed. The process involves the co-decontamination of uranium and plutonium as a whole, excluding their mutual separation, thus making it a non-proliferating process. An automatically controlled laboratory scale plant is described. The results of a typical extraction run are presented.

### INTRODUCTION

IMPUREX (IMproved PUREX) process was first published by Schmieder and Petrich from the Institut für Heiße Chemie, Kernforschungszentrum Karlsruhe, in 1989 [1]. This is a solvent extraction process for the reprocessing of spent nuclear fuel elements that are dissolved in nitric acid and extracted with a suitable organic extractant like tri-butylphosphate (TBP). In the original publication it includes the partition of uranium and plutonium enabling their recovery separately.

A modified process, avoiding the later U-Pu partition (which would have made it a proliferating process) but keeping the IMPUREX main guidelines unchanged, has been developed and tested in facilities of the Ezeiza Atomic Center (CAE) [2, 3].

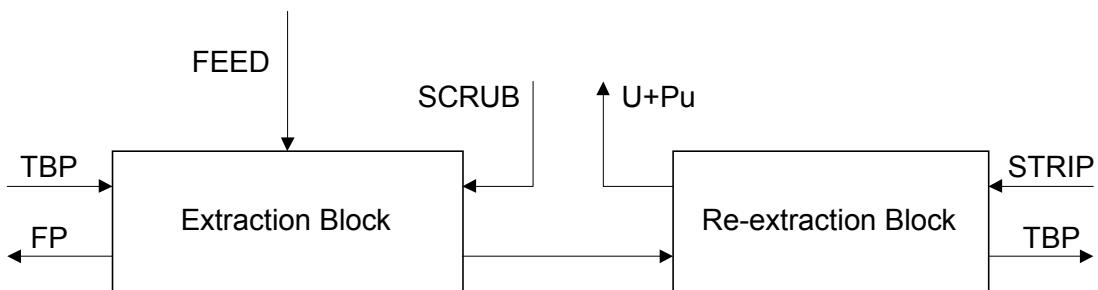

Following these guidelines, an automatically controlled laboratory-scale extraction plant has been designed and operated using a nitric acid solution of natural U (0.7% U235) as feed to simulate the spent fuel.

In this paper experimental data and cycle performance calculations are presented.

### PROCESS DESCRIPTION

The main goal of this process is the separation of uranium and plutonium from other fission products generated in a spent nuclear fuel. The process basically consists of two blocks, namely the extraction and the re-extraction blocks (Figure 1).

In the first block, a highly acidic aqueous phase (FEED) carrying uranium (U), plutonium (Pu) and several fission products (FP) is fed and contacted with a 30% tri-butylphosphate solution in hydrocarbon (TBP). An extra aqueous stream (SCRUB) ensures the FP scrubbing.

*Figure 1. Schematic of a modified IMPUREX process.  
Uranium and plutonium are extracted without further partition.*

While FP remain in the aqueous phase and leave the system, U and Pu are extracted to the organic stream and therefore conducted to the second block. In the re-extraction block the organic stream is contacted with a fresh low-acid aqueous phase (STRIP). Due to the different acidity, U and Pu are extracted from the TBP to the aqueous stream. The TBP can be recycled for reuse.

While room temperature is high enough to achieve a reasonably high separation of U-Pu from fission products in the extraction block, a higher temperature is needed when dealing with re-extraction.

## LABORATORY-SCALE PLANT DESCRIPTION

Mixer settlers were chosen as suitable extraction equipment for the two main blocks. Mixer-settler prototypes were used in both the extraction and re-extraction blocks. These devices were designed and constructed after information gathered from repeated extraction experiments. In the extraction block, a 7-stage mixer settler was installed, while in the re-extraction block a 9-stage mixer settler was preferred due to the lower mass transfer rate of the re-extraction process.

Mixing in both mixer-settlers is achieved by air pulse injection. The air injection performs both the mixing of the organic and aqueous phases and the generation of a pulse in the liquid which is mainly responsible for the organic phase flowing. While organic phase flows by gravity and mixing generated pulses, the aqueous phase is pumped through air lifts drilled in the mixer-settler's body. In this way the aqueous phase does not obstruct the normal flow of the lighter organic phase. Streams are pumped by automatically controlled diaphragm pumps.

Uranium concentration is sensed in a separate cell connected to the extraction mixer-settler. This cell is made out of glass or any other suitable transparent material which allows light transmission. A 435 nm light beam corresponding to a uranium maximum absorption peak, is taken from a spectrophotometer and conducted through a bundle of optical fibres to the cell's wall. An additional optical fibre bundle in the opposite wall receives the diminished light beam and transmits it back to the spectrophotometer where its decrease in intensity is measured. This decrease is a function of uranium concentration in the aqueous phase contained in the cell. Optical fibres are attached to the cell with its face parallel to the glass wall, to ensure minimum light losses.

## AUTOMATIC CONTROL LOOP PERFORMANCE

Concentration vs. time curves were plotted to evaluate the mixer-settler's response to a concentration step input (Figure 2). Following these results it was obvious that the system had a slow response to changes and that a simple on-off control system was enough to keep the high uranium concentration front between desirable bounds and at the same time avoid uranium losses in the raffinate.

PC control software was developed and installed. Control parameters are minimum and maximum aqueous phase uranium concentration limits, and corresponding minimum and maximum TBP flow rates. The aqueous phase flow rate was kept constant.

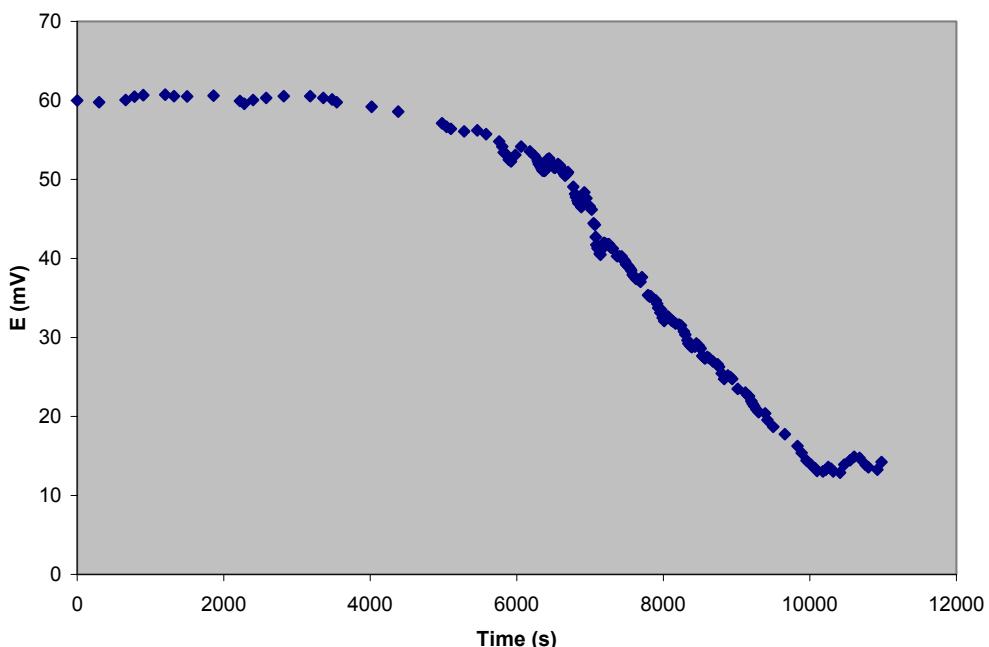

Figure 2. Concentration proportional  $E$  plotted against time in a mixer-settler stage without control action. Concentration input step took about 2 hours to completely leave the stage.

When the sensed aqueous uranium concentration reaches the maximum, the TBP flow rate is increased to a suitable value to reduce aqueous uranium concentration to the minimum. Inversely when a minimum limit is reached, TBP flow rate is decreased to let the uranium concentration in the mixer-settler raise. A control loop set this way proved to be suitable for 12-14 hours/day of continuous operation.

## EXPERIMENTAL

In the extraction block, there are three input streams: the uranium feed solution ( $[H^+] = 5 M$ ), the organic extractant, and an additional aqueous scrubbing stream ( $[H^+] = 5 M$ ) which is used to "wash" the aqueous phase and helps to scrub it from fission products. In the re-extraction block, there are only two input streams: the organic extractant carrying uranium, and an aqueous stripping stream ( $[H^+] = 0.05 M$ ) which is used to re-extract uranium back to the aqueous phase.

Settings for all the streams are listed in Table 1.

*Table 1. Process settings. Indicated TBP flow rates are the control flow rate limits.*

Stream	Flowrate (mL/h)	[U] (g/L)	[H <sup>+</sup> ] (M)	T (°C)
Feed	150	247	5	25
Strip	400	0	0.05	50
TBP	240-400	0	0.1	25
Scrub	50	0	5	25

According to the IMPUREX guidelines, a front with high uranium concentration is required to gain proper cycle performance. This condition is reached through a control loop as described earlier (see Tables 2 and 3).

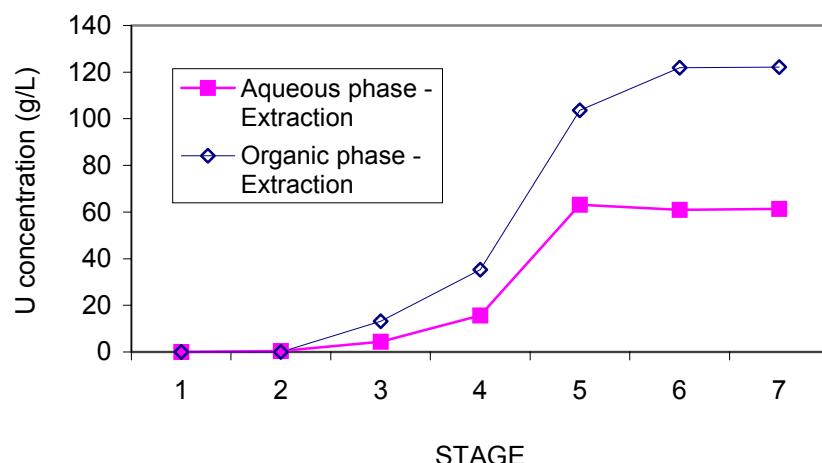

*Table 2. Uranium concentration (g/L) in extraction mixer-settler.*

Stage	1	2	3	4	5	6	7
Aqueous	0.0	0.36	4.4	15.62	63.2	60.9	61.3
Organic	0.0	0.0	13.2	35.3	103.6	121.9	122.1

*Table 3. Uranium concentration (g/L) in re-extraction mixer-settler.*

Stage	1	2	3	4	5	6	7	8	9
Aqueous	67.2	49.5	31.6	17.7	8.10	0.59	0.32	0.0	0.0
Organic	85.6	44.6	31.2	16.3	5.3	0.0	0.0	0.0	0.0

Tables 2 and 3 were plotted to show typical concentration profiles in both mixer-settlers (Figures 2 and 3, respectively). These profiles were taken under controlled operation and therefore concentration steps are somewhat expected to occur.

*Figure 3. Uranium concentration profile in extraction mixer-settler under automatic control action. Uranium is fed in stage 5. Uranium concentration is sensed in stage 2.*

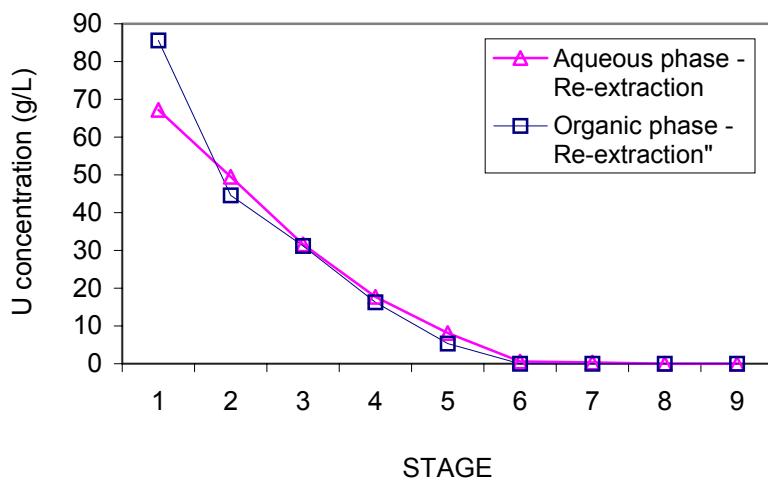

Figure 4. Uranium concentration profile in re-extraction mixer-settler.  
This mixer-settler is not under automatic control.

Equilibrium curves calculated by software were traced for the process experimental conditions. Operation points in extraction and re-extraction were also plotted. Operation lines were fitted to help visualisation of the process, even when they should not necessarily be straight due to the scales used (non free solvent). The slope of the lines should approximate to the flow rate relationship.

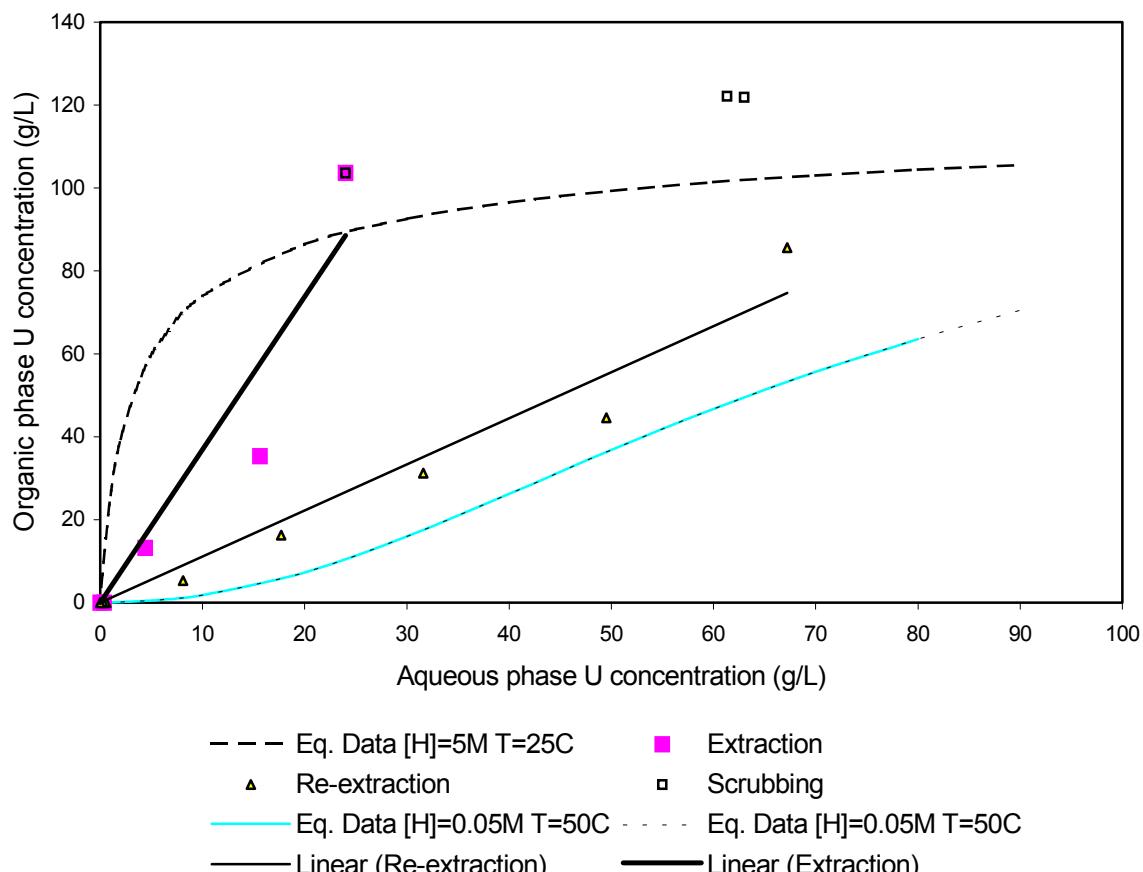

Figure 5. Equilibrium curves and operation points for both extraction and re-extraction mixer-settlers. Fitting lines were traced to suggest operation lines.

## **CONCLUSIONS**

Continuous operation has demonstrated reliability of an automatic control loop in keeping the process variables within the desired bounds for several hours.

No uranium losses were detected in the aqueous waste streams (raffinates).

Analytical results confirm an overall good cycle performance under high uranium concentration process conditions such as IMPUREX process.

\*\*\*A. N. Frumkin Electrochemistry Institute, Russian Academy of Science, Moscow, Russia

The Universal Extraction process was developed to facilitate removal of all major radionuclides from acidic waste, simultaneously in a single process. The solvent composition developed for the Universal Extraction process is 0.08 M chlorinated cobalt dicarbollide, 0.35 to 0.5 vol.% polyethylene glycol-400, and 0.01 to 0.02 M diphenyl-N,N-dibutylcarbamoylphosphine oxide in phenyltrifluoromethyl sulfone. Numerous solvent diluents and extractants, as well as extractant concentrations were evaluated to develop an optimal solvent composition. Results of numerous evaluations indicate the solvent is highly resistant to thermal, chemical or radiological degradation and meets safety criteria for flammability.

## INTRODUCTION

Treatment of highly radioactive wastes may require the removal of cesium, strontium, actinides (AN), and rare earth elements (RE) to allow contact handling and economic disposal of the bulk (inert) constituents of the waste. Numerous processes have been demonstrated to effectively remove a single element, or group of related elements, from the waste in a single unit operation. However, decontamination of a highly radioactive waste stream would require two or three discrete processes. For example, cesium can be effectively removed from acidic waste using inorganic ion exchange technology, strontium can be removed using a solvent extraction process and the AN/RE fraction can be removed using another solvent extraction process [1-3]. Simultaneous separation of cesium, strontium, AN and RE elements in a single process offers significant potential capital and operating cost savings over the use of multiple unit operations. A universal extraction (UNEX) solvent was developed to provide such a capability.

The UNEX solvent is based on the chemistry of chlorinated cobalt dicarbollide (CCD). The extraction properties of cobalt dicarbollide were first described by Rais *et al.* [4]. Chlorinated cobalt dicarbollide (CCD), shown in Figure 1, is a large hydrophobic anion which exhibits the properties of a strong acid. Chlorinated cobalt dicarbollide selectively extracts cesium through a cation-exchange mechanism with dissociation of the solvated species in the organic phase. Dipicrylamine, tetraphenylborate, polyiodide, and heteropolyacids extract cesium by the same mechanism, but only CCD is simultaneously a strong acid, such as

heteropolyacids, and extremely hydrophobic, such as tetraphenylborate. This combination of properties enables CCD to extract cesium from strongly acidic media and provides low solubility of CCD in aqueous solutions. Chlorinated cobalt dicarbollide and its salts are highly polar compounds. They are essentially insoluble in low-polar solvents such as saturated and aromatic hydrocarbons. Furthermore, solutions of CCD in polar solvents like alcohols, ketones, ethers, or esters have very low extraction abilities. Aromatic and aliphatic nitrocompounds are the best diluents for CCD [4,5].

Halogenated derivatives of cobalt dicarbollide, especially chlorinated cobalt dicarbollide, exhibit high resistance to acid hydrolysis, reductants, and radiation, was well as excellent thermal stability [6]. Therefore, in the majority of studies, especially in radiochemistry, the hexachloro-derivative of cobalt dicarbollide, as indicated in Figure 1, is the preferred choice.

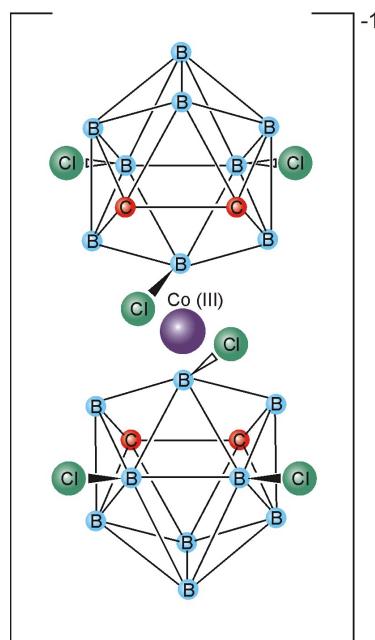

Figure 1. Structure of hexachlorocobalt dicarbollide anion.

The co-extraction of strontium, and other alkaline earth elements has been shown by the addition of polyethylene glycols (PEG) to the CCD solvent [7]. This process has been implemented in Russia to process approximately 750 m<sup>3</sup> of highly radioactive waste, and recover megacurie quantities of cesium and strontium.

The development of a universal solvent required addition of an AN/RE extractant to the CCD/PEG solvent, and development of a non-nitroaromatic diluent, suitable for use in the United States. An appropriate diluent for radiochemical waste treatment must have high chemical and radiation stability, low aqueous solubility, low viscosity, and a density substantially different than the aqueous process solutions. Furthermore, the extractant and the solvated metal complex must be readily soluble in the diluent to prevent formation of an immiscible third phase.

## SELECTION OF ACTINIDE/RARE EARTH EXTRACTANT

Several bifunctional neutral organophosphorus compounds, known to be effective AN/RE extractants, were studied. These included substituted diphosphine dioxides, triphosphine trioxides and substituted carbamoylphosphine oxides (CMPO). All extractants exhibited high AN/RE distribution coefficients, but carbamoylphosphine oxides were selected because their synthesis is less complex, they are more soluble in polar diluents, and they have been demonstrated to extract actinides in combination with CCD [8]. There has also been a significant amount of work with CMPO in the development and testing of the transuranic extraction (TRUEX) process. Distribution coefficients, measured from 3 M HNO<sub>3</sub>, are indicated in Table 1 for a constant solvent composition of 0.06 M CCD, 1 vol % Slovalfol-909, and 0.02 M CMPO oxide in *m*-nitrobenzotrifluoride (MNBTF).

*Table 1. Extraction of metals from 3 M HNO<sub>3</sub> by 0.06 M CCD, 1 vol % SLOVAFOL-909, and 0.02 M CMPO in MNBTF.*

CMPO	Distribution coefficient				
	Cs	Sr	Eu	Pu	Np
Ph <sub>2</sub> Bu <sub>2</sub>	4	12	300	700	> 500
OctPhBu <sub>2</sub>	5	15	4	200	80
OctO <sub>2</sub> Bu <sub>2</sub>	3	9	0.4	60	10

Ph<sub>2</sub>Bu<sub>2</sub> = diphenyl-N,N-dibutylcarbamoylmethylphosphine oxide

OctPhBu<sub>2</sub> = octyl(phenyl)-N,N-diisobutylcarbamoylmethylphosphine oxide

OctO<sub>2</sub>Bu<sub>2</sub> = dioctyl-N,N-dibutylmethylcarbamoyl phosphonate

The use of diphenyl-N,N-dibutylcarbamoylmethylphosphine oxide (Ph<sub>2</sub>Bu<sub>2</sub>CMPO) exhibits the best overall extraction properties based on Eu, Pu and Np distributions. Additional studies using simulated radioactive wastes, indicate that the solvent mixture containing Ph<sub>2</sub>Bu<sub>2</sub>CMPO provided higher solubility of metal complexes, reducing the likelihood of forming a third phase. Distribution measurements were also made over Ph<sub>2</sub>Bu<sub>2</sub>CMPO concentrations ranging from 0.01 to 0.06 M. Increasing the Ph<sub>2</sub>Bu<sub>2</sub>CMPO concentration in the solvent mixture obviously provides for higher AN/RE distribution ratios, but decreases cesium and strontium distribution ratios. Therefore, concentrations of Ph<sub>2</sub>Bu<sub>2</sub>CMPO in the range of 0.01 – 0.02 M were determined to be adequate.

## SELECTION OF POLYETHYLENE GLYCOL (STRONTIUM EXTRACTANT)

As mentioned earlier, PEG added to CCD has been demonstrated to synergistically extract strontium. The mechanism of this extraction process has not yet been established, but it is believed that the PEG and CCD form a complex with a crown-like cavity providing solvation of the strontium cation. Substituted PEGs are less soluble in the aqueous phase, but do not sufficiently extract Sr in the CCD/PEG/CMPO mixture. Unsubstituted PEGs exhibit adequate Sr extraction in the CCD/PEG/CMPO mixture, as shown in Table 2. Increasing the molecular weight of PEG reduces metal distributions, and decreases solubility in the aqueous phase.

*Table 2. Extraction of radionuclides by a mixture of 0.15 M CCD, 0.025 M Ph<sub>2</sub>Bu<sub>2</sub>CMPO, and 1 vol % PEG in MNBTf from simulated acidic waste.*

Polyethylene glycol	Distribution coefficients		
	Cs	Sr	Eu
Slovafol-909	8.9	0.46	37
OP-10	9.1	0.3	7.2
PEG-1500	6.3	0.6	41
PEG-400	4.5	4.1	43
PEG-300	6.7	4.0	60

Increasing PEG concentration in the solvent mixture suppresses Cs extraction; therefore, it is necessary to minimize the concentration of PEG. Concentrations of PEG-400 in the range of 0.35 to 0.5 vol % were determined to be optimal.

### SELECTION OF DILUENT FOR THE UNIVERSAL SOLVENT

Nitrobenzene and its derivatives, are the most widely used diluents for cobalt dicarbollide-based extraction systems. Regulatory, environmental and health issues make the use of nitro-aromatic diluents impractical in the United States. The high chemical and radiation stability of fluoro-organic compounds, coupled with their highly polar nature and favorable hydrodynamics, make them promising substitutes for nitro-aromatic diluents. A detailed description of the compounds evaluated and test results is provided by Romanovskiy *et al.* [9,10]. A new class of compounds, showing promise as diluents was introduced-fluorinated sulfones. Polyfluoroalkyl sulfones with different substituents were synthesized, and the main characteristics in the UNEX solvent were defined. These data indicate the introduction of polyfluoroalkyl substituents in the sulfone molecule decreases the basicity and significantly increases the extraction ability of CCD. The effect of sulfone substituents on the Cs extraction ability of CCD follows the order: HCF<sub>2</sub>CF<sub>2</sub> ≈ CF<sub>3</sub> > HCF<sub>2</sub> > HCF<sub>2</sub>CF<sub>2</sub>CH<sub>2</sub> >>Aryl, Alkyl. The extraction of cesium, strontium and europium in universal solvents utilizing different sulfone diluents as compared to MNBTf is shown in Table 3.

*Table 3. Extraction of Cs, Sr and Eu from simulated INEEL acidic tank waste by mixtures of 0.08 M CCD, 0.02 M PH<sub>2</sub>Bu<sub>2</sub>CMPO, and 0.6 vol % PEG-400 in different diluents.*

Diluent	Distribution coefficients		
	Cs	Sr	Eu
MNBTf	4.0	3.2	4.1
40 vol% S-612 & 60 vol% toluene	2.8	2.6	1.4
100% FS-24	2.0	2.2	1.1
100% FS-13	1.0	1.7	2.7

S-612 = hexyldifluoromethyl sulfone

FS-24= phenyltetrafluoroethyl sulfone

FS-13= phenyltrifluoromethyl sulfone

From Table 3, it can be seen that the sulfones have lower extraction ability than *m*-nitrobenzotrifluoride, but given the complexity of the waste stream, which contains molar quantities of alkali metals, the distribution coefficients shown are acceptable. Considerations other than extraction ability (diluent synthesis, cost, extractant and metal solubilities, physical properties) led to the selection of phenyltrifluoromethyl sulfone as the diluent for the UNEX process. The solvent composition: 0.08 M chlorinated cobalt dicarbollide, 0.35-0.5 vol.%

Polyethylene glycol-400, and 0.01-0.02 M diphenyl-N,N-dibutylcarbamoylphosphine oxide in phenyltrifluoromethyl sulfone provides the needed recovery of Cs, Sr, AN and RE, with suitable physio-chemical properties of the solvent. The distribution of Cs, Sr, AN and RE elements is dependent on temperature, which allows for enhancement of the extraction operation by cooling and of the strip section by heating. Stripping of the extracted metals is accomplished using a solution containing 1 M guanidine carbonate and 20 g/L diethylene triamine pentaacetic acid (DTPA).

### PROPERTIES OF THE UNIVERSAL SOLVENT

The universal solvent has a density of 1.417 g/cm<sup>3</sup> and a viscosity of 4.6 mPa-s at 20 °C. As for explosion and fire safety, the UNEX solvent greatly surpasses the typical PUREX solvent of 30% tri-*n*-butyl phosphate in *n*-dodecane. The flash point of the UNEX solvent is above 90 °C, while that of the PUREX solvent is about 70 °C. The UNEX solvent exhibits high chemical stability in that it does not react with 14 M HNO<sub>3</sub> at temperatures up to 120 °C. Gas evolution above 120 °C proceeds uniformly without the presence of an exotherm. At higher temperatures (about 120-150 °C) weak uniform gas evolution is observed without any heat release. At about 160 °C, a weak exotherm is observed, with self-heating of 15-17 °C for a duration of 10-15 minutes. The thermal stability of the UNEX solvent is much higher than for the PUREX solvent, which exhibits a strong exotherm at about 90 °C.

Gamma irradiation of the universal solvent, in both one and two-phase systems was conducted using a Co-60 source at a dose rate of 10 kGy and at 25-27 °C. The universal solvent was exposed to an absorbed dose of 20 W·h/L. This equates to the expected dose for about 350 extraction cycles of contact with Idaho National Engineering and Environmental Laboratory (INEEL) tank waste. The total yield of phenyltrifluoromethyl sulfone radiolytic decomposition products is 4.5 to 5.0 molecules/100 eV (loss of sulfone in 350 cycles is less than 1%). The primary radiolysis products include hexafluoroethane and benzenesulfonic acid, which do not accumulate in the organic phase. The radiolytic gas-evolution rate does not exceed 4.5 mL/h·L at a dose rate of 10 kGy/h. The extraction and hydrodynamic properties of the UNEX solvent did not change with absorbed doses of 20 W·h/L.

The universal solvent losses due to solubility do not exceed 0.02% vol. in a 3 M HNO<sub>3</sub> aqueous phase. Phenyltrifluoromethyl sulfone solubility in INEEL tank waste and the proposed stripping reagents is even lower. These data indicate the plausibility of using the UNEX solvent for radiochemical waste processing.

### CONCLUSIONS

A universal extraction solvent has been developed that allows for the simultaneous extraction and recovery of cesium, strontium, actinides and rare earth elements from acidic radioactive wastes. A new class of polar diluent has been introduced, replacing nitroaromatic diluents commonly used in cobalt dicarbollide extraction systems. The solvent is composed of 0.08 M chlorinated cobalt dicarbollide, 0.35 to 0.5 vol.% polyethylene glycol-400, and 0.01 to 0.02 M diphenyl-N,N-dibutylcarbamoylphosphine oxide in phenyltrifluoromethyl sulfone. This solvent composition has favorable physical/hydrodynamic properties, which allow its use in centrifugal extraction equipment, and has been shown to have chemical and thermal stability far exceeding the well known PUREX solvent. Radiation doses expected in 350 cycles of operation have no deleterious effect on the solvent's extraction or hydrodynamic properties. The combination of extraction properties as well as thermal, chemical and radiation stability make it technically feasible for the universal solvent to be utilized for the treatment of highly radioactive acidic wastes.

# DEVELOPMENT AND PILOT SCALE TESTING OF SOLVENT EXTRACTION FLOWSHEETS FOR THE SEPARATION OF RADIONUCLIDES FROM ACIDIC RADIOACTIVE WASTE

J. D. Law, T. A. Todd, and R. S. Herbst

Idaho National Engineering and Environmental Laboratory, Idaho Falls, Idaho, USA

The presence of long-lived radionuclides presents a challenge to the management of radioactive wastes. Separation of the radionuclides from the waste solutions has the potential of significantly decreasing the costs associated with the immobilization and disposal of the waste by minimizing waste volumes. Several solvent extraction processes have been developed for the separation of transuranic elements (TRUs),  $^{90}\text{Sr}$ , and/or  $^{137}\text{Cs}$  from acidic radioactive waste solutions. These processes have been tested at the Idaho National Engineering and Environmental Laboratory using pilot scale centrifugal contactor equipment ranging in size from 2.2-cm to 5.5-cm diameter, including contactors installed in a shielded cell facility for testing with actual radioactive wastes. The most recent results of the flowsheet testing are summarized and information on the centrifugal contactor equipment used for the testing is provided.

## INTRODUCTION

The Idaho National Engineering and Environmental Laboratory (INEEL) previously reprocessed spent nuclear fuel to recover enriched uranium. The radioactive raffinate stream from reprocessing was stored and subsequently solidified at 500°C in a fluidized bed calciner. The INEEL currently has approximately 4,400 cubic meters of radioactive calcine stored onsite in above ground stainless steel bins enclosed in concrete vaults. The average composition of the two most prevalent types of this calcine are given in Table 1. A secondary acidic aqueous waste was generated during equipment decontamination between processing campaigns and from solvent cleanup activities. Currently, approximately 4.8 million liters of liquid acidic radioactive tank waste are stored in underground, concrete enclosed stainless steel tanks at the INEEL. This liquid waste is not directly amenable to calcination due to its high sodium content which causes agglomeration of the fluidized bed. The average composition of this tank waste is given in Table 2.

Separation processes are being evaluated as alternatives to calcination for treating the remaining liquid tank waste. Additionally, separation processes are being developed for treatment of INEEL calcine (after dissolution in nitric acid solution). The goal of the separation processes is to remove fission products and/or actinides from the calcine and liquid wastes so the bulk of the treated waste can be disposed of as a contact handled transuranic (TRU) or non-TRU waste. It is anticipated that the combined low-activity waste (LAW) raffinate streams resulting from the separation unit operations would be grouted for near surface disposal. The high-activity waste (HAW) resulting from separation processes would be vitrified for disposal at a geological repository.

Solvent extraction processes are being developed worldwide for the treatment of acidic high-level liquid waste [1]. At the INEEL, several solvent extraction technologies have been developed for the separation of the transuranic elements (TRUs), <sup>137</sup>Cs, and/or <sup>90</sup>Sr from INEEL radioactive waste solutions (liquid wastes and dissolved calcine solutions) in centrifugal contactor pilot plants. The solvent extraction technologies developed include the Transuranic Extraction (TRUEX) process, the Strontium Extraction (SREX) process, a chlorinated cobalt dicarbollide (ChCoDiC) process, a chlorinated cobalt dicarbollide/polyethylene glycol process, a phosphine oxide (POR) process, and a universal solvent extraction process (UNEX). For each of these solvent extraction processes, considerable experimental development and flowsheet testing was performed in order to develop the flowsheets. In order to test the solvent extraction technologies with the solid calcines, the calcines are dissolved in 3.0 M to 5.0 M nitric acid at 95 °C for 60 minutes. Under these conditions, approximately 95% of the calcine is dissolved. It should be noted that the separation of <sup>99</sup>Tc is not required for treatment of INEEL waste since the activity of <sup>99</sup>Tc (~0.01 Ci/m<sup>3</sup> in liquid waste) is well below the NRC Class A LLW limit of 0.3 Ci/m<sup>3</sup>. However, it has been determined that the TRUEX and POR processes extract the majority of the <sup>99</sup>Tc with the flowsheets tested. The ChCoDiC and UNEX processes do not extract <sup>99</sup>Tc to any appreciable extent.

## EQUIPMENT DESCRIPTION

Liquid-liquid extraction processes have been utilized in nuclear fuel reprocessing for over 40 years. There have been three types of solvent extraction contacting equipment successfully used in the nuclear industry: pulsed columns, mixer-settlers, and centrifugal contactors. All solvent extraction flowsheet development work at the INEEL is being performed using centrifugal contactors.

There are three centrifugal contactor pilot plants at the INEEL. The rotor diameters and the basic design of each set of centrifugal contactors is different, as shown in Table 3. The 3.3-cm and 5.5-cm contactor pilot plants are set up for testing with non-radioactive solutions. The 2.0-cm contactors are located in a shielded cell facility, which allows for testing with highly radioactive solutions.

*Table 3. Description of the centrifugal contactor pilot plants.*

Size	2.0-cm rotor diameter	3.3-cm rotor diameter	5.5-cm rotor diameter
Manufacturer	Argonne National Lab.	NIKIMT, Moscow, Russia	Oak Ridge National Lab.
Number of stages	24	26	16
Rotor rpm	3,600 rpm (not adjustable)	2,780 rpm	0 – 4,000 rpm
Maximum throughput	40 mL/min	250 – 400 mL/min	3,000 mL/min
Weir system	Not adjustable	Adjustable light phase	Not adjustable
Configuration	Single stage units. Stages are connected using U-tubes.	Single stage units. Stages are connected using U-tubes.	Block of four contactors (4-pack) machined from a single block of metal.

Each of these centrifugal contactor pilot plants have been used to develop flowsheets for the treatment of INEEL wastes. Typically, initial flowsheet development work is performed using non-radioactive waste simulants in the 5.5 or 3.3-cm centrifugal contactor pilot plants. Testing then progresses to the 2.0-cm centrifugal contactors where the flowsheets are demonstrated with actual waste solutions and/or waste simulants spiked with radiotracers.

## RESULTS AND DISCUSSION

For each of the flowsheets developed for the treatment of INEEL liquid and dissolved calcine waste solutions, the status of the development work and a summary of the results obtained are given below. In addition, removal efficiencies for the components of interest are presented for each of the technologies in Table 4.

### Transuranic Extraction Process

The TRUEX process was developed at Argonne National Laboratory for the separation of TRUs from acidic waste solutions [2]. The process uses octyl(phenyl)-N,N-diisobutylcarbamoylmethyl phosphine oxide (CMPO) as the active extractant, tributyl phosphate (TBP) as a phase modifier, and a hydrocarbon diluent. A research program began in 1993 to develop the TRUEX process for the removal of TRUs from acidic radioactive wastes at the INEEL. Numerous countercurrent pilot-scale flowsheet tests with simulated liquid waste and dissolved pilot plant calcine solution have been performed [3,4], including extended operation integrated with the SREX process and cesium ion exchange [5]. TRUEX flowsheets have also been demonstrated using actual liquid waste in a 2-cm centrifugal contactor pilot plant [6,7], including integrated testing with the SREX process and cesium ion exchange (CSIX) [5].

**Table 4. Summary of the removal efficiencies obtained from demonstrations of various solvent extraction processes with actual or simulated acidic radioactive waste.**

Comp	TRUEX[5,7] (liq. waste) (%)	SREX[5,15] (liq. waste) (%)	POR[24] ChCoDiC/ (liq. waste) (%)	PEG[24] (liq. waste) (%)	ChCoDiC[24] (liq. waste) (%)	UNEX[27] (liq. waste) (%)	UNEX (calcine) (%)	TRUEX[4] <sup>c</sup> (calcine) (%)	SREX[24] <sup>c</sup> (calcine) (%)

a. (x/y) where x is data from a TRUEX test and y is data from the TRUEX portion of an integrated CSIX/TRUEX/SREX test.

b. (x/y) where x is data from a SREX test and y is data from the SREX portion of an integrated CSIX/TRUEX/SREX test.

c. Data from flowsheet testing with simulated waste.

d. d = Data were not obtained.

A TRUEX flowsheet has been demonstrated with actual liquid tank waste several times, most recently as part of an integrated TRUEX/SREX/CSIX process. With these tests, the removal efficiencies ranged from 99.2% to 99.8% for the total alpha activity. Also, 74% to 95% of the Hg and 29% to 42% of the Zr were extracted and exited with HAW strip product.

A TRUEX flowsheet has also been developed for the treatment of dissolved zirconium calcine. This flowsheet has been tested using simulated dissolved calcine spiked with <sup>241</sup>Am and <sup>95</sup>Zr. With this flowsheet, a removal efficiency of >96.4% was obtained for <sup>241</sup>Am. An ammonium fluoride scrub was effectively used to back-extract the Zr from the TRUEX solvent. Less than 0.25% of the <sup>95</sup>Zr was extracted and exited with the strip product. Cerium was extracted from the calcine (>98.7%); however, the expected concentration of Ce in the dissolved INEEL calcine is ~1.3E-04 M which will not impact the capacity of the extractant.

### Strontium Extraction Process

The SREX process uses the crown ether 4,4'-(5')di-(t-butylcyclohexano)-18-crown-6 (DtBuCH18C6) which has been determined to be a selective and efficient extractant for Sr [8-10]. A research program began in 1993 to develop the SREX process for the removal of <sup>90</sup>Sr from liquid wastes and dissolved calcine solutions at the INEEL. This research has focused on the use of DtBuCH18C6 with a TBP phase modifier in a hydrocarbon diluent. Numerous countercurrent pilot-scale flowsheet tests have been performed with simulated liquid waste and dissolved calcine solutions [10-14], including extended operation integrated with the TRUEX process and cesium ion exchange [5]. A SREX flowsheet has also been demonstrated with actual liquid waste solution in a 2-cm centrifugal contactor pilot plant [15].

The SREX flowsheet that was demonstrated several times with actual liquid tank waste resulted in  $^{90}\text{Sr}$  removal efficiencies ranging from 99.994% to 99.997%. With these flowsheets, >94% to 98% of the Pb, >82% of the Zr, 16% to 31% of the K, 87% to >89% of the Hg, and 64% to 81% of the Ba were extracted and exited with the HAW strip product. It should be noted that U and Pu are extracted by the TBP present in the SREX solvent.

A SREX flowsheet has also been developed for the treatment of dissolved zirconium calcine. This flowsheet has been tested using simulated dissolved calcine spiked with  $^{85}\text{Sr}$ . With this flowsheet, a removal efficiency of 99.6% was obtained for  $^{85}\text{Sr}$ . An efficiency of 60% in the extraction section of the flowsheet reduced the removal efficiency for Sr. A sodium nitrate scrub was effectively used to back-extract the K from the SREX solvent resulting in only 6.4% of the K exiting with the strip product.

### **Phosphine Oxide Process**

A phosphine oxide solvent extraction process has been developed for the treatment of acidic radioactive waste at the INEEL [16]. The solvent consists of an alkylated phosphine oxide in a hydrocarbon diluent. A joint research program with the Khlopin Radium Institute in St. Petersburg, Russia was initiated in 1993 to develop the POR process for the removal of TRUs from acidic radioactive waste at the INEEL. Countercurrent pilot-scale flowsheet testing with simulated liquid waste has been performed [16,17]. This testing has culminated in the development of a POR flowsheet which has been demonstrated using actual liquid waste solution in a 2-cm centrifugal contactor pilot plant [17].

The POR flowsheet that was demonstrated with actual liquid tank waste resulted in a total alpha removal efficiency of 98.9%. With this flowsheet, 92% of the Hg, 28% of the Zr, and 2.1% of the Fe were extracted and exited with the high-activity waste strip product. A POR flowsheet has not been developed for the treatment of dissolved zirconium calcine.

### **Cobalt Dicarbollide-Based Processes**

Chlorinated cobalt dicarbollide (ChCoDiC) has been developed as an extractant for Cs from acidic waste solutions [18-21]. With the addition of polyethylene glycol (PEG) to the solvent, Sr can also be partitioned from acidic waste streams [22,23]. A joint research program with the Khlopin Radium Institute in St. Petersburg, Russia was initiated in 1993 to develop ChCoDiC based processes for the removal of  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$  from acidic radioactive waste at the INEEL. Numerous countercurrent pilot-scale flowsheet tests with simulated liquid waste have been performed [17]. This testing has culminated in the development of ChCoDiC flowsheets (with and without PEG for the extraction of Sr) which have been demonstrated using actual liquid waste solution in a 2-cm centrifugal contactor pilot plant [24].

The ChCoDiC/PEG flowsheet that was demonstrated with actual liquid tank waste resulted in removal efficiencies of 96.2% for  $^{90}\text{Sr}$  and 99.3% for  $^{137}\text{Cs}$ . Also, 98.5% of the Pb, 45.2% of the K, 26.4% of the Hg, 2.1% of the Na, 1.4% of the Ca, <5.8% of the Zr, and <2.1% of the Fe were extracted and exited with the high-activity waste strip product.

The ChCoDiC flowsheet that was demonstrated with actual liquid tank waste resulted in a removal efficiency of >99.998% for  $^{137}\text{Cs}$ . Also, 50% of the K and 37.5% of the Hg were extracted and exited with the high-activity waste strip product. A ChCoDiC flowsheet has not been developed for the treatment of dissolved zirconium calcine.

The use of a single solvent extraction process to remove the desired radionuclides, as opposed to a combination of processes in separate unit operations that remove these same radionuclides in sequential steps, evolved from the previous collaborative work with the Khlopin Radium Institute. The development of a universal solvent extraction (UNEX) process containing ChCoDiC with PEG to remove  $^{137}\text{Cs}$  and  $^{90}\text{Sr}$ , and a carbamoylmethylphosphine

oxide derivative (diphenyl CMPO) to remove the TRUs was initiated in 1996. Numerous countercurrent pilot-scale flowsheet testing with simulated liquid waste have been performed [24,25], including extended operation of the UNEX process [26]. A universal solvent extraction flowsheet has also been demonstrated using actual liquid waste and actual dissolved calcine solution in a 2-cm centrifugal contactor pilot plant [24,27].

The UNEX flowsheet that was demonstrated with actual liquid tank waste resulted in removal efficiencies of 99.995% for  $^{90}\text{Sr}$ , 99.4% for  $^{137}\text{Cs}$ , and 99.96% for the actinides. Also, 87% of the Zr, 98.8% of the Pb, 28% of the K, >99% of the Ba, and 8% of the Fe were extracted and exited with the high-activity waste strip product.

The UNEX flowsheet that was demonstrated with actual dissolved calcine resulted in removal efficiencies of 99.7% for  $^{90}\text{Sr}$ , 99.99% for  $^{137}\text{Cs}$ , and 99.9% for the actinides. Also, 99.4% of the Pb, 42% of the K, >99.8% of the Ba, 7% of the Zr, and 13% of the Fe were extracted and exited with the high-activity waste strip product.

Idaho National Engineering and Environmental Laboratory, Idaho Falls, Idaho, USA

\*V. G. Khlopin Radium Institute, St. Petersburg, Russia

The universal solvent extraction (UNEX) process has been developed as a collaborative effort between the Idaho National Engineering and Environmental Laboratory (INEEL) and the Khlopin Radium Institute in St. Petersburg, Russia for the simultaneous separation of Cs, Sr, and the actinides from acidic radioactive waste. The UNEX process was recently tested for an extended length of time at the INEEL to evaluate the UNEX process for the treatment of acidic tank waste at the INEEL. The UNEX flowsheet tested was operated continuously for 66 hours using 26 stages of 3.3-cm diameter centrifugal contactors and a tank waste simulant. The UNEX process solvent used for this testing contained chlorinated cobalt dicarbollide (Cs extractant), polyethylene glycol-400 (Sr extractant), and diphenyl-N,N-dibutylcarbamoylphosphine oxide (actinide extractant) in a diluent consisting of phenyltrifluoromethyl sulfone. The UNEX solvent was recycled a total of 89 times during the testing. The buildup of metals in the solvent was not observed. Removal efficiencies of 97.5% to 98.6% were obtained for Cs, >99.993% were obtained for Sr, and 17.2% to 34.1% were obtained for Eu (Am surrogate). Loading of the actinide extractant with Fe, Zr, and Mo resulted in the low removal efficiency for Eu. Laboratory experiments using individual stage process solutions and Am and Pu tracers indicate >99.99% of the Pu and very little of the Am (<2%) would be removed from actual waste solutions with this flowsheet. With minor adjustments, the UNEX process was subsequently successfully tested with actual dissolved calcine waste solution, resulting in removal efficiencies of 99.99%, 99.7%, 99.9% and >99% for <sup>137</sup>Cs, <sup>90</sup>Sr, total alpha, and <sup>241</sup>Am, respectively.

### INTRODUCTION

The Idaho National Engineering and Environmental Laboratory (INEEL) previously reprocessed spent nuclear fuel to recover enriched uranium. The radioactive raffinate stream from reprocessing was stored and subsequently solidified at 500 °C in a fluidized bed calciner. The INEEL currently has approximately 4,400 cubic meters of radioactive calcine stored onsite in above ground stainless steel bins enclosed in concrete vaults.

A secondary acidic aqueous waste was generated during equipment decontamination between processing campaigns and from solvent cleanup activities. Currently, approximately 4.8 million liters of liquid acidic radioactive tank waste are stored in underground, concrete enclosed stainless steel tanks at the INEEL. This liquid waste is not directly amenable to calcination due to its high sodium content, which causes agglomeration of the fluidized bed.

Separation processes are being evaluated as alternatives to calcination for treating the remaining tank waste. The goal of the separation processes is to remove fission products and/or actinides from the calcine and liquid wastes so the bulk of the treated waste can be disposed of as a contact handled transuranic (TRU) or non-TRU waste. It is anticipated that the combined low-activity waste (LAW) raffinate streams resulting from the separation unit operations would be grouted for near surface disposal. The high-activity waste (HAW) resulting from separations processes would be vitrified for disposal at a geological repository.

Several separation technologies (TRUEX [1], SREX [2], trialkylphosphine oxide [3], cobalt dicarbollide [3,4], and Cs ion exchange [5,6]) have been demonstrated at the INEEL using actual tank waste and 2-cm centrifugal contactors. The use of a single process to remove the desired radionuclides, as opposed to a combination of the above mentioned unit operations that remove these same radionuclides, evolved from the previous collaborative work with the scientists from the KRI. A process based on a universal solvent may provide a more simple and cost effective method for waste treatment than a method that utilizes two or three separate processes. Development and batch contact testing of a universal solvent was performed in 1997 using actual INEEL tank waste [7], a countercurrent flowsheet test of the Universal Solvent Extraction (UNEX) process using simulated tank waste was performed in 1997 [8], and countercurrent flowsheet tests using actual tank waste were performed in 1998 and 1999 [9,10], all with very positive results. The most recent flowsheet demonstration resulted in removal efficiencies of 99.4%, 99.995% and 99.96% for Cs, Sr, and total alpha activity, respectively [10].

After this highly successful flowsheet demonstration with actual tank waste, testing was performed at the KRI in which the process flowrates and solution compositions were optimized in order to reduce the volumes of the waste streams. The resulting flowsheet was tested at the INEEL with simulated tank waste over approximately 66 hours of operation with continuous recycle of the UNEX solvent. This document reports the results of this extended flowsheet testing of the UNEX process with simulated tank waste. Removal efficiencies of the Cs, Sr, and Eu (Am surrogate), as well as some of the other metals present in the tank waste are reported.

## EQUIPMENT DESCRIPTION

Flowsheet testing was performed using 26 stages of 3.3-cm diameter centrifugal contactors. The 3.3-cm contactors were designed and fabricated in Moscow, Russia by the Research and Development Institute of Construction Technology (NIKIMT).

Heat tape was wrapped around the strip section centrifugal contactors in order to operate the strip section at an elevated temperature. The temperature of the solution in these contactors was maintained at approximately 60 °C by monitoring the temperature of the solution in the stages and adjusting the current to the heat tape as necessary. In addition, the strip feed solution was heated to approximately 60 °C by pumping the solution through a heating coil submerged in a heated water bath. Solvent exiting the strip section was cooled prior to recycle to the extraction section by pumping the solvent through a cooling coil submerged in an ice water bath.

## EXPERIMENTAL PROCEDURE

### Concentrated Tank Waste Simulant

Approximately 45 liters of a simulant of the INEEL tank waste were prepared as feed for this flowsheet testing. This simulated waste was diluted by 10 vol.% with 3.3 M HF. The feed is diluted to reduce the concentration of metals, thus decreasing the loading of the actinide extractant in the solvent. Fluoride is added to the feed to complex Fe and Zr, thus minimizing the extraction of these bulk matrix components. Also, additional stable Cs, Sr, and Eu were added to the feed to facilitate analysis of these components in the aqueous raffinate. Two feeds were used for this testing, each for approximately half of the operational time. The differences in the two feed simulants is primarily the Eu concentration, which was decreased by approximately one order of magnitude in Feed #2 due to concerns that the Eu in Feed #1 was loading the UNEX solvent resulting in reduced Eu removal (*vide infra*). The compositions of the adjusted tank waste simulant feeds are shown in Table 1.

Table 1. Tank waste simulant feed compositions after 10% dilution with 3.3 M HF.

Component	Feed #1	Feed #2	Component	Feed #1	Feed #2
Acid (M)	2.0	2.0	K (M)	0.16	0.17
Al (M)	0.63	0.62	Mn (M)	0.012	0.013
Ba (M)	5.4E-05	5.2E-05	Mo (M)	6.1E-04	6.1E-04
Ca (M)	0.051	0.050	Na (M)	1.45	1.53
Ce (M)	2.5E-05	2.0E-05	Nd (M)	1.9E-05	1.7E-05
Cl (M)	0.028	0.029	Ni (M)	2.1E-03	2.0E-03

Hg (M)	1.6E-03	1.8E-03			

### Solvent

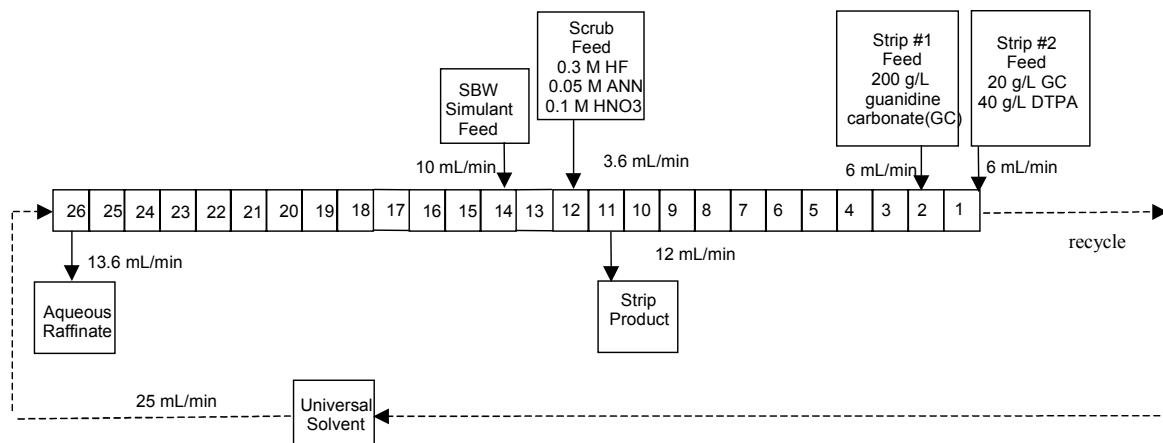

The UNEX process solvent used in this testing is a “universal extraction mixture” which was developed to remove all of the radionuclides of concern, both fission product and actinides, in a single solvent extraction unit operation. The target solvent composition was 0.08 M chlorinated cobalt dicarbollide, 0.35 vol.% polyethylene glycol-400 (PEG-400), and 0.008 M diphenyl-N,N-dibutylcarbamoylphosphine oxide ( $\text{Ph}_2\text{Bu}_2\text{CMPO}$ ) in a diluent consisting of phenyltrifluoromethyl sulfone (FS-13). The solvent was continually recycled during the testing.

### Flowsheet Configuration and Testing

Based on the results of universal solvent development studies performed at the KRI and at the INEEL, a flowsheet was developed and recommended for extended countercurrent flowsheet testing in the 3.3-cm diameter centrifugal contactors. This flowsheet tested is shown in Figure 1.

The duration of the flowsheet testing was 66 hours. Samples were taken from each of the effluent streams every hour for the first five hours, then every five hours until the end of the test. The contactors were then shut down by simultaneously stopping the contactor motors and feed pumps. Each stage remains approximately at steady-state operating conditions with this type of shutdown. This allowed aqueous and organic samples to be taken from each stage and, therefore, distribution coefficients to be determined for any of the 26 stages. Each

effluent was collected in an individual product vessel for the duration of the testing. At the end of the test, each product vessel was mixed and sampled to obtain a composite analysis. Two sets of product composite solutions were collected and sampled, one while operating with Feed #1 and one while operating with Feed #2.

*Figure 1. Flowsheet for UNEX extended testing.*

## RESULTS AND DISCUSSION

The primary species of interest for evaluating UNEX flowsheet characteristics were Cs, Sr, and Eu (Am surrogate). Composite samples were obtained from the product tanks after concluding the experiment. Concentrations of the target metals, e.g., Cs, Sr, and Eu, and the percentage of each component in the various composite products are indicated in Table 2. A discussion of each of the components evaluated with this testing follows.

*Table 2. Percentages of components in the composite effluents for the extended UNEX testing.*

Effluent	Cs		Sr		Eu	
	Feed #1	Feed #2	Feed #1	Feed #2	Feed #1	Feed #2
Raffinate	2.5%	1.4%	0.007%	<0.007%	83%	70.4%
Strip	98.3%	91.4%	107.0%	101.0%	17.2%	34.1%
Solvent	<0.19%	0.35%	0.56%	0.47%	<0.05%	<0.5%
Material Balance	100.8%	92.8%	107.0%	101.0%	100.2%	104.5%

### Cesium

As shown in Table 2, 97.5% Cs removal was obtained with Feed #1 and 98.6% Cs removal was obtained with Feed #2. These removal efficiencies are greater than the required removal efficiency of 95% necessary to reduce the activity of  $^{137}\text{Cs}$  in the average tank waste to below the NRC Class A LLW requirement of 1.0 Ci/m<sup>3</sup> in a grout waste form.

The removal efficiency for Cs varied throughout the test due to fluctuations in ambient temperature. The Cs removal efficiencies were highest during the coolest part of the day and lowest during the hottest part of the day. Removal efficiencies for Cs ranged from 97.2% to 99.3% during the test, and are all above the required 95% removal efficiency.

### **Strontium**

As shown in Table 2, 99.993% Sr removal was obtained with Feed #1 and >99.993% Sr removal was obtained with Feed #2. These removal efficiencies are greater than the required removal efficiency of 99.98% necessary to reduce the activity of  $^{90}\text{Sr}$  in the average tank waste to below the NRC Class A LLW requirement of 0.04 Ci/m<sup>3</sup> in a grout waste form.

The effect of temperature on the Sr removal efficiencies could not be evaluated since the concentrations of Sr in the raffinate stream were below analytical detection limits throughout the test, resulting in removal efficiencies which ranged from >99.94% to >99.993%.

### **Europium**

As shown in Table 2, 17% Eu (Am surrogate) removal was obtained with Feed #1 and 29.6% Eu removal was obtained with Feed #2. With Feed #1, the amount of Eu present is sufficient to completely consume the Ph<sub>2</sub>Bu<sub>2</sub>CMPO in the UNEX solvent. Therefore, at approximately the midpoint of the test the Eu concentration in the feed was reduced by an order of magnitude (Feed #2) in order to prevent the loading of the Ph<sub>2</sub>Bu<sub>2</sub>CMPO. The Eu removal efficiency did increase when the feed was switched to Feed #2; however, a much greater increase was expected. The extraction distribution coefficients for Eu ranged from 0.62 to 0.16, decreasing steadily from the solvent feed stage (stage24) to the scrub section. These low Eu distribution coefficients, combined with the fact that they decreased as the solvent contacted the aqueous feed, indicates the Ph<sub>2</sub>Bu<sub>2</sub>CMPO was still being consumed, likely by other extractable metals such as Fe, Mo, and Zr.

The total alpha activity in the average tank waste is 579 nCi/g (511 nCi/g Pu, 65 nCi/g Am and 2.6 nCi/g Np). The total alpha activity must be reduced to below 100 nCi/g in order to be classified as a non-TRU waste. Therefore only Pu removal is required in order to be classified as non-TRU. Europium (III) is a surrogate for Am (III). The low removal efficiencies obtained for Eu, which indicate Am removal efficiencies will be low with this flowsheet, are not applicable to Pu (IV). Laboratory testing with solutions from this flowsheet test and Pu tracers were performed to determine what the Pu distribution coefficients would have been and, therefore, what total alpha removal efficiency could be expected. The aqueous and organic stage samples taken at the completion of the test were spiked with  $^{239}\text{Pu}$  or  $^{241}\text{Am}$ , re-equilibrated, and the two phases analyzed to determine distribution coefficients. The resulting  $^{239}\text{Pu}$  and  $^{241}\text{Am}$  distribution coefficients correspond to >99.99% Pu removal and <2%  $^{241}\text{Am}$  removal with the tested flowsheet, which is sufficient to reduce the total alpha activity in a grouted LAW form to approximately 30 nCi/g. Although it appears the flowsheet tested is adequate to achieve the non-TRU limit, it is desirable to prevent the loading of the Ph<sub>2</sub>Bu<sub>2</sub>CMPO by the metals and increase the extraction of  $^{241}\text{Am}$ . The flowsheet would then be capable of treating wastes which vary significantly above the average activity of  $^{241}\text{Am}$ . Increasing the concentration of Ph<sub>2</sub>Bu<sub>2</sub>CMPO in the UNEX solvent and/or reducing the amount of Zr extracted by adding additional F to the feed would prevent the loading of Ph<sub>2</sub>Bu<sub>2</sub>CMPO. It should be noted that the UNEX process, with minor adjustments, was subsequently tested using actual dissolved calcine waste, resulting in removal efficiencies of 99.99%, 99.7%, 99.9% and >99% for  $^{137}\text{Cs}$ ,  $^{90}\text{Sr}$ , total alpha, and  $^{241}\text{Am}$ , respectively.

### **Other Matrix Components**

The samples of the composite products were analyzed for a variety of matrix metals to evaluate or further confirm their behavior in the UNEX process. Ba, and Pb were nearly completely extracted from the feed. In addition, Ca, Ce, Fe, K, Pb, Mo, Ni, Pr, and Zr were partially extracted. Al, Cr, Na, Mn, and Hg were essentially inextractable. The results obtained for Feed #1 were very comparable to the results for Feed #2. Note that the amount of Ce, Mo, and Zr extracted increased with Feed #2. This is consistent with having a lower Eu concentration in Feed #2, resulting in less of the Ph<sub>2</sub>Bu<sub>2</sub>CMPO being consumed by Eu. A buildup of metals in the UNEX solvent was not observed.

## CONCLUSIONS

The universal solvent extraction process was successfully operated for an extended period of time using simulated waste solution. The UNEX flowsheet was operated for 66 continuous hours and the solvent was recycled 89 times. Based upon this testing it can be concluded that 1) components extracted from the tank waste will not build up in the UNEX solvent and adversely effect operation of the UNEX process during extended operation, 2) cesium and strontium were effectively separated from the concentrated tank waste simulant. An average removal efficiency of >99.993% was obtained for Sr. The average Cs removal efficiency was 98.6% while operating with Feed #1 and 97.5% with Feed #2, and 3) europium (Am surrogate) was not effectively removed from the tank waste simulant due to loading of the Ph<sub>2</sub>Bu<sub>2</sub>CMPO in the UNEX solvent with metals. However, results of testing using actual stage solutions spiked with Pu tracers indicate >99.99% Pu separation can be expected with this flowsheet. The activity of <sup>241</sup>Am expected in the average tank waste is 65 nCi/g, which is already below the 100 nCi/g non-TRU limit. Flowsheet modifications are necessary to prevent the loading of the Ph<sub>2</sub>Bu<sub>2</sub>CMPO in the UNEX solvent in order to effectively process batches of concentrated waste with higher <sup>241</sup>Am activity. The UNEX process was subsequently tested using actual dissolved calcine waste, resulting in removal efficiencies of 99.99%, 99.7%, 99.9% and >99% for <sup>137</sup>Cs, <sup>90</sup>Sr, total alpha, and <sup>241</sup>Am, respectively.

# COMPARISON OF SOLVENT EXTRACTION PROCESSES AND ION EXCHANGE RESINS FOR REPROCESSING ACTINIDE EFFLUENTS

L. Pescayre, C. Douche and C. Thiébaut

CEA, DTMN, Centre de Valduc, Is sur Tille, France

Nuclear recycled materials which are generated at the Valduc Centre have been chemically reprocessed since the 1970s. Solvent extraction and ion exchange resin processes have been used at large scale to separate plutonium from the other actinides and inert materials. Technologies have evolved in recent decades to contend better with cost, safety and environment.

However, major differences in criteria between these two purification processes exist and this study aims to point out the advantages and drawbacks of each. Significant results deal with the performance (degree of purification with various fuels to be reprocessed), the chemical and radiolytic stabilities, the control of the operating point and the generation of waste.

## INTRODUCTION

The activities of the Valduc Nuclear Centre generate various plutonium-contaminated residues (such as glass containers, impure scraps, etc.) and plutonium metal which does not meet the required purity specifications to be directly reused. A nitric acid-based process enables the recovery of plutonium in a purified form. It consists of four main stages:

- Dissolution of the nuclear materials,
- Purification of plutonium nitrate,
- Conversion into plutonium dioxide,
- Reduction treatment.

The efficiency of the entire process is mainly characterised by the purification stage of the plutonium nitrate solution, which determines the recovery rate as well as the volume of the waste generated. Two different technologies can be used to perform the purification: liquid-liquid solvent extraction and ion exchange resin processes [1]. Each one has specific characteristics and operating conditions.

The objectives of this study are to present the background of the Valduc Centre concerning several decades of exploitation of successive resin and solvent extraction facilities. A description of the two processes is followed by a comparison of the results obtained in order to point out general choice criteria for optimal operating conditions.

## PROCESSES

### Ion Exchange Resin Process

Plutonium is one of the few metals that forms stable anions in nitric acid solutions, inducing the creation of the Pu(IV) complex  $\text{Pu}(\text{NO}_3)_6^{2-}$  [1]. For an acid concentration of about 7 M, the Pu(IV) anions preferentially sorb to the resin by displacing or exchanging with nitrate anions.

Porous beads made from resin are packed into a column through which the 7 M nitric acid solution flows. The plutonium sorbs to the resin while impurity elements wash away (U, Am and inert materials). Once the resin has been sufficiently loaded with plutonium, the solution conditions are changed (0.5 M nitric acid). The plutonium is released from the resin and is recovered as pure plutonium solution (Figure 1).

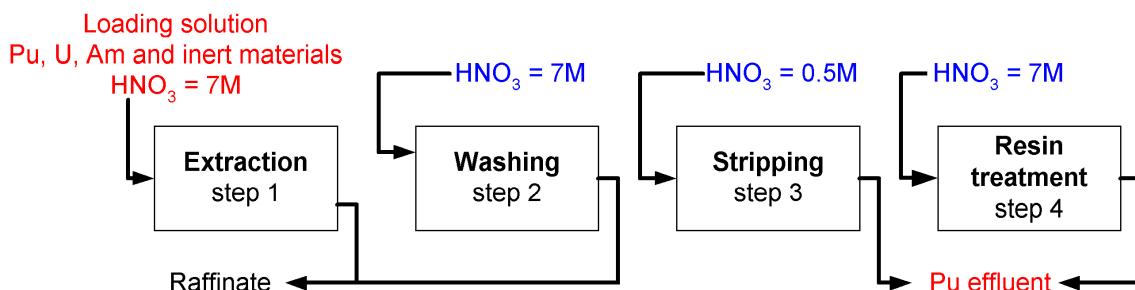

Figure 1. Flowsheet for the recovery of plutonium with an anionic resin.

For several decades, studies have focused on the resin to improve the efficiency of the process. During the 1980s, gel-type resins were used (such as Dowex 21K from Dow Chemical). They were replaced in early 1990s by macroporous resins which are cross-linked (e.g., Lewatit MP 500 from Bayer) with extra large pores that greatly increase the effective surface area and consequently the kinetics. More recently, studies have been performed using a macroporous polyvinylpyridine resin (mono or bifunctional) which offers better sorption and desorption kinetics, greater capacity and higher resistance to nitric acid and radiation damage (Reillex HPQ from Reilly Industries) [2].

### Liquid Extraction Process

Tetravalent plutonium is extracted from nitric acid by an organic phase (tributylphosphate: TBP) and forms a neutral, unhydrated complex  $(\text{PuNO}_3)_4 \cdot (\text{TBP})$  [1]. The well-known Purex process, based on this principle, has widely supplanted the other solvent extraction processes because 30% TBP in an aliphatic diluent (like dodecane) presents good selectivity and radiolytic stability [3].

Various equipment is suitable to perform the extraction. However, major constraints have led to the choice of mixer-settlers as contactors: pulsed columns can not be used in a glove box because of their height, while multistage centrifugal contactors are not suitable for use during normal working hours only because the starts and stops need many processes and controls.

After a nitric acid adjustment to 4 M, plutonium solution is fed to the center of the extraction mixer-settler. The organic phase, containing plutonium and uranium, overflows from the first mixer-settler battery into the center of the second mixer-settler battery. An aqueous acid stream, containing ferrous sulfamate, enters from the opposite end and strips the plutonium(III). The organic phase, containing uranium, overflows into the end of the third mixer-settler battery. A dilute acid stream strips the uranium. At the end, alkaline sodium reagents partially strip the degradation products from the solvent in mixer-settlers with an internal recycle of the aqueous phase (Figure 2). Mechanical barriers perform the destruction of micro-emulsion of each aqueous solution before storage.

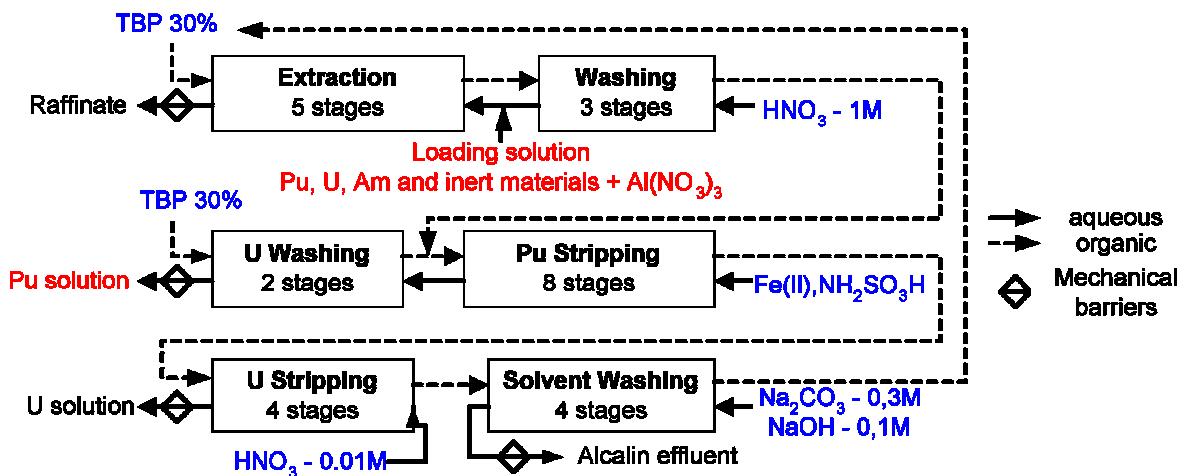

Figure 2. Flowsheet for the recovery of plutonium by extraction with 30% TBP.

## COMPARISON OF THE PROCESSES

These two plutonium extraction processes can be characterised by three main guidelines:

- the efficiency: to meet the end-product specifications (classified information) and to achieve high recovery of these products,
- the environmental consideration: to comply with radioactive release restrictions, to reduce the volume of wastes and to reprocess these wastes for final disposal,
- the engineering aspect: to take into account the objectives of an industrial approach (cost, safety, reliability and operating availability).

### Efficiency of the Processes

The efficiency of the anionic resin is determined by the  $Kd$  coefficient which characterises the sorption affinity. It is defined as:

$$Kd = \left( 1 - \frac{[B]}{[A]} \right) \frac{V}{M} \quad (1)$$

where  $[A]$  and  $[B]$  are the concentrations of the element in solution before and after contact respectively,  $V$  is the volume of solution (l) and  $M$  is the mass of resin (kg).

The characteristics of the solutions to be purified have evolved during the years but the  $Kd$  value of Pu was always near 100, that is 30 times higher than for Am. Consequently the extraction is extremely efficient and selective. Moreover, the recovery rate is high; an average value of 98 % is obtained in Valduc facilities, but a large volume of stripping solution is needed (see next section).

Nevertheless, the average plutonium concentration in the raffinate is not negligible. This might be due to a local channelling effect which considerably lowers the efficiency of the operation. This effect could be linked with a chemical swelling of the resin and its weight loss due to radiolysis. A specific arrangement which packs the resin in the column has been developed to decrease this phenomenon but the plutonium concentration is still about 50 mg/l.

The use of resin allows the reprocessing of solutions for which plutonium concentrations vary significantly (between 1 to 60 g/l).

The efficiency of the Purex process is determined by the extraction coefficient  $D$ , defined as:

$$D = \frac{\text{concentration of the element in solvent after contact}}{\text{concentration of the element in solution after contact}} \quad (2)$$

The  $D(\text{Pu})$  values decrease quickly between the first and the subsequent mixer-settlers, and can be as low as 10 for the first mixer-settler, and 2 for the last one. This is linked with the presence of strong complexants in the solution. However, introducing  $\text{Al}(\text{NO}_3)_3$  to the feed solution increases the  $D(\text{Pu})$  value (Figure 3).

With a five-stage mixer-settler battery, and after  $\text{Al}(\text{NO}_3)_3$  introduction, the plutonium concentration in raffinate is measured near 5 mg/l (see the evolution during the process in Figure 4). Both in the raffinates and in the unloaded solvent, the plutonium losses are extremely low (recovery rate higher than 98 %). The modification of feed concentration implies a need to change the operating parameters.

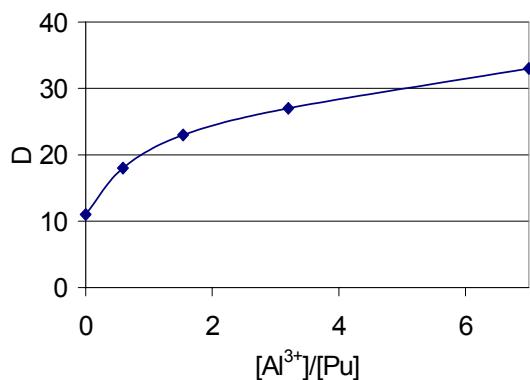

Figure 3.  $D(\text{Pu})$  versus  $[\text{Al}^{3+}]/[\text{Pu}]$  ratio in the first mixer-settler.

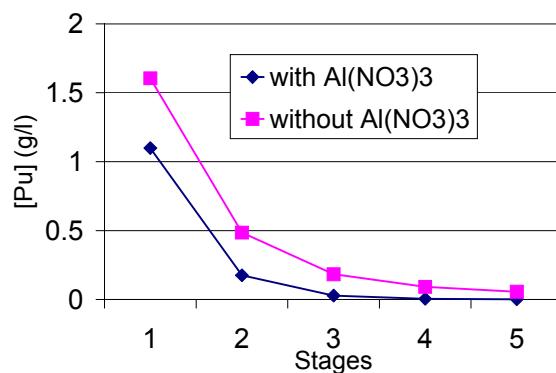

Figure 4. Pu extraction with and without  $\text{Al}(\text{NO}_3)_3$ .

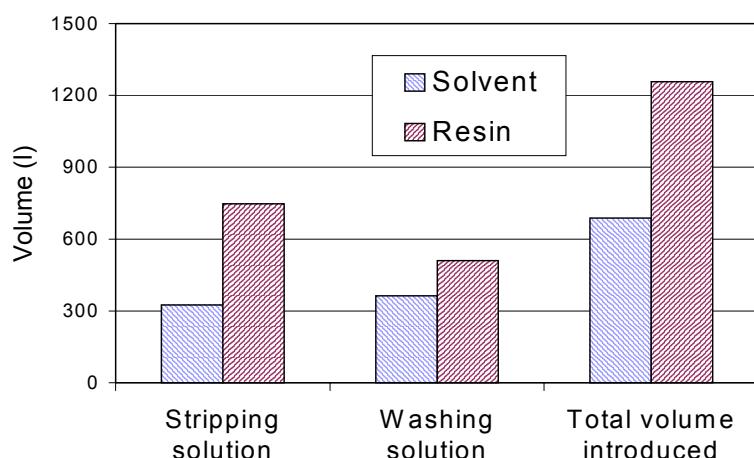

### Environmental Considerations

The effluent management system of the Valduc Nuclear Centre aims to decrease the amount of waste solutions sent to the effluent treatment station and to reprocess all wastes for final disposal.

Two significant aspects differ between the solvent and resin processes. The first one is the volume of aqueous effluent introduced during the process. Concerning the resin extraction, two types of solutions have to be introduced: the 7 M nitric acid solution which is necessary for the washing and resin treatment and the 0.5 M nitric acid used for Pu stripping. For the solvent extraction treatment, various solutions are introduced: nitric acid with various concentrations, sulfamate ferrous solution, and alkaline sodium solution.

The total volume introduced for the solvent extraction process is one half of the volume introduced for the resin process (Figure 5). Liquid-liquid extraction thus presents an advantage over the resin process, but the nature of the waste effluents is more diversified and impurities are introduced.

Instead of Fe and sulfamate as the back-extraction agents, a mixture of hydroxylamine/hydrazine could be used and later eliminated as gases. However, this is not used at the Valduc centre because it presents a safety hazard and increases the costs due to the hydroxylamine/hydrazine treatment.

*Figure 5. Comparison of the solution volumes introduced for solvent and resin processes to purify 1 m<sup>3</sup>.*

The second significant difference between the two processes is the nature of the organic wastes. The nuclear aqueous solution induces radiolytic and chemical degradation of the solvent and the resin. The degradation products of the solvent or the resin process are responsible for the loss of efficiency of the extraction.

Concerning the solvent process, a widely used scrubbing solution containing sodium carbonate and caustic soda eliminates solvent degradation products which can combine with metal ions. However, efficiency is partial and after one year interfacial sludge is observed which contributes to the clogging of the extraction battery. The sludge is currently stored and could be mineralised in the future [4].

In case of the resin process, no specific treatment is realised. However anionic resins have evolved for several decades to offer superior resistance to degradation. The current resins have to be replaced after two years. The irradiated resins are stocked and we plan to reprocess them by an oxidising cobalt or silver dissolution treatment [5].

### **Engineering Aspects**

Every new reprocessing facility set up at the Valduc Centre has been an opportunity for technological progress and a step to reach an industrial maturity.

The liquid-liquid extraction process is a continuous process whereas the resin process is a semi-continuous process. The facilities operate five days a week during the usual working hours (8 h/day).

Suitable automation makes these processes easier to control. In particular, in-line analysers enable the operator to monitor the plutonium residual content in the aqueous streams as well as organic streams in the case of the solvent extraction facility. A germanium gamma spectrometer and a neutron measurement station are used for monitoring the processes.

Concerning the throughput range, the liquid-liquid extraction offers a significant advantage over the resin extraction process. For this second one, the strong influence of the throughput on the pressure in the bottom of the column requires operation at a flow below 15 l/h.

Regulatory constraints must be respected to avoid safety hazards. The mixer-settlers were built with reduced height to make them geometrically safe but wide enough to handle the throughputs. In the same manner, the diameter of the resin glass column, which is surrounded by a stainless steel grid, forms geometrically safe equipment. Furthermore, to avoid explosion hazards, a stripping step is necessary after each week of operation. The resin has to be kept in a nitrate solution between the cycles and maintained at room temperature.

The investment costs are higher for the solvent extraction process (150 %) as well as maintenance costs because this process needs more complex equipment (volumetric pumps, electric motors and agitators have to be regularly replaced). The highest reliability has been achieved with the resin extraction process, for which the equipment is simpler.

## CONCLUSIONS

Close attention is paid to the reliability and flexibility of the plutonium purification process to avoid rework of out-of-spec products. This implies efficient processes and adequate safety margins during usual operation as well as a suitable process control system. The advantages and drawbacks of the two processes tested at Valduc Centre are summarised in Table 1.

*Table 1. Advantages and drawbacks of the two processes.*

Process	Advantages	Drawbacks
Liquid-liquid extraction	<ul style="list-style-type: none"> <li>• High decontamination factor</li> <li>• Large throughputs</li> <li>• Continuous process</li> </ul>	<ul style="list-style-type: none"> <li>• Waste generation due to solvent</li> <li>• Modification of operating parameters</li> </ul>
Ion exchange resin	<ul style="list-style-type: none"> <li>• Low investment costs</li> <li>• Simple maintenance</li> <li>• Simple technology</li> <li>• Wide range of plutonium concentrations</li> </ul>	<ul style="list-style-type: none"> <li>• Waste generation due to resin</li> <li>• Waste generation due to the large volume of solutions introduced (Figure 5)</li> <li>• Limited throughputs</li> </ul>

The resin extraction process offers more advantages at low throughput (lower than 15 l/h), but for higher values liquid-liquid extraction can not be overlooked.

In the future, the variety of generated wastes has to be reduced and a choice should be made between the two processes. It is recommended that solvent extraction processes be utilized for future processing because higher throughputs can be handled, which is a major criterion in an industrial context.

## PREPARATION OF N, N'-DIACYLPIPERAZINES AND THEIR EXTRACTION PROPERTIES FOR U(VI)

Yang Xing-Cun, Bao Bo-Rong<sup>\*</sup> and Cao Wei-Guo<sup>\*</sup>

Shanghai Institute of Nuclear Research, Chinese Academy of Sciences,  
Shanghai, P.R. China

\* Department of Chemistry, Shanghai University, Shanghai, P.R. China

Four amide extractants of the type N,N'-diacylpiperazine (DAPEZ), including N,N'-dihexanoylpiperazine (DHPEZ), N,N'-dioctanoylpiperazine (DOPEZ), N,N'-didecanoylpiperazine (DDPEZ), and N,N'-dilauroylpiperazineare (DLPEZ), were synthesized and characterized for the first time. Their extraction of U(VI) from aqueous nitric acid media has been studied. The relation between structure and property of the extractant has also been investigated. From the experimental results, it is shown that the extraction performance of DAPEZ for U(VI) is good compared to other diamides and that the longer acyl chain benefits the extraction. The extracted complexes were  $\text{UO}_2(\text{NO}_3)_2(\text{DAPEZ})_2$  and  $\text{UO}_2(\text{NO}_3)_2\text{DAPEZ}$ .

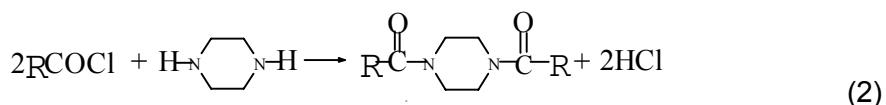

### INTRODUCTION

During the last forty years there have been numerous publications concerning amides. Amides have been proposed as an alternative to tri-n-butylphosphate (TBP) for the reprocessing of spent nuclear fuel [1-5]. They not only selectively extract U(VI) effectively from nitric acid media, but also have other advantages compared with TBP, such as their complete incinerability, innoxious degradation products, easier preparation and back extraction. However, when the acidity or the U(VI) content is higher, third-phase formation usually appears [6,7]. In order to modify the chemical structure of the amide and improve the extraction properties, a series of amides of the type N,N'-diacylpiperazine (N,N'-dihexanoylpiperazine (DHPEZ), N,N'-dioctanoylpiperazine (DOPEZ), N,N'-didecanoylpiperazine (DDPEZ), and N,N'-dilauroylpiperazine (DLPEZ)) were synthesized and characterized. Some physical properties of the four amides are given and the U(VI) extraction properties studied.

### EXPERIMENTAL

#### Preparation of N, N'-Diacylpiperazine

The synthesis of DAPEZ can be expressed as follows:

where R=C<sub>5</sub>H<sub>11</sub>, C<sub>7</sub>H<sub>15</sub>, C<sub>9</sub>H<sub>19</sub>, C<sub>11</sub>H<sub>23</sub>.

DAPEZ was synthesized by adding a stoichiometric quantity of chloride dropwise into a round-bottomed flask containing a mixture of piperazine and triethylamine in dichlorethane, being cooled to 0°C. After the addition, the mixture was heated under reflux for 10 hours at 75–80°C. On cooling, the contents in the flask were washed three times with distilled water, twice each with 5 % hydrochloric acid and 5 % sodium hydroxide, and finally with distilled water until free from alkali. The thick brown liquid obtained was dried overnight with an excess of anhydrous sodium sulfate. The solvent was evaporated under vacuum and the rough product was recrystallized in ether and then the noncolored (or light yellow) crystal was obtained with higher yields.

### Characterization of DAPEZ

The purity of DAPEZ was checked by IR spectrometry, elemental analysis and <sup>1</sup>H NMR spectrometry.

The elemental analyses for C, H, N were obtained. They are, respectively, for DHPEZ: 68.34% (68.04%), 10.58% (10.71%), 9.90% (9.92%); for DOPEZ: 70.86% (70.91%), 11.52% (11.31%), 8.15% (8.27%); for DDPEZ: 72.97% (73.04%), 11.47% (11.75%), 7.15% (7.09%); and for DLPEZ: 74.85% (74.61%), 11.87% (12.08%), 6.16% (6.21%). The theoretical values (in brackets) agree well with the experimental values, indicating that the products are sufficiently pure.

The data of IR spectra of DAPEZ help us to observe the  $\nu(\text{C=O})$  stretching band. Strongly absorptive peaks are found at 1643.3, 1646.5, 16544.8, 1643.1  $\text{cm}^{-1}$ , respectively for the four amides, in the IR spectra. They are the characteristic peaks of  $\nu(\text{C=O})$  of amide.

The data of <sup>1</sup>H NMR spectra fit the structure of diacylpiperazine well.

### Extraction Procedure

Extraction was performed by shaking 1 ml of benzene solution containing DAPEZ and 1 ml nitric acid solution containing uranyl nitrate in a stopper tube at  $298 \pm 1$  K for 40 minutes. After centrifugation and phase disengagement, the concentration of U(VI) in aqueous phase was analyzed by the arsenazo-III spectrophotometric method, and that in organic phase was calculated according to the difference between initial and final concentration of U(VI) in the aqueous phase. The distribution ratio,  $D$ , was then calculated.

## RESULTS AND DISCUSSION

### Effect of Nitric Acid Concentration

Figure 1 denotes the dependence of the distribution ratio on nitric acid concentration in the range of 1~9 mol/L. The values of  $D$  first increase rapidly with increasing concentration of nitric acid, then decrease gradually at higher acidity after a maximum value at the concentration of  $\text{HNO}_3$  about 6.2 mol/L. This is because DAPEZ not only extracts U(VI), but also extracts  $\text{HNO}_3$  from the aqueous phase especially at higher acidity. Accordingly the concentration of free extractant decreases greatly, which decreases the distribution ratios at higher acidity.

For all the extractants, owing to the similar chemical structures, the variation trends of plots of  $D$  versus  $C_{\text{HNO}_3}$  are similar and the acidities of nitric acid at the maximum values of  $D$  are almost same. But the maximum values of distribution ratios are different due to the different length of the acyl chain. That of DLPEZ is the highest and the others are nearly equal. The longer substituted groups not only enhance the solubility of the complex in the organic phase leading to an increase of extraction ability, but also increase the steric hindrance resulting in a decrease of extraction ability. The value of  $D$  is effected by both factors at the same time. In the case of DLPEZ, the effect of the former dominates, and for the others the both effective degrees are nearly equivalent.

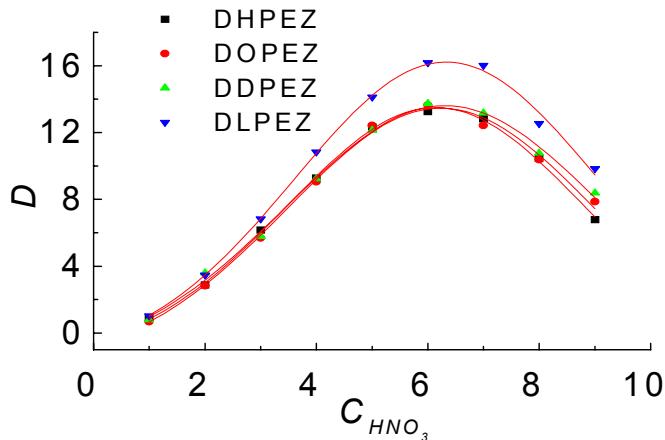

Figure 1. Dependence of distribution ratio on initial aqueous nitric acid concentration for the extraction of U(VI) by DAPEZ in benzene.

$[UO_2^{2+}] = 5.0 \times 10^{-3} \text{ mol/L}$ ;  $[DAPEZ]_{(o)} = 0.5 \text{ mol/L}$ ;  $T = 298 \text{ K}$ .

### Effect of Extractant Concentration

The dependence of distribution ratio on extractant concentration is shown in Figure 2. The plots of  $\log D$  versus  $\log [DAPEZ]_{(o)}$  are all straight lines with slopes of 1.46, 1.44, 1.46, 1.35, respectively. Although the substituted groups of DAPEZ are different, the values of slopes are near, being non-integer and close to 1.5. This suggests that there are probably two kinds of extracted species. The number of  $NO_3^-$  ions in the extracted species could be proved to be 2 by IR spectra [10], viz.,  $UO_2(NO_3)_2(DAPEZ)_2$  and  $UO_2(NO_3)_2DAPEZ$ . The extraction reactions were given as follows:

where the subscript (o) refers to the species in organic phase. For the above reactions, the distribution ratio,  $D$ , is

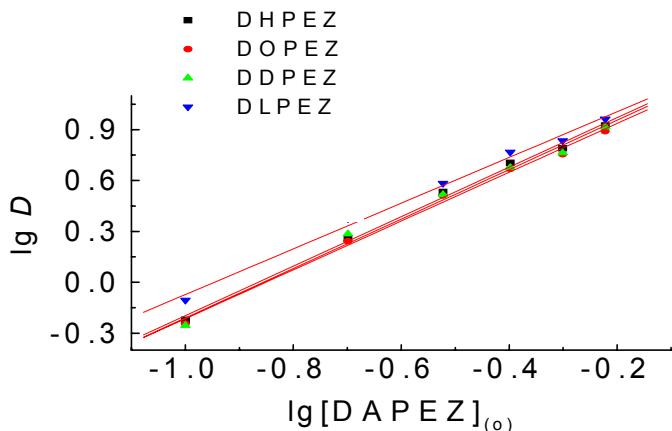

$$D = K_1[NO_3^-]^2[DAPEZ]_{(o)} + K_2[NO_3^-]^2[DAPEZ]_{(o)}^2 \quad (5)$$

The values of  $K_1$  and  $K_2$  were calculated by the curve-fitting method [8,9], for the given values of  $[NO_3^-]$  and  $[DAPEZ]_{(o)}$ , as shown in Table 1.

Table 1. Equilibrium constants of U(VI) by different extractants in benzene.

Extractant	DHPEZ	DOPEZ	DDPEZ	DLPEZ
$K_1$	0.98	1.07	1.07	0.93
$K_2$	1.65	1.01	1.16	2.40

$[UO_2^{2+}] = 5.0 \times 10^{-3} \text{ mol/L}$ ;  $[HNO_3] = 3.0 \text{ mol/L}$ ;  $T = 298 \text{ K}$ .

*Figure 2. Effect of DAPEZ concentration in benzene on distribution ratio of U(VI).  $[UO_2^{2+}] = 5.0 \times 10^{-3} \text{ mol/L}$ ;  $[HNO_3] = 3.0 \text{ mol/L}$ ;  $T = 298 \text{ K}$ .*

According to the results above, it implies that the acyl length of DAPEZ influences the values of  $K_1K_2$ , but there is no relationship between the  $K_1K_2$  value and carbon number of the acyl moiety. The carbon number of the acyl moiety does not influence the composition of the extracted species under the conditions studied.

## CONCLUSIONS

A series of novel amide extractants have been synthesized for the first time. The preparation procedures for DAPEZ are reliable. The extraction properties of DAPEZ are better than other extractants of this class. The carbon number of the acyl group affects the extraction ability and the longer acyl benefits extraction for U(VI).

## DESIGNER SOLVENTS FOR LIQUID-LIQUID EXTRACTION

Braam van Dyk and Izak Nieuwoudt

The University of Stellenbosch, Stellenbosch, South Africa

A method is proposed for the computer-aided molecular design of solvents for liquid-liquid extraction. The method is based on a genetic algorithm and uses group contribution methods to predict solvent properties. Modified UNIFAC is used to estimate the selectivity of the proposed solvent. Any number of properties may be specified simultaneously. The basic genetic algorithm is enhanced by the addition of biased gene selection, viability checks, evolving fitness functions and seeding.

The method is applied to a system of industrial significance. The proposed solvents compare favourably with those recommended in literature.

### INTRODUCTION

The effectiveness of a liquid-liquid extraction (LLX) process depends greatly on the choice of solvent. As the technology of LLX has developed, a number of methods have been proposed to help in the selection of solvents. Unfortunately, these methods are mostly qualitative.

In recent years, a number of methods for Computer-Aided Molecular design (CAMD) have been proposed [1-14]. In these methods the required properties for a molecule are specified and using group-contribution methods, a molecular structure is then found that will satisfy these requirements.

Many different CAMD algorithms have been proposed. They may be broadly classified as interactive, combinatorial, knowledge-based and mathematical programming methods. In this work a genetic algorithm is used. This retains the efficiency of the mathematical programming methods, whilst performing well in difficult search-spaces. Genetic algorithms are also not as susceptible to local minima traps as are other mathematical programming methods. A detailed description of the method may be found in [13-15].

### GENETIC ALGORITHMS AND CAMD

#### **The Basic Algorithm**

A genetic algorithm is an optimisation method based on the theory of evolution. The method was first proposed by Holland in 1975 [16] and has been applied to numerous types of problems since [17, 18]. The method relies in the principle of survival of the fittest. Individuals that are better suited to their environment will have a better chance of passing their genetic material on to the next generation.

To apply this principle in molecular design, molecules are encoded as strings of sub-molecular groups. These groups are often referred to as genes, in reference to their biological equivalents. Similarly, the molecules are referred to as chromosomes.

The properties of each chromosome are calculated using group-contribution methods and measured against the required values for these properties. Each chromosome is then assigned a fitness, based on how well it matches the requirements.

The algorithm typically starts with a randomly created population of chromosomes. New generations are then created through mutation and recombination of parent chromosomes in the current generation. Once a new generation has been created, it replaces the current generation in its entirety. The probability of any chromosome to be used as a parent chromosome is directly proportional to its fitness. To prevent the loss of good candidates to random mutations, an elitist policy is followed in which the best 10% of each generation is copied to the next generation unchanged.

Genetic algorithms require that the chromosomes be encoded as linear data structures. This does not limit the search space to linear molecules. Genes of arbitrary complexity may be constructed by combining structural groups.

To satisfy the octet rule two types of genes are constructed. These are start/end genes with one free bond each and middle genes with two free bonds each. To construct cyclic molecules, only middle genes are used.

The use of these predefined genes has a number of advantages:

1. Physically unfeasible combinations of structural groups can be avoided to a large extent.
2. It allows the construction of more complex molecules than through the simple linear combination of structural groups, such as those used by UNIFAC.
3. It allows for the simultaneous design of aromatic and aliphatic molecules.

As molecules may vary greatly in size, the chromosomes must also be able to vary in length. This type of genetic algorithm is often called a 'messy' genetic algorithm [18].

The process may be summarised as follows (See Figure 1):

1. Initialise a population of chromosomes
2. Evaluate each chromosome against the property requirements.
3. Copy best 10% unchanged to new generation.
4. Create new chromosomes through mutation and recombination to fill up the remaining 90% of the population.
5. Replace the old generation with the new chromosomes.
6. Repeat the process a specified number of times.
7. Evaluate the final generation.
8. Return a list of best chromosomes.

### **Improvements to the Algorithm**

Although the basic algorithm described above gives satisfactory results, there are a number of ways in which it may be improved upon.

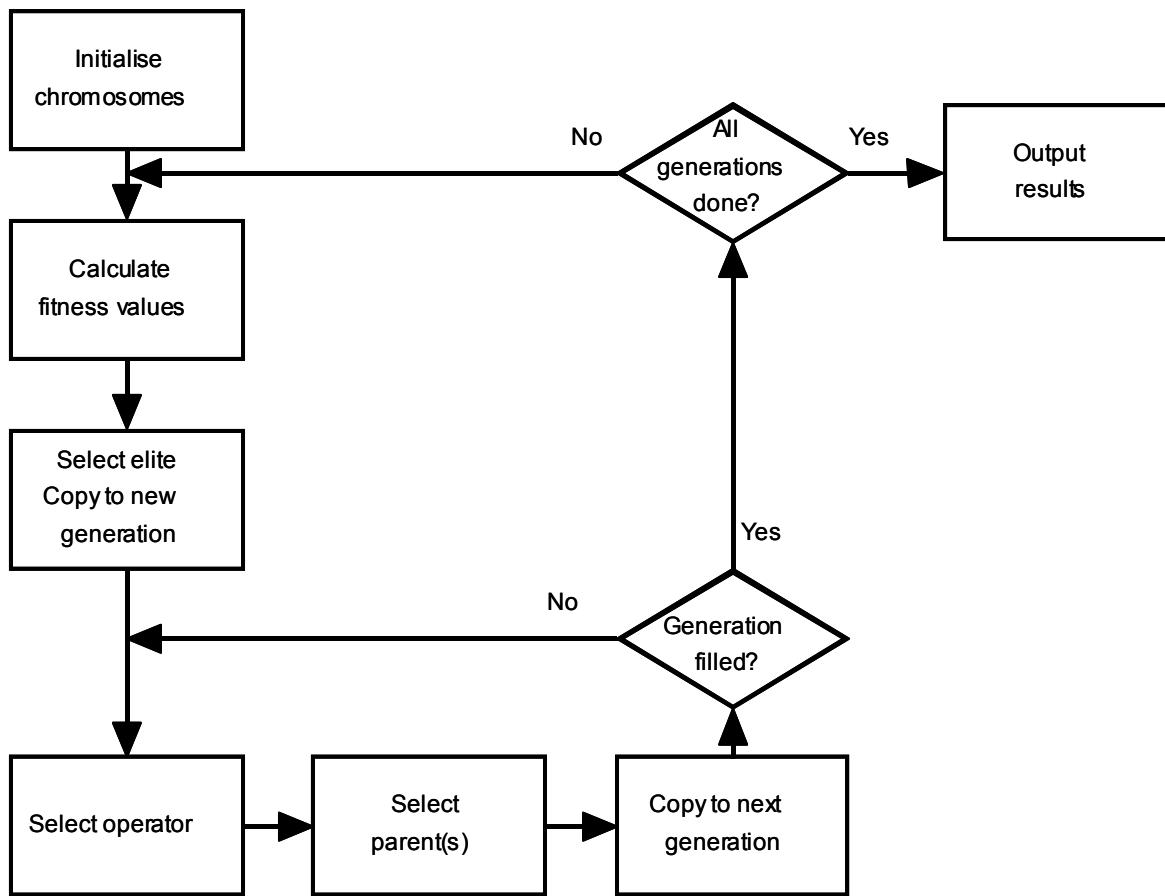

Figure 1. The basic genetic algorithm.

### **Missing interaction parameters**

As CAMD algorithms rely on group-contribution methods to estimate the macroscopic properties of candidate structures, these methods are sensitive to the accuracy and generality of these methods. As the principal property of a solvent is its ability to assist the separation, the UNIFAC method is of great importance in the design of solvents. The availability of UNIFAC interaction parameters is especially important.

Since the introduction of the UNIFAC method in 1975 [19], the matrix of interaction parameters has been greatly extended through the work of Gmehling and others [20]. Gmehling has also published a modified version of UNIFAC [21, 22] that offers improved estimation of liquid-liquid equilibria. Unfortunately, it may still be some time before the current matrix is complete. This leaves the problem of dealing with missing interaction parameters.

Missing interaction parameters may be set to zero [23], but this may lead to gross errors in the calculation of activity coefficients and is not acceptable. One could disqualify all chromosomes that require these missing parameters, or as a less harsh alternative, introduce a penalty system. A small value is then subtracted from the fitness for each missing interaction parameter it requires. This will cause these chromosomes to be eliminated through natural selection within a few generations, while still allowing any good traits of these chromosomes to be passed on to future generations.

### ***Biased gene selection***

The many heuristics that have been developed to assist in solvent selection are based on experimental observation and experience. A good example of this is the Robbins chart [24]. This knowledge should not be discarded out of hand and can be used to speed up the convergence of the genetic algorithm. This is achieved by using these heuristics to adjust the selection probability for each gene. The selection probability of a gene is increased whenever a heuristic indicates that a functional group in the gene will aid the separation and vice versa.

This biasing of gene selection also allows genes containing certain functional groups to be excluded from the design process. This can be done for safety or environmental reasons, or because a certain functional group may cause the solvent to react with the feed.

### ***Physical feasibility***

Although the use of predefined genes will help prevent physically impossible combination of functional groups within a gene, it is still possible that certain combinations of genes will result in infeasible structures. Physical viability is tested against a simple set of rules and a penalty is applied for each violation. These rules are mostly concerned with the number of heteroatoms bonded to a carbon atom.

### ***Incorporating the user's experience***

A great advantage of the interactive design methods is that the user's knowledge and experience is available to the program. This is also possible when using a genetic algorithm. The initial population may be seeded with candidate solvents that are either known or suspected to perform well in the specific separation. As these solvents should perform better than the randomly generated initial population, the algorithm will spend more time in these areas of the search space in the initial generations. As the functional groups that allow these solvents to assist the separation will be present in the population from an early stage, the speed of convergence will be greatly increased.

### ***Automatic tuning of operator selection***

The selection probabilities of the genetic operators (insertion, deletion, mutation and recombination) may be determined so as to optimise the speed of convergence and the quality of the final result. Unfortunately the optimal values for these probabilities vary depending on the system under consideration.

It is possible to determine the optimal parameters for the algorithm run-time through automatic parameter tuning. Whenever a new chromosome is created, the fitness of the new chromosome is compared with that of its parent chromosome. If the new chromosome has a higher fitness, the selection probability of the operator that created the chromosome is increased and vice versa. This method allows the selection probabilities to quickly converge to the optimal values for the specific system.

## **CASE STUDY**

The power of CAMD in solvent design may be illustrated through a case study. The genetic algorithm discussed here was implemented in a Windows application – SolvGen. [13-15]. The SolvGen program uses a set of 531 start/end genes and 368 middle genes. Each gene may consist of up to six types of UNIFAC groups and each chromosome may contain up to eight genes. This gives a total solution space in the order of  $10^{20}$  molecules. Each generation contains 10 000 chromosomes.

A problem of industrial significance is the separation of phenolics from nitrogen bases. Although such mixtures would normally consist of numerous components, for purposes of illustration the problem may be simplified by using only representative species. In this example phenol and aniline represent the phenolics and nitrogen bases respectively.

The use of co-solvents and anti-solvents is common practice in industry. To assure a liquid-liquid split, it was decided to use water and hexane as the co- and anti-solvents respectively. The feed composition used is given in Table 1

*Table 1. The feed composition (combined with water and hexane).*

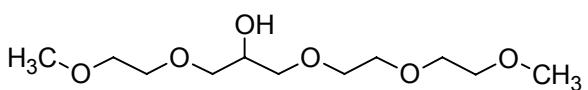

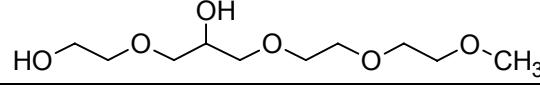

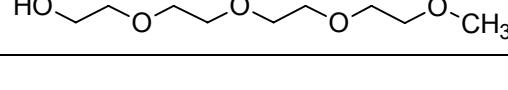

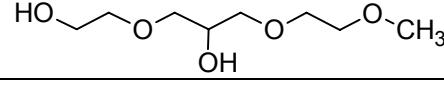

Component	Mass Fraction	Molar Fraction
Phenol	0.148	0.084
Aniline	0.019	0.011
Water	0.167	0.492
Hexane	0.666	0.413

The algorithm was allowed to run for 15 generations (approx. 10 minutes on a Pentium II desktop PC). The molar fraction of the solvent was set to 0.15 and a temperature of 315K was specified. Table 2 lists some of the chromosomes from the final generation and their estimated selectivities, as calculated according to equation (1) with Modified UNIFAC (Dortmund) [21].

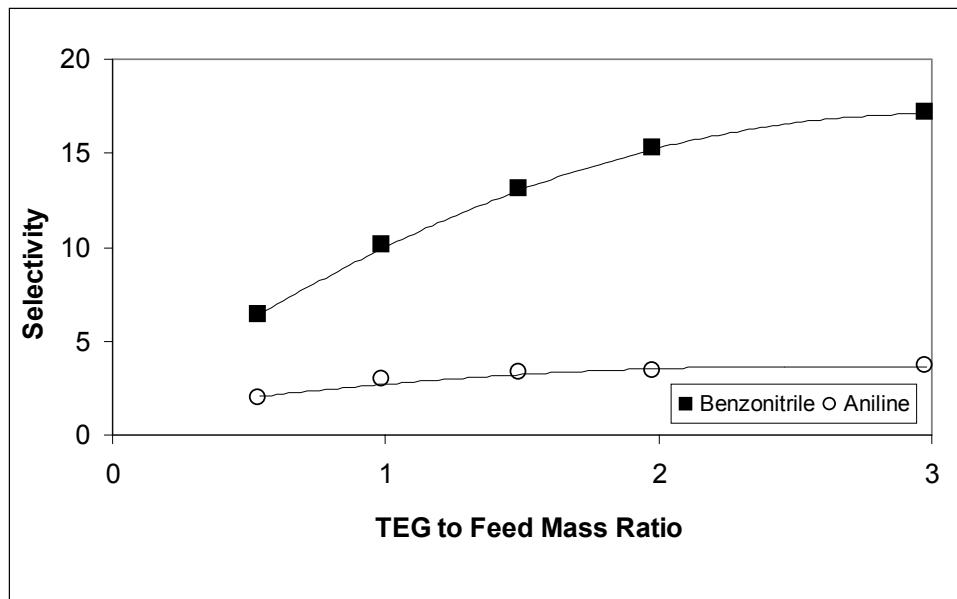

These solvents are very similar in structure to the polyethylene glycols. Polyethylene glycols are relatively easily obtainable and as such much cheaper than solvents that have to be specially synthesised. Using the interactive mode of SolvGen we find that the predicted selectivity for triethylene glycol, using the same solvent fraction, is 7.475, for tetraethylene glycol it is 7.840 and for pentaethylene glycol it is 8.141.

Venter and Nieuwoudt did a detailed study on the separation of phenolics from neutral oils and nitrogen bases [25-27], using complex feeds so as to accurately represent industrial streams. They report that the polyethylene glycols, combined with water and hexane, are indeed very effective solvents for this separation. They recommend triethylene glycol, based on their experimental results, some of which are summarised in Figure 2.

*Table 2. Some candidate solvents.*

Solvent Structure	Selectivity $\alpha$ Phenol / Aniline
	8.322
	8.447
	7.652
	8.177

$$\alpha_{ij} = \frac{x_i^I}{x_j^I} / \frac{x_i^{II}}{x_j^{II}} \quad (1)$$

## REVAMP OF AN AROMATICS EXTRACTION COMPLEX USING HIGH PERFORMANCE MASS TRANSFER INTERNALS

Jose Bravo and Sergio Bergerman

Shell Global Solutions International BV, Amsterdam, The Netherlands

This paper discusses the reconfiguration of an Aromatics Extraction Unit that uses Sulfolane technology, to enable it to process segregated feeds in two extractors in parallel. The existing RDC extraction columns were retrofitted with Shell HiFi Extraction trays to provide about 10% more hydraulic capacity and about 20% more stages for separation. The design was based on a process model that was tuned to actual plant performance based on test run data, and later modified to reflect the new unit line up and operating conditions. The process design also required to increase the lean solvent purity, in order to achieve the necessary extraction performance within the capacity of the equipment. Special measures were undertaken in the design of equipment modifications to ensure this stringent solvent quality.

### INTRODUCTION

Sieve trays are often used for continuous extraction processes in the chemical and petrochemical industries. The sieve tray extractor is simple in design, requires no moving parts, reforms drops at every tray, reduces backmixing, and can handle some slurries. The extraction column consists of a series of perforated plates that are connected by downcomers (or upcomers). The perforations are designed to pass the dispersed phase and the downcomers (or upcomers) are to pass the continuous phase. A completely coalesced layer is supposed to exist underneath the tray (light phase dispersed) for the purpose of reforming drops and preventing backmixing of the continuous phase.

Two studies using larger equipment to examine extraction column flooding have been reported by Seibert and Fair [1] and Eldridge and Fair [2]. Sieve tray flooding studies [4] that have been carried out using 10.2 and 42.8 cm diameter columns, often with "actual" industrial mixtures, indicate that there are several mechanisms that can limit tray capacity, among them

- Spray column flood (ultimate capacity);
- Cross-flow velocity of the continuous phase;
- Length of flow path.

This paper will address a revamp of a column that removes the three limitations mentioned above.

### **Spray and Rotating Disc Contactor (RDC) Column Flood**

The capacity of the spray column is generally limited by entrainment of dispersed phase by the continuous phase and high dispersed phase hold-up. As a result of a distribution in drop sizes, entrainment of smaller drops is the most common mechanism of flooding in a spray column. In larger diameter columns, tray capacity may exceed that of a large diameter spray column depending on the phase flow ratio and the degree of continuous phase recirculation. Spray column axial mixing experiments at the Separations Research Program have indicated that the actual velocity of the continuous phase can be increased by backmixing [4]. Nevertheless one would expect the maximum capacity of a sieve tray extractor to approach that of a spray column free of backmixing but in reality, backmixing will always be present in industrial scale spray extractors. The capacity of RDCs is even more limited than that of spray columns due to the additional dispersed phase holdup present due to shear and the higher velocity flow across baffles. Many RDCs in Sulfolane aromatics extraction service operate as simple baffle columns since the operators have found empirically that stopping the rotation of the discs increased extractor capacity with no detriment to separation performance. In this case the capacity of the static RDCs is limited by the smaller effective cross section available between the discs and the stators. Revamps of RDCs with sieve trays often have yielded more capacity and efficiency, as this paper illustrates.

## **PROCESS DESIGN**

### **Process Description**

The Sulfolane Extraction Unit (SEU) is an industrial process applied in oil refineries and chemical complexes to separate aromatic-containing feedstocks in the gasoline range (platformate, pygas) into two fractions: the extract (mainly consisting of benzene and toluene), and the raffinate (mainly consisting of the non-aromatics components). A liquid-liquid extraction process is used for this purpose, using sulfolane as extraction solvent, in view of its selectivity for dissolving aromatics and its significant density difference with hydrocarbons. The SEU process consist of three main steps: liquid-liquid extraction (aromatics recovery from the feedstock), extractive stripping of the rich solvent (separation of the extract from the rich solvent), and solvent recovery by distillation (purification of the solvent). The raffinate stream is routed to other refinery processes for further processing, while the extract is routed to a fractionation section to separate and purify a benzene and a toluene stream, what is done in a number of conventional distillation columns.

In the SEU unit under consideration in this paper, two different feedstocks (reformate and pygas) coming from other refinery/chemical processes, were mixed together and processed as a single stream in two RDC extractor columns lined up in series. In this way, a maximum number of separation stages were available for the extraction step of the process, but of course a single raffinate stream was resulting from the unit.

### **Project Objective**

The revamp project that was developed for this SEU unit had two main objectives: the segregation of the processing of pygas and reformate feedstocks, and an increase in the unit throughput. The segregated processing of the two feedstocks is achieved by using one of the existing extractor columns for pygas processing, and the other one for reformate processing, thus operating these two columns in parallel (both on the feed side and also within the solvent circulation loop) rather than in series as in previous operation. In this way, two separate raffinate streams would be resulting ("reformate raffinate" and "pygas raffinate"), one from each extractor column, while a single extract stream (mainly benzene and toluene) will still be produced (since the rich solvent streams from each extractor would be combined together before routing them to the extractive stripper).

The economic incentive of obtaining segregated raffinate streams out of the two feedstocks is resulting from the possibility to select different processing routes for each of these streams. The pygas raffinate has much higher content of naphthenic components than the reformate raffinate, thus making it a high quality feedstock for the catalytic reformer unit (in this refinery process unit, naphthenes are converted to high-valued aromatics with high yields). The reformate raffinate, in view of its low content of naphthenic components, is not an attractive feedstock for the catalytic reformer, and thus would be routed as feedstock to the ethylene cracker unit in the chemicals area of the complex. Overall, the segregated processing of the feedstocks to the SEU unit represented a significant improvement to the economic margin of the refinery.

In addition to the feed segregation, an increase of 13% in the total feed intake to the unit was also considered in the project, in order to take full advantage of the potential economic benefits of the unit revamp.

### **Process Modelling and Process Design Considerations**

As a starting point for the process design of the revamp project, a process simulation model of the unit was prepared, representing the existing line up and typical process operating conditions. A key feature for an accurate representation of the process in this model was the selection of suitable thermodynamic package data to predict the L-L equilibrium in the extractor columns, and the V-L-L equilibrium in the extractive stripper and solvent recovery column. The characterisation of the different feedstocks was done based on a set of 48 individual chemical components, for all of which the relevant interaction parameters for the prediction of L-L and V-L-L equilibria were available.

The simulation model was tuned against actual operating data from a unit test run, and the number of theoretical stages in each of the RDC extractor columns was varied until a good match between predicted and actual extraction performance was obtained.

After establishing in this way the base case for the project (both the existing operating conditions and unit line up), the simulation model was adjusted to reflect the required / expected changes in the unit. The main changes are summarised as follows:

- parallel line up of the two extractor columns in the solvent circulation loop;
- segregated line up of the two feedstocks, one to each extractor;
- increased number of theoretical stages in each extractor column, due to higher mass transfer efficiency of sieve trays vs. RDCs;
- new feed flows and composition;
- addition of a tertiary (lean) solvent stream to the pygas extractor;
- addition of a new reformate raffinate water wash column;
- optimised line-up / split for the backwash recycle from the extractive stripper to extractors, and from the top of reformate extractor to the pygas extractor;
- general tuning of the different process conditions for the new requirements.

As a result of the higher total feed intake and the reduced number of theoretical stages available for the solvent extraction step, as compared to the existing conditions (due to the parallel line-up of the extractors instead of in series), a significant increase in the solvent circulation flow was required. In order to limit this increase, and thus the required modifications to existing equipment, an improved quality (*i.e.*, concentration of benzene + toluene) of the lean solvent was specified in the revamp process design. In this way, a larger driving force for mass transfer resulted in the extractors, and the additional solvent circulation was cut down. For this purpose, additional separation stages were added in the (steam) stripping section of the solvent recovery column, so as to reduce the aromatics content of the lean solvent without increasing the reboiler duty or operating temperature in the column.

A summary of the key process parameters of the unit, both for the pre- and post- revamp conditions, is shown in Table 1.

*Table 1. Comparison of process parameters pre- and post- revamp.*

		Previous operation Extractors in series	Revamp design Extractors in parallel
<b>Unit feed</b>			
Total unit intake		100% (base)	113% of base
Pygas feed		100% (base)	95% of base
Reformate feed		100% (base)	173% of base
<b>Solvent properties</b>			
Total lean solvent circulation		100% (base)	143% of base
Solvent / feed ratio	w/w	2.19	<sup>(1)</sup> 2.37 <sup>(2)</sup> / 3.01
Benzene + toluene in lean solvent	%w	0.42	0.30
Benzene + toluene in rich solvent	%w	23.7	<sup>(1)</sup> 22.1 / 19.4
Hydrocarbon load in rich solvent	%w	28.1	<sup>(1)</sup> 27.2 / 23.6
<b>Product quality &amp; recovery</b>			
Benzene in raffinate	%w	1.12	<sup>(1)</sup> 0.81 / 0.95
Toluene in raffinate	%w	1.82	<sup>(1)</sup> 0.91 / 1.14
Benzene recovery	%	98.9	99.1
Toluene recovery	%	93.0	93.9

(2): includes primary + tertiary solvent

## EQUIPMENT MODIFICATIONS

### Extractor Columns

In order to accommodate the higher feed and solvent flows resulting from the desired revamp process conditions, an increase in the hydraulic capacity of the existing extractor columns was required. On the other hand, the reduced number of theoretical stages available for the extraction of each feedstock as compared to the existing conditions (due to the parallel line-up of the extractors instead of in series), represented also an incentive to find alternatives to increase the mass transfer efficiency of the column.

The conversion of the existing columns from RDC type to trayed extractors, equipped with high capacity Shell HiFi™ extraction trays, fulfilled both requirements, as is further described later on in this article.

The conversion of both columns from a RDC to a trayed extractor involved the following main hardware modifications:

- removal of all existing elements associated with RDC operation (motor, shaft, rotor discs, bearings, supports, etc.);
- dismantling/cutting of existing stator discs to make them suitable as support rings for the new sieve trays;
- new (radial) inlet nozzles for feed, solvent and backwash recycles at suitable locations;
- blanking of existing (tangential) inlet nozzles;
- installation of new sieve trays, on existing support rings;
- installation of new spider-type inlet devices for feed, solvent and backwash recycles;
- required modifications to instrument connections, external piping, etc.

The rating of the hydraulic capacity of the extractor columns, when equipped with the new sieve trays, was done with the help of a computer design program for L-L extractors named LLE 5.07, that was developed by the Separation Research Program, of the University of Texas at Austin, based on extensive research and development work. This program allows the determination of the hydraulic capacity of extractor columns, as it is determined from the physical properties of the system and the type of contacting device.

The interfacial tension of the system is a key parameter in this respect, both because it has a large influence in the hydraulic capacity itself, and also because its value is very difficult (when not impossible) to determine under actual plant conditions. Nevertheless, this uncertainty can be solved to some extent by performing a hydraulic rating of the extractors under the existing (pre-revamp) conditions, and using the interfacial tension as tuning parameter to let the columns be just below the flooding point. This approach will result with the lowest value for the interfacial tension that prevents the columns to flood under present conditions, and thus can be used conservatively for the revamp design.

An additional (new) extractor column was specified as part of the revamp project, for the service of reformate raffinate wash. This column is also equipped with high capacity Shell HiFi™ extraction trays, although the service is less critical than the sulfolane extractors, in view of the much higher interfacial tension and lower impact in the overall process.

Relevant hardware details on the extractor columns are shown in Table 2 below.

*Table 2. Hardware details.*

		Column C-8210	Column C-8211
Extractor service previous operation revamp design		Reformate + Pygas extractor Pygas extractor 3200 19782	Reformate + Pygas extractor Reformate extractor 3500 16250
Column diameter	mm		
Column T-T length	mm		
Number of stages previous operation revamp design		56 RDC compartments 55 trays	30 RDC compartments 32 trays

### Distillation Columns

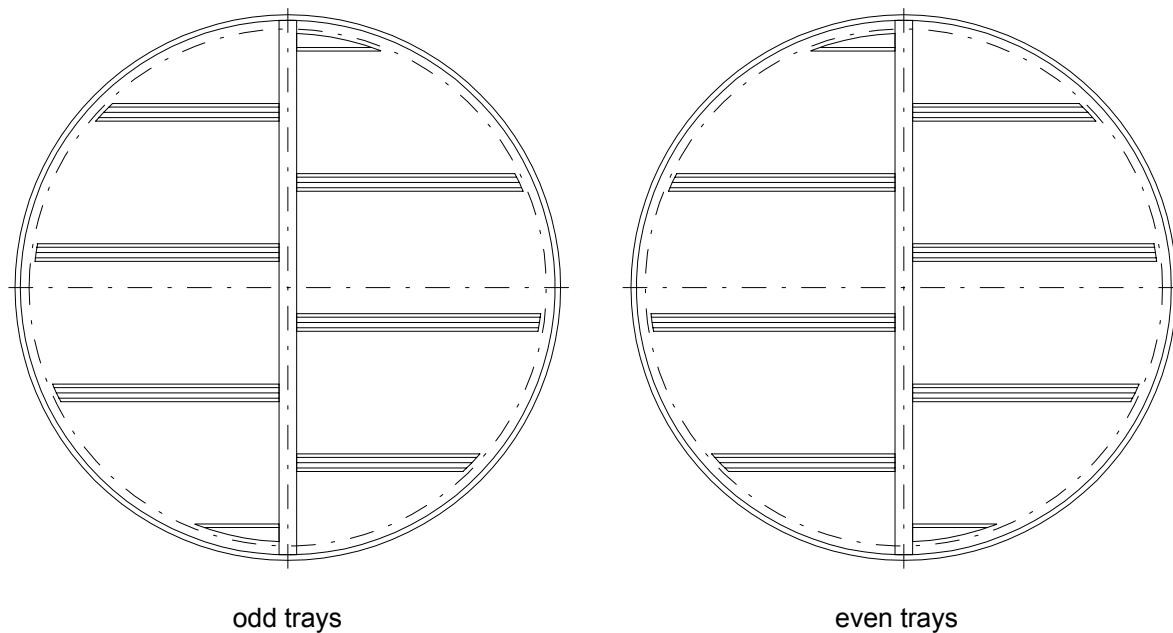

The distillation columns associated with this process were also revamped for more solvent recovery capacity at a higher purity since the solvent purity is the key process variable for aromatics recovery in extraction. These modifications are not discussed in this paper.

## FEATURES OF THE HIGH PERFORMANCE EXTRACTION TRAYS

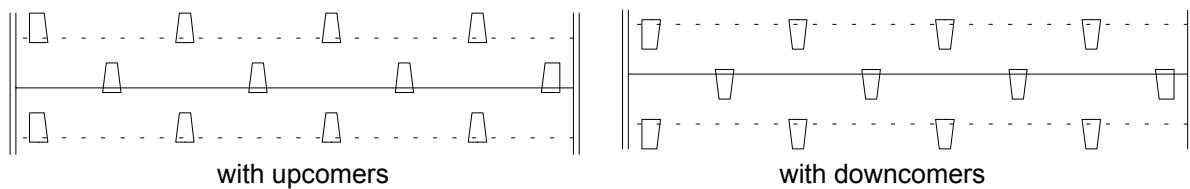

The Shell HiFi Extraction sieve trays combine several features that make them achieve larger capacities when compared with RDCs and conventional sieve trays:

- a) Short flow paths for the continuous phase. This feature reduces the amount of intertray recirculation of the continuous phase and thus allows for more hydraulic capacity without loss of tray efficiency. Large diameter conventional sieve trays are prone to this intertray recirculation of the continuous phase. The typical flow path length of a Shell HiFi extraction tray in the order of 300 to 600 mm which is the same as that tested in pilot columns. This allows for very reliable scale-up of capacity information.

- b) Higher efficiency than RDCs. Trays significantly reduce the amount of axial mixing of both the continuous and dispersed phases when compared to spray columns and RDCs. This leads to higher volumetric efficiency and larger numbers of theoretical stages achieved.
  - c) Better flow distribution and avoidance of high velocity zones. As can be seen from Figures 1, 2 and 3, the Shell HiFi Extraction trays are designed to provide a close approach to pure plug flow of both phases that translate to better capacity and efficiency.

## A NEW APPROACH TO IMPROVE THE SULFOLANE AROMATIC EXTRACTION COLUMN

Weiyang Fei and Xiaoming Wen

Department of Chemical Engineering, Tsinghua University, Beijing, China

Sieve tray columns are widely used for aromatics extraction with sulfolane. However, they suffer from limited mass transfer efficiency due to the very low interfacial tension of the system in the feedstock inlet section and the serious axial mixing inside the column. As an alternative approach to improve column performance, the use of Super Mini Ring (SMR) packing has been investigated. The hydrodynamics and mass transfer of SMR have been studied in the laboratory using a 30% tri-*n*-butylphosphate (kerosene) / acetic acid / water system and in a pilot plant using a real pyrolysis gasoline / sulfolane system. The results show that the mass transfer efficiencies for SMR packing are more than 30% higher than for the sieve trays. A reliable scale-up approach based on the characteristic velocity and diffusion model has been formulated for the retrofit design of an aromatic extraction column that contains SMRs. In a case study, an existing sieve tray extraction column, after being retrofitted with SMR packing, is shown to have significantly improved capacity and mass transfer efficiency characteristics.

### INTRODUCTION

The Sulfolane Extraction Process is widely used because of its ability to produce high purity BTX (benzene, toluene and xylene) products with high recoveries [1,2]. However, technological developments and changing feedstocks have forced many existing units to be retrofitted to meet the demands of higher capacity and aromatic recovery. For example, if the feedstock is changed from the reform liquid to pyrolysis gasoline, the solvent ratio has to be increased significantly to ensure the proper aromatic recovery but the capacity declines.

Most of the extraction columns used for aromatic extraction with sulfolane are sieve tray columns. They have several advantages, such as being simple to manufacture, easy to maintain, and at low cost, etc. However, a commercial operation that uses sieve plates has been shown to suffer from limited mass transfer efficiency problems. The column's tray efficiency was as low as 17% [3]. There is clearly a need for development of new column internals for the Sulfolane Process to increase the mass transfer efficiency and to ensure high aromatics recovery, high capacity and a lower solvent ratio.

The SMR (Super Mini Ring), shown in Figure 1, was developed for liquid-liquid extraction, high-pressure distillation and absorption with high liquid loading at the Tsinghua University in 1989 [4]. The small height/diameter ratio (about 0.3) ensure that most of the rings orient themselves at less than 30° from the horizontal in the columns. They have no flanges and their inner space is divided into 4 spaces by three arc stripes. These features of the packing enhance the dispersion-coalescence recycle, control the non-ideal flow in the packed bed and thus increase column capacity and efficiency. Extensive experiments have shown that

the new packing has superior characteristics for solvent extraction and gas-liquid mass transfer with high liquid loading both in term of capacity and mass transfer efficiency. For example, when the SMR is used for the solvent extraction of low and middle interfacial tension systems, its mass transfer efficiency is much high than those of Intalox Saddle, Pall Ring and Mellapak structure packing while the capacity is almost the same [5]. More than 50 SMR packed columns have been put into operation successfully for lube-oil refining, aromatic separation, waste water treatment, LPG desulfurization, gasoline desulfurization, methanol recovery, deasphalt by propane and so on [6]. The excellent performance of commercial applications has demonstrated the superior characteristics and the reliability of scale up of the SMR.

*Figure 1. SMR packing.*

In this paper the results of laboratory and pilot-plant investigations on the comparative use of SMR packing and sieve trays for the Sulfolane Aromatics Extraction Process are presented. In addition a case study of the retrofitting of an existing sieve-plate column with SMR packing is described.

## EXPERIMENTAL PROCEDURES

### Laboratory Tests

The hydrodynamics and mass transfer of SMRs and sieve trays were tested in the laboratory using a 30% tri-*n*-butylphosphare (TBP) in kerosene / acetic acid / water system. Their physical properties are shown in Table 1. The experimental column had an internal diameter of 100 mm and an effective height of a mass transfer unit of 1000 mm. The geometries of two kinds of SMR packing tested are shown in Table 2. The sieve tray column used had the same geometry as that used in the commercial sulfolane process (Table 3) [7,8].

*Table 1. Physical properties of the system tested.*

	Continuous phase	Dispersed phase
Density (kg/m <sup>3</sup> )	837	997
Viscosity (Pa.s)	0.00172	0.00094
Diffusivity (m <sup>2</sup> /s)	7.8x10-10	1.04x10-9
Interfacial tension (N/m)		0.000929

*Table 2. Properties of the SMR.*

Size (mm)	$\varepsilon$	A ( $m^2/m^3$ )
16	92.3%	348
25	93.6%	228

*Table 3. Properties of sieve-plate extraction column.*

Hole diameter	Free area of holes	Free area of up upcomer	Upcomer height
0.007 m	7 %	10 %	0.055 m

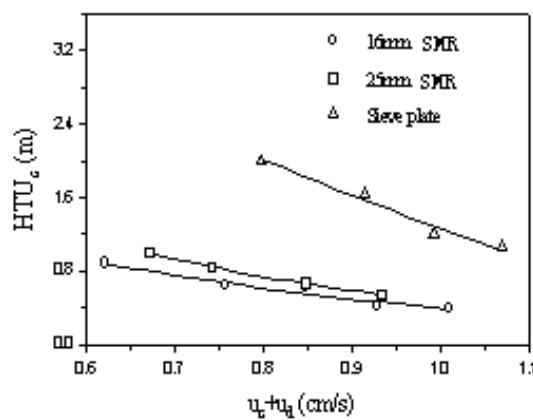

### Pilot-Plant Tests

The pilot-plant tests were carried out in a 150 mm internal diameter column using a real pyrolysis gasoline / sulfolane system. Both the pyrolysis gasoline feedstock and solvent were taken from the commercial units. The 16 mm SMR and the sieve tray with the geometry shown in Table 3 were used in the tests. The working section of the column was 1 m high into which five sieve trays or SMR packing were installed. The distributors for the two phases were appropriately designed for each of the internals. According to the hydrodynamic experiments, the capacities of both kinds of column internals were very high because of the large density difference of the two phases. The special capacities of both internals were more than  $45 \text{ m}^3/\text{m}^2/\text{h}$  and the flooding velocities could not be reached due to the limitations of the pumping systems.

## RESULTS

### Laboratory Tests

Typical results of laboratory mass transfer experiments are shown in Figure 2. It was clear that the HTUs for SMRs were far lower than for the sieve trays, demonstrating the superior mass transfer efficiency of SMRs. When comparing the two kinds of SMRs tested, the smaller the nominal diameter of the SMR, the higher was its mass transfer efficiency.

*Figure 2. Laboratory comparison of SMR and sieve tray performance.*

## Pilot-Plant Tests

The performance of the SMR and sieve tray pilot-plant systems tested is compared in Figure 3. The superiority of SMRs was confirmed for the real system [9,10].

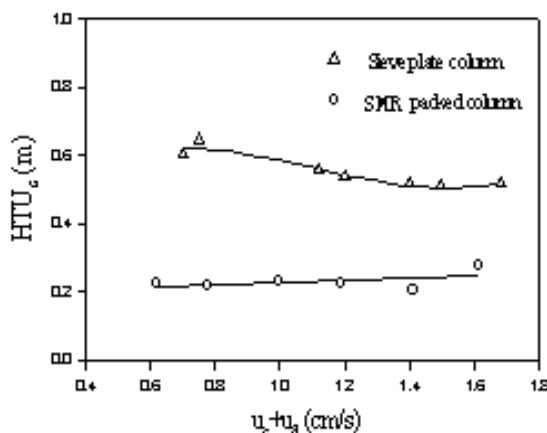

Figure 3. Pilot-plant comparison of SMR and sieve tray columns.

## CASE STUDY

Based on the laboratory and pilot-plant experiments and on previous studies, a reliable scale-up approach of SMR packed column for sulfolane process was worked out. The flooding velocity was calculated from the characteristic velocity and the mass transfer efficiency was estimated according to a diffusion model [11]. This was used to design the retrofit for a commercial sieve-tray extraction column.

### Trouble Shooting

It was shown from a troubleshooting exercise, based on the non-equilibrium stage model, that the main problems of the existing extraction column were as follows [12]:

1. The tray efficiency for the benzene was only 17% while that for C8 and C9 aromatics was much lower. This was because of the significant difference between the diffusivities and drop mass transfer coefficients of benzene, toluene, xylene and C9 aromatics.
2. The flow rates of the two phases varied tremendously along the column. However, the sieve tray geometry was kept the same right through the column. Therefore, many trays were operating in the wrong regime. This was one of the main reasons for the low tray efficiency.
3. The sieve tray number in the extraction section of the column was not enough for the recovery of C8 and C9 aromatics.
4. The nozzle velocities of the feed and solvent distributors were too high, causing emulsions and localized flooding.

### Retrofitting

According to the laboratory and pilot-plant tests, the mass transfer efficiency of the SMRs was more than 30% higher than for sieve trays. Therefore, it was decided to replace 50 sieve trays with SMR packing in the extraction section of the column in order to increase the number of theoretical stages and to thus meet the separation demands. The distributors were redesigned using CAD software to ensure the optimal jet velocity through the nozzles and uniform distribution of drop swarm across the column cross section.

## The Benefits of Retrofitting

The retrofitting exercise was completed successfully. The total aromatic concentration in the raffinate was reduced by more than 6.0 % (from 10% to less than 4 %), while the solvent to feed ratio and the purity of the aromatic products remained the same. The recovery of the aromatics increased significantly and the capacity of the unit increased by 10% after the revamping. It is clear from the simulation that the mass transfer efficiency of the SMR packed extraction is more than 30% higher than that of the traditional sieve tray column [12,13]. The total economic benefit of the revamp is US\$ 700,000 per year with an investment recovery period of less than three months [14].

## CONCLUSION

1. It is shown from the comparison of SMR packing and sieve trays, using 30% TBP (kerosene) / acetic acid / water system that the mass transfer efficiency of the SMR is much higher than that of the sieve tray.
2. The pilot-plant tests using real pyrolysis gasoline / sulfolane system have demonstrated the superior characteristics of SMR packing.
3. The revamping of an existed aromatic extraction column by replacing 50 sieve trays with SMR packing in the extraction section was completed successfully. The economic benefit is significant and the simulation results of the commercial column have confirmed the advantage of the SMR packed extraction column.

## ACKNOWLEDGEMENTS

This work was completed in the Solvent Extraction Laboratory, State Key Laboratory of Chemical Engineering (China), and was supported by the Nature Science Foundation of China who is gratefully acknowledged.

## NON-EQUILIBRIUM STAGE MODELLING OF LUBE EXTRACTION PROCESSES

A. K. Jain, P. K. Sen and S. J. Chopra

Research and Development Division, Engineers India Limited, Gurgaon, India

A non-equilibrium stage model has been developed to simulate the lube extraction column using *n*-methyl-2-pyrrolidone as solvent. The equilibrium constants and overall mass transfer coefficients are estimated at each cell for each component. The complex feed to the column was characterised in terms of pseudo components representing each hydrocarbon class. The model provides the detailed flow and composition profile along the column and can be used to analyze data from pilot-plant or bench-scale columns. The model along with a regression method can also be used to determine mass transfer coefficients and back mixing coefficients for carrying out scale up to commercial scale extraction column.

### INTRODUCTION

Solvent extraction of raw lube distillates to manufacture base oils for lubricant formulation continues to be an integral step in the conventional process sequence. The straight run lube oil fractions and deasphalted oil contain naturally occurring unstable lower viscosity index constituents such as condensed aromatics and other polar components. Solvent extraction partially removes these components and improves viscosity index, oxidation stability, colour and oxidation inhibitor response. The present day solvent for the purpose is *n*-methyl-2-pyrrolidone (NMP).

The lube extraction units are operated in blocked-out mode with different vacuum distillate cuts and deasphalted oil as feed. Each feedstock requires specific extraction operating conditions like solvent-to-oil ratios, solvent-water content, etc., to maximise throughput and raffinate yield. Multistage simulation models based on the equilibrium stage concept accomplish the detailed design of extraction columns. Normally, five to eight theoretical stages are required to achieve the desired separation. Packed extraction columns filled with modern random packings are now well proven in this service. The design is preceded by detailed laboratory and bench-scale column studies with individual feedstocks to evaluate the extraction performance against different process variables. Due to the complex nature of feedstocks, the end composition of the phases from single-stage and multi-stage experimental runs is rarely available and performance is evaluated based on the physical characteristics of the products.

The evaluation of bench-scale column data is a critical step in the process development. The simulation of bench-scale data with conventional models based on equilibrium concepts is of limited success since fractional stages cannot be simulated and detailed behaviour of components as they flow along the column is not estimated. To overcome these limitations, a non-equilibrium stage model has been developed for lube extraction process and is presented in this paper.

The non-equilibrium stage model concepts are now well established. Krishnamurthy [1] developed the detailed generalized model for simulation of a counter-current multi-component distillation column. Commercial simulators like Aspen have also incorporated non-equilibrium module 'RATEFRAC' for distillation processes. For liquid-liquid extraction processes, the non-equilibrium models are also available [2-6]. In this work, the calculation method proposed by Spencer [4] was selected for the development of a model for the lube extraction process.

## THE APPROACH

The feed to the solvent-extraction process is characterised in terms of the pseudo components, *i.e.*, paraffins, naphthene and aromatic compounds which are assigned carbon and hydrogen numbers. This characterisation is based on the prediction of experimentally determined liquid-liquid equilibrium data using the UNIFAC group contribution model and feed physicochemical characteristics like distillation, detailed Z-no analysis and specific gravity. The model compounds are defined in terms of UNIFAC groups, such as CH<sub>3</sub>–, CH<sub>2</sub>–, ACH–, etc., that are then used for carrying out non-equilibrium multi-stage extraction computations. The packed extraction column is divided into an arbitrary number of cells. The mass transfer coefficients were estimated from the correlations available in literature. Isothermal operation of the liquid-liquid extraction process is assumed so that the enthalpy balance equations and other associated variables can be eliminated from the calculations.

The cell back mixing model with mass transfer rate approach of a counter-current extractor is shown schematically in Figure 1. Solvent and hydrocarbon feed phases are assumed to enter stages 1 and N respectively. Back mixing between cells k and k+1 is represented by  $f^{k+1}U^{k+1}$  for the hydrocarbon phase and rate g<sup>k</sup>. V<sup>k</sup> represents the extract or solvent phase. f<sup>k</sup> and g<sup>k</sup> are back mixing coefficients of individual flow rates U<sup>k</sup> (raffinate phase flow) and V<sup>k</sup> (extract phase flow). The mass transfer direction is from raffinate to extract phase while the mass transfer rate r<sub>j</sub><sup>k</sup>, in mass flow unit is expressed as

$$r_j^k = K_j^k (m_j^k x_j^k - y_j^k) \quad (1)$$

where, K<sub>j</sub><sup>k</sup>, the overall mass transfer coefficient for the j<sup>th</sup> species, is the product of the conventional mass transfer coefficient, the interfacial area and mass of each cell. The equilibrium constant, m<sub>j</sub><sup>k</sup> is estimated from the UNIFAC group contribution model with pseudo components. It has been observed that the equilibrium constants can be defined as a function of the solvent composition in the extract phase (Figure 2). The following function was found to mimic the behaviour accurately.

$$\ln m_j^k = a_j + \frac{b_j}{s^k} + c_j s^k + d_j (s^k)^2 \quad (2)$$

where, s<sup>k</sup> is mole fraction of solvent in extract phase at cell k. a<sub>j</sub>, b<sub>j</sub>, c<sub>j</sub>, and d<sub>j</sub> are constants regressed for each component from equilibrium values calculated from UNIFAC. The incorporation of this equation makes the model efficient.

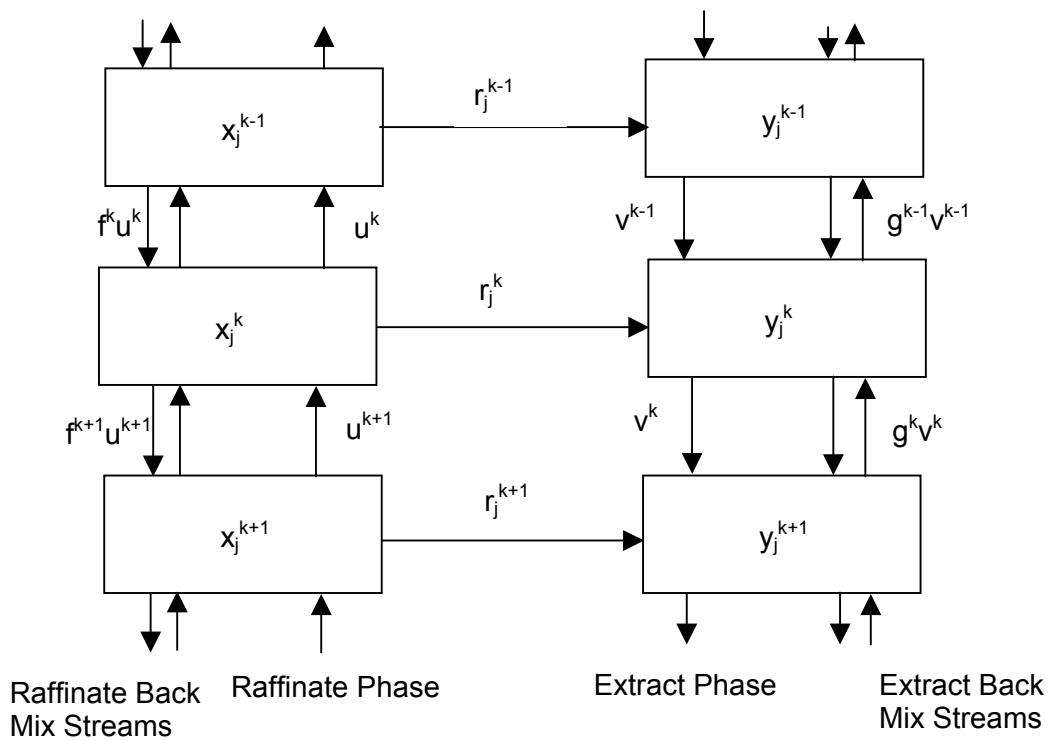

Figure 1. Non-equilibrium model with cell back mixing representation.

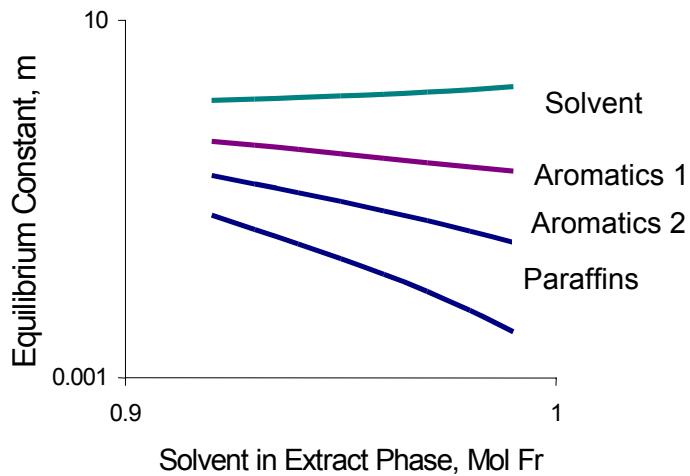

Figure 2. Equilibrium constants as function of solvent composition in extract phase.

Mass balance equations for raffinate phase and extract phase were developed separately for each component at each cell except paraffin components in the extract phase and solvent components in the raffinate phase. For cell k and component j, the mass balance in the raffinate phase is

$$f^k U^k x_j^{k-1} - (1+f^k)U^k x_j^k - f^{k+1}U^{k+1}x_j^k - r_j^k + (1+f^{k+1})U^{k+1}x_j^{k+1} = 0 \quad (3)$$

For the extract phase, the mass balance for component j in cell k is

$$(1+g^{k-1})V^{k-1}y_j^{k-1} - (1+g^k)V^k y_j^k - g^{k-1}V^{k-1}y_j^k + r_j^k + g^k V^k y_j^{k+1} = 0 \quad (4)$$

The overall balance for the k<sup>th</sup> cell, raffinate phase is

$$U^k = U^{k+1} - \sum_{j=1}^C r_j^k \quad (5)$$

and for the extract phase is

$$V^k = V^{k-1} + \sum_{j=1}^C r_j^k \quad (6)$$

These are 2NC independent nonlinear algebraic equations, which determine the 2NC variables, represented by U<sup>k</sup>, V<sup>k</sup> and 2N(C-1) composition vector.

The generalized equation in matrix form for 2(C-1) components in the extract and raffinate phases for the k<sup>th</sup> stage can be expressed as

$$A^k W^{k+1} + (B^k + R^k)W^k + C^k W^{k+1} = a^k \quad (7)$$

where A<sup>k</sup>, B<sup>k</sup>, R<sup>k</sup> and C<sup>k</sup> are 2(C-1)\*2(C-1) matrices, W<sup>k</sup> are 2(C-1) composition matrices for both phases and a<sup>k</sup> is a 2(C-1) dimensional vector. It may be noted that A and C are diagonal matrices. The set of equations described above can be solved using the Thomas algorithm [7] in conjunction with a Gaussian reduction. The developed extraction model incorporates the back mixed flow as well as the true mass transfer coefficient. Thus it can be used directly to evaluate the actual number of stages for staged counter-current extractors. For differential contactors, which is the current application, the number of stages called cells are chosen arbitrarily and mass transfer rates are estimated for each cell, thus, providing detailed composition and flow profiles.

## APPLICATION OF THE MODEL TO LUBE EXTRACTION

One of the refineries located in the Eastern part of India is processing a vacuum distillate, known as "wide cut" in an extraction unit to produce high waxy raffinate. The unit is being revamped to NMP solvent from present highly toxic phenol solvent. The feed characteristics of the vacuum distillate [8] are provided in Table 1.

*Table 1. Feed analysis of vacuum distillate obtained from Indian Eastern Region crude.*

Parameter	Value
Density @ 15 C, g/ml	0.9313
Kinematics viscosity, cst @ 100 C	9.54
Saturates, % wt	50.9
Aromatics, % wt	49.1
ASTM D 1160, Deg C	
IBP/ 50% / EP	315/ 430/ 505

The estimation of pseudo components (Table 2) is based on the prediction of experimentally determined liquid-liquid equilibrium data as explained in the previous section.

*Table 2. Characterisation of vacuum distillate obtained from Eastern Sector Region.*

Component	Wt%	Z No	UNIFAC groups
Paraffins	21.07	2	CH3-1, CH2-29
Naphthenes	29.07	-4	CH2-16, CH-1, CH2r-12, CHr-3
Monoaromatic	20.55	-10	CH2-12, CH-1, CH2r-10, CHr-2, ACH-5, AC-1
Diaromatics	15.07	-24	CH2-1, CH2r-6, CHr-1, ACH-9, AC-5
Polyaromatics	14.24	-30	CH2-1, CH2r-6, CHr-1, ACH-11, AC-7

The details of experimental studies carried out for extraction column design are provided elsewhere [9]. Table 3 provides the experimental data generated in a glass-packed column with the above feed at a solvent-to-feed ratio close to 1.0 (by volume) and compares these data with the results obtained from the present non-equilibrium model. For calculation purposes, the column was divided in 10 cells of equal volume. The back-mixing coefficients were ignored since velocities of both phases were on the lower side. The diffusivity for estimating the mass transfer coefficients was estimated based on the group contribution model of Fei [10]. The continuous phase and dispersed phase mass transfer coefficients were estimated with Seibert [11] Model. The composition profile so obtained, could not be validated, as the experimental profile is not available. However, end properties agree well with the measured values.

*Table 3. Comparison of model results with laboratory scale experimental data.*

Parameter	Experimental	Predicted with model
Solvent in extract phase, wt%	71.7	71.8
Raffinate yield, wt%	64.4	62.4
Raffinate Density @15C, g/ml	0.8781	0.8782

Figure 3 shows the column profiles for mono aromatics (long chain alkyl aromatics) and condensed aromatics along the column. While condensed aromatics in the raffinate continue to decrease as they go up, mono aromatics behave differently. Mono aromatics being the desired component in lube due to their high viscosity index characteristics, needs to be maximized in the raffinate. These mono aromatics reach their maximum composition in the raffinate at close to the upper end of the column and then decrease slightly. Packing above this height is required for reducing condensed aromatics to meet product specification.

The model developed for lube extraction can also be used to estimate mass transfer coefficients from bench-scale or pilot-scale data [12]. For this purpose, a non-linear regression technique is incorporated in the model. These coefficients can then be used for scale up/trouble shooting of commercial-size columns.

## CONCLUSIONS

A non-equilibrium stage model has been developed and is applied to the lube extraction process. The model provides detailed composition and flow profile along the length of the column, which helps in better understanding the column performance. The model is especially useful for analyzing the bench-scale extraction column data where equilibrium model simulates the performance with fractional stages.

## SELECTIVE RECOVERY OF ALDEHYDES AND KETONES FROM HYDROCARBON MIXTURES BY REACTIVE EXTRACTION WITH AQUEOUS SALT SOLUTIONS

Boris Kuzmanović, Rimon Jallo, Norbert JM. Kuipers, André B.de Haan, Gerard Kwant\*

University of Twente, Enschede, The Netherlands

\*DSM Research, Geleen, The Netherlands

Reactive extraction of carbonyl compounds (aldehydes, ketones) from hydrocarbon mixtures applying aqueous solutions of several amino and bisulfite salts was studied. Results obtained for hydrazone formation salts and sodium bisulfite show an increase of distribution ratio of benzaldehyde of up to 1000 times. For Schiff base formation salts the exhibited increase of the distribution ratio compared to the no-salt conditions is up to 50 times. The regeneration of chemically extracted aldehyde by a simple temperature shift was also considered. The Schiff base formation salts showed a change of the distribution ratio of up to 3 times when increasing the temperature from 25°C to 75°C. For other salts the influence of temperature was weaker.

### INTRODUCTION

Aldehydes and ketones are often present in relatively small concentrations in organic solutions from which they should be recovered. Very common industrial examples are the hydrocarbon oxidation processes, in which carbonyl compounds are present as solutes in an apolar hydrocarbon solvent (toluene, cyclohexane or p-xylene oxidation processes [1]). Although large amounts of energy are required for evaporation of the solvent, the most commonly applied methods for the recovery of a carbonyl compound from such systems are still based on distillation [2]. Other options are reported, for example use of ion-exchange membranes [3], adsorption or absorption on a polymeric reagent [4] or electrophoresis [5], but industrial applications are rare.

The low concentrations of an aldehyde or a ketone and the difference in chemical structure of a carbonyl and the solvent justify the consideration of extraction technology for the recovery of carbonyls. In the case when large amounts of solvent are evaporated in distillation process, the superiority of extraction compared to the distillation in respect to the energy efficiency is obvious. On the other hand, the use of common organic extraction solvents that would be adequate for extraction of carbonyls is usually not acceptable when carbonyls are going to be applied in the food or pharmaceutical industry. An alternative is to use water as a solvent. Concerning its immiscibility with apolar organic solvents, its environmental acceptability and the fact that does not cause contamination of the system since it is generated in the oxidation process this seems to be a feasible option. Nevertheless, its potential as a pure solvent is limited due to the poor capacity and selectivity towards the most of the carbonyl products.

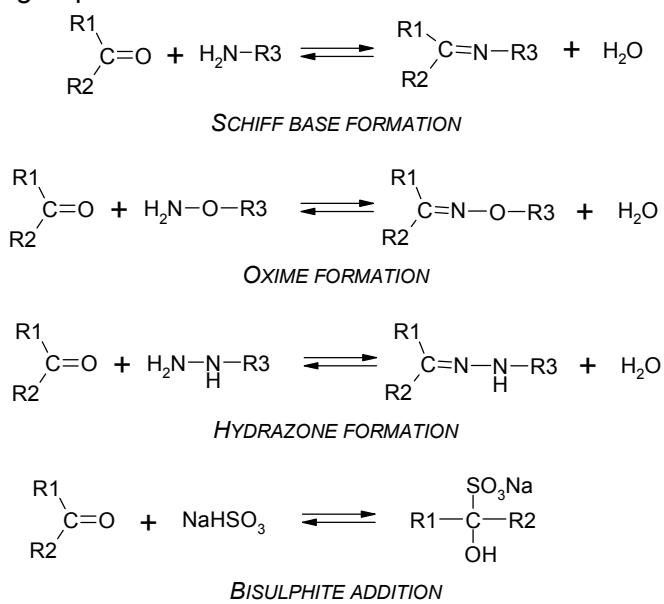

To overcome these disadvantages an environmentally benign modifier that can significantly and selectively improve solubility of carbonyl in water without contaminating the organic solution can be used. An option to satisfy those requirements is to introduce a charged compound in water, which will be able to complex or react with carbonyl product selectively, producing another charged species. Being charged, *i.e.*, salt generally implies good solubility in water and insolubility in apolar organic media. Furthermore, the environmental acceptability of the compound has to be satisfied. Hence, the aqueous solutions containing appropriate salts as extractants can be a feasible option for the recovery of carbonyl compounds from the apolar hydrocarbon mixtures.

To prove technical feasibility of the proposed principle we considered the recovery of benzaldehyde from toluene solution, as a typical industrial case of carbonyl compound present in apolar organic solvent.

## EXTRACTION OF CARBONYLS WITH AQUEOUS SALT SOLUTIONS

### Characteristic Reactions of Carbonyl Compounds

Several reversible chemical reactions are evaluated for use in the reactive extraction of aldehydes or ketones using aqueous salt solutions. All reactions are based on the nucleophilic addition mechanism that is highly characteristic for carbonyl groups. Condensation of carbonyl compounds with nitrogen bases, *i.e.*, Schiff base formation, hydrazone formation and oxime formation, as well as bisulfite addition (Figure 1), are typical examples [6]. For our purpose, the reactant has to be a salt, *i.e.*, R3 in Figure 1 has to be a charged hydrocarbon group.

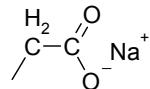

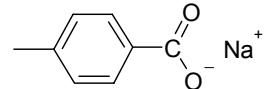

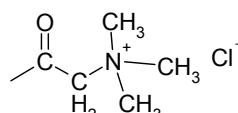

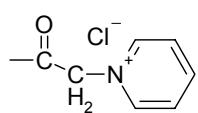

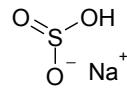

*Figure 1. Reactions characteristic for carbonyl compounds [6, 7].*

### Evaluated Salt Solutions

Several suitable and commercially available amino and bisulfite salts are evaluated experimentally. These are listed in Table 1. To investigate the influence of the structure of the R3 hydrocarbon group, both, an aromatic and an aliphatic group for Schiff base formation salt, as well as for hydrazone formation salt, were considered. Salts able to perform oxime formation with a carbonyl are not evaluated up till now because the oxime formation reaction is considered comparable to the hydrazone formation. The assumption on comparability is based on similar characteristics of the oxygen (oxime) and nitrogen (hydrazone) atom that are bonded to the primary amino group, as well as on the findings given in [6]. Hence, the results obtained for hydrazone are expected to be indicative for oxime as well.

Table 1. Salts evaluated as carbonyl compound extractants.

	Aliphatic R3	Aromatic R3
Schiff base formation salt ( $\text{H}_2\text{N}-\text{R}3$ )	Sodium glycine: 	Sodium p-aminobenzoate: 
Hydrazone formation salt ( $\text{H}_2\text{N}-\overset{\text{H}}{\underset{\text{N}}{\text{N}}}-\text{R}3$ )	Carbazoylmethyl-trimethylammonium chloride (Girard T): 	1-(carbazoylmethyl)pyridinium chloride (Girard P): 
Bisulfite adduct formation salt	Sodium bisulfite: 	

### Definition of the Evaluated Extraction Parameters

The distribution ratio of a component  $i$  ( $D_i$ ) is defined as the ratio of its equilibrium concentrations in the aqueous and organic phase. When the chemically modified form is a charged molecule, its concentration in the apolar organic phase is negligible and the distribution ratio can be defined as:

$$D_i = \frac{c_i^{\text{aq}} + c_{i^*}^{\text{aq}}}{c_i^{\text{org}}} = (K_D)_i + \frac{c_{i^*}^{\text{aq}}}{c_i^{\text{org}}} \quad (1)$$

$c_i$  represents the concentration of original component and  $c_{i^*}$  the concentration of  $i$  in its chemically modified form. The distribution constant  $(K_D)_i$  represents the physical distribution in the aqueous/organic system. The separation factor ( $\alpha_{A,B}$ ) is the ratio of the distribution ratios of two components, A and B:

$$\alpha_{A,B} = \frac{D_A}{D_B} \quad (2)$$

### EXPERIMENTAL PROCEDURE

Benzaldehyde (purity 99%), toluene (purity 99%), Girard P (purity 98%), Girard T (purity 99%) and sodium bisulfite (39% solution in water) were supplied by Merck, Germany and sodium glycine (purity 99%) and sodium p-aminobenzoate (purity 99%), by Acros Organics, Belgium. The chemicals were used as received.

As mentioned before, the principle of reactive extraction of carbonyls with aqueous salt solutions was evaluated on a single solute hydrocarbon solution. A solution of benzaldehyde in toluene was used as the model system. The initial concentration of benzaldehyde in the solution was 1.5 wt% in all experiments. This concentration of benzaldehyde is typical for the industrial toluene oxidation process in combined production with other products [11]. Aqueous salt solutions were prepared by dissolving a salt in demineralised water in the whole range of its solubility in water.

The experiments were performed in 100 ml jacketed glass vessels. Equal volumes (40 ml) of organic and aqueous salt solutions were introduced in the thermostated ( $\pm 0.04^\circ\text{C}$  at  $30^\circ\text{C}$ ) vessel, stirred vigorously for 30 minutes and left to settle for 1.5 hours that phase splitting and equilibrium can occur. By monitoring concentration change in time, it was found that in the system when no salt was present the equilibrium is reached in less than 30 minutes. When sodium glycine salt solution is contacted with the organic solution, concentrations reached their equilibrium values after settling of approximately 90 minutes. Furthermore, it is reported that reaction equilibrium in case of bisulfite adduct formation is reached in not more than 5 minutes [7], for hydrazone formation a period of not longer than 2 hours is required (for benzaldehyde itself), while for Schiff base formation with benzaldehyde it takes one hour [7]. Considering all these facts, a contact time of 2 hours (30 minutes mixing and 1.5 hours settling) is adopted as sufficient. For the experiments with sodium p-aminobenzoate, the vessels were covered with aluminium foil to prevent decomposition to aniline and benzoate, which would take place during exposure to light.

Samples of both phases were taken through side sampling ports. The samples were dissolved in ethanol to prevent possible phase splitting due to a temperature difference between experimental and sampling vessel. In case of ethanol-insoluble salts, the dissolution was done by water. The samples were analysed by HPLC, using dibenzofuran as an internal standard or resorcinol for water diluted samples. By analysing a sample of known concentration of benzaldehyde for 15 times, it has been determined that the deviation of the arithmetic mean value of measurements from the true value was 1.8%, with a maximum of around 6%. The repeatability of the analysis, quantified by the relative standard deviation in percentage (coefficient of variation), was just above 2%.

## RESULTS AND DISCUSSION

### Distribution Ratio and Selectivity

Figure 2 presents the distribution ratios for the analysed salt extractants, as a function of the initial salt concentration ( $C_s^0$ ) in the aqueous solution. At the higher salt concentrations, Girard P, Girard T and sodium bisulfite increased the benzaldehyde distribution ratio approximately 1000 times comparing to the no-salt conditions. Under the same conditions, an increase of 10 to 20 times for sodium glycine and sodium p-aminobenzoate was found.

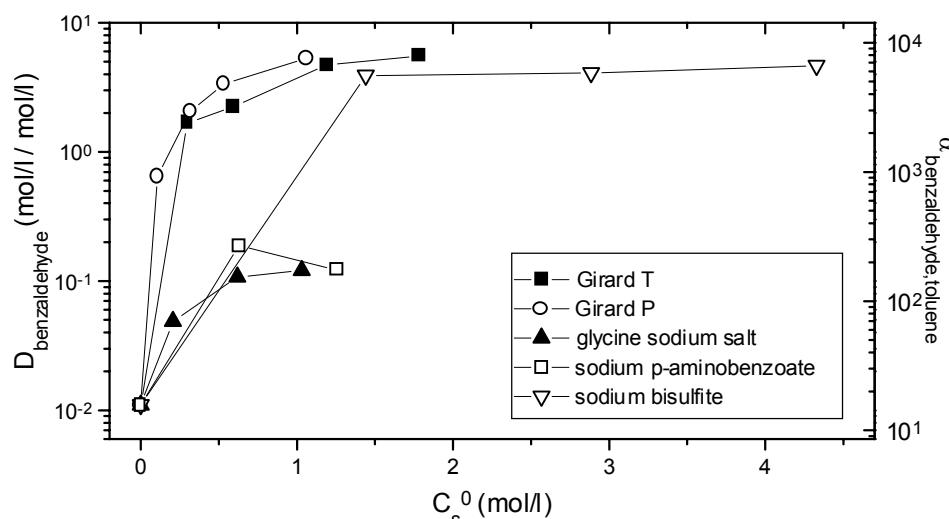

Figure 2. Distribution ratio of benzaldehyde and selectivity compared to toluene as a function of initial salt concentration in the aqueous phase ( $25^\circ\text{C}$ ).

The significant difference in distribution ratios of Schiff base and hydrazone formation salts, although the mechanisms of reactions are very similar, can be explained by the fact that the condensation reaction, in comparison with the reverse, hydrolysis reaction is much more favourable in the case of hydrazones than in the case of Schiff bases [6, 8]. For example, results given in [8] indicate that the equilibrium constant for acetone in a hydrazone formation reaction is 20 times higher than for Schiff base formation at the same conditions.

In the case of nitrogen bases (Schiff base or hydrazone formation) the reaction mechanism involves nucleophilic addition followed by elimination of water, while only an addition step is involved in the reaction of bisulfite. Since bisulfite addition does not involve water elimination, good extraction performance of sodium bisulfite in the aqueous system may be expected.

No strong influence of the structure of the hydrocarbon group R<sub>3</sub> was noticed. As a confirmation of this finding, the values of equilibrium constants (yields) given in [9] for the same carbonyl compound, but different primary amine, can be mentioned. Certain differences exist, but no systematic dependence could be established.

The selectivity of the extraction solvent towards benzaldehyde compared to toluene ( $\alpha_{\text{benzaldehyde}, \text{toluene}}$ ) is also shown in Figure 2. A 1000 fold increase, from around 10 for no-salt conditions up to the values of around 10000 for higher salt concentration of Girard T, Girard P or sodium bisulfite, was achieved. A salting-out effect of the salts on the toluene distribution was noticed, but since it was minor comparing to the influence on the distribution of benzaldehyde, its influence on the selectivity is neglected.

### **Regeneration of Chemically Modified Carbonyl by Temperature Shift**

Although different methods for regeneration of modified carbonyl compounds back to its original form are reported in the literature, regeneration by a simple temperature shift would be the most convenient for a large-scale industrial application. The use of a pH shift [8, 7] as commonly done in organic chemistry or microwave irradiation [10] can be mentioned as interesting alternatives. A temperature shift does not involve introduction of any contaminant, as required for a pH shift, and could be performed with the most common process equipment. Hence, the influence of the temperature on the distribution of benzaldehyde between aqueous and organic phase was investigated.

Figure 3 shows the distribution ratio as function of the initial salt concentration ( $C_s^0$ ) at temperatures of 25°C and 75°C. For both Schiff base formation salts noticeable differences in the distribution ratio exist for different temperatures, while for hydrazone formation salts or bisulfite such differences are small.

## **CONCLUSIONS**

Aqueous solutions of hydrazone formation and bisulfite salts show good extraction capacity for extraction of aldehydes present in the small concentrations in an apolar organic solvent. Schiff base formation salt solutions exhibit a much poorer performance due to lower values of the reaction equilibrium constants. On the other hand, reconversion of the chemically extracted aldehyde by a temperature shift is feasible for the Schiff base formation salt solutions, but not for the other two cases. Other options of reconversion, like pH shift for example, should be considered.

Although the extraction behaviour of oxime formation salt solutions is considered to be very similar with the hydrazone case, their performance should be evaluated experimentally. Extraction of other carbonyl compounds should be undertaken to generalise conclusions about the application of analysed aqueous salt solutions for the recovery of aldehydes and ketones.

# EXTRACTION OF SULPHONATED TRIPHENYLPHOSPHINES FROM OLEUM AND SEPARATION OF REAGENTS FROM HYDROFORMYLATION OF HEXENE CARRIED OUT IN MICROEMULSION

Ireneusz Miesiac, Wilhelm Tic\*, Anna Sobczynska and Jan Szymanowski

Institute of Chemical Technology and Engineering, Poznan University of Technology,

\*Institute of Heavy Organic Synthesis, Kedzierzyn-Kozle, Poland

Sulphonated triphenylphosphines used for the manufacture of the hydrophilic rhodium-based catalysts are separated from excess oleum by extraction with tributyl phosphate. Sodium salts of mono-, di- and trisulphonated triphenylphosphines could be then recovered as precipitates and further separated by crystallisation. The extraction gave separated phosphines with higher purity (by 5-10%) and yield (by 3-6%) than the direct crystallisation from different solvents. The conditions for the formation and separation of microemulsion in six component system, containing water, sodium tri(m-sulphophenyl)phosphine (Na-TPPTS), hydridocarbonyl tris[sodium tri(m-sulphophenyl)phosphine]rhodium, hexene or heptanal, sodium dodecylsulphate (SDS) and butanol, were elaborated.

## INTRODUCTION

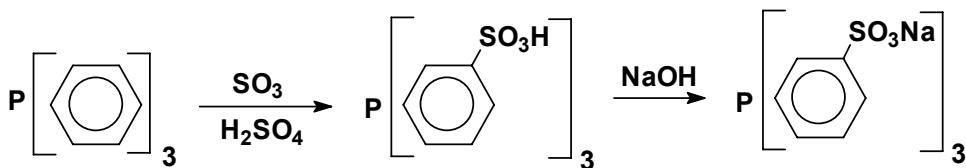

The hydroformylation of olefins, including propylene, is an important industrial process used to synthesise various alcohols and aldehydes. The synthesis is usually carried out using rhodium type catalysts dissolved in the reaction medium. The products are separated by distillation [1]. The use of water-soluble rhodium-based complexes allows the hydroformylation of olefins to be carried out in an aqueous-organic system. Hydroformylation can be also carried out in microemulsion [2].

Water solubility of the catalytic complexes can be obtained when sulphonated triarylphosphines are used both for the preparation of the rhodium-based complexes and as the free ligand present in an excess in the reaction system [3, 4]. Among the water-soluble phosphines, hydrophilic trisodium salt of tri(m-sulphophenyl)phosphine (NaTPPTS) is advantageous as a modifying ligand. The sulphonation of triphenylphosphine gives mono-, di- and trisulphonated derivatives which are usually separated by crystallisation.

The aim of this work was i) to use solvent extraction to separate sulphonated triphenylphosphines from the post-reaction mixture containing concentrated sulphuric acid, ii) to separate mono-, di- and triderivatives and iii) to formulate microemulsion suitable to carry out hydroformylation of hexene and to separate into two phases with the extraction of the products to the organic phase.

## EXTRACTION OF SULPHONATED TRIPHENYLPHOSPHINES FROM OLEUM

Triphenylphosphine was first dissolved in concentrated sulphuric acid and then treated with oleum, containing 60% free sulphur trioxide, at temperature below 15°C under argon atmosphere. The sulphonation occurred at 3 position of the phenyl ring giving subsequently derivatives containing 1, 2 and 3 sulphonyl groups.

Both sulphonated phosphines and sulphuric acid could be extracted with solvating and basic extractants, including tributyl phosphate, trialkylphosphine oxides (CYANEX reagents) and trialkylamines (ALAMINE reagents). The use of trialkylphosphine oxides was disregarded because compounds containing phosphorus(V) could be introduced as undesirable impurities in NaTPPDS and NaTPPTS. Some separation problems (hazy phases and/or formation of emulsion) are also observed with these extractants. Trialkylamines were protonated with sulphuric acid and strongly extracted mineral acids, even above typical mole ratio. They had to be used in a hydrocarbon diluent and an addition of the hydrophobic modifier was necessary to avoid the formation of stable emulsions. As a result, the use of tributyl phosphate (TBP) was selected. Undiluted TBP without any solvent and modifier was used. However, this reagent underwent slow hydrolysis giving butanol and di- and monoesters. The negative effect of this process on the purity of Na TPPDS and NaTPPTS was not observed.

Sulphonated phosphines were less hydrophilic than sulphuric acid and their extraction with TBP was preferred. The distribution coefficient, calculated as the ratio of P<sup>3+</sup> content in the TBP phase and sulphuric acid phase, amounted to nearly 30 for SO<sub>3</sub>/TPP ratio corresponding to 10-15 mol/mol (Table 1). It meant that about 97% of sulphonated phosphines was transferred to the TBP phase. However, the distribution coefficient decreased to 0.75 for a SO<sub>3</sub>/TPP ratio = 35 mol/mol, indicating that the extraction of sulphuric acid instead of sulphonated phosphines occurred. A high value of the distribution coefficient was obtained for an SO<sub>3</sub>/TPP ratio equal to 5 mol/mol, but this ratio did not permit high yields of the desired di- and tri sulphonated phosphines to be obtained. Actually sulphonated phosphines were extracted twice, each time with new portions of TBP using 80 ml TBP per 12 g of triphenylphosphine used for sulphonation.

*Table 1. Extraction of sulphonated triphenylphosphine with undiluted tributyl phosphate.*

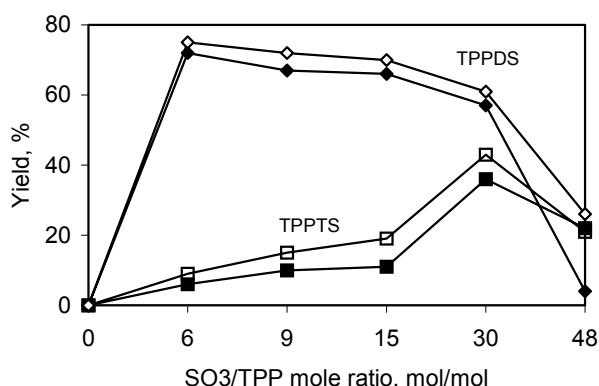

SO <sub>3</sub> /TPP ratio (mol/mol)	SO <sub>3</sub> content (%)	P <sup>3+</sup> content (%)		Distribution coefficient*
		TBP phase	Sulphuric acid phase	
5	5	0.920	0.00	high
10	10	0.900	0.030	30.0
15	15	0.950	0.035	27.1
25	20	0.485	0.088	5.5
35	25	0.220	0.220	0.75

\*calculated as the ratio of phosphorus(III) content.

Stripping of the sulphonated phosphines was achieved by washing TBP phase with 50% NaOH. Sulphonated phosphines precipitated as sodium salts (equilibrium pH of the aqueous phase = 11). It was also possible to precipitate both sodium sulphate and sodium salts of sulphonated phosphines. Sodium sulphate was then separated from phosphines by the dissolution of the precipitate in water and the precipitation of the inorganic salt with methanol.

The sodium salt of diphenyl(m-sulphophenyl)phosphine (NaTPPMS) was isolated with a low yield of 5% up to the SO<sub>3</sub>/TPP ratio equal to 6 mol/mol. No important difference between crystallisation and solvent extraction-crystallisation was observed. The chemical purity calculated as the ratio P<sup>3+</sup>/P<sub>total</sub>, was estimated as high as 94 and 96.5% for crystallisation and extraction-crystallisation, respectively. Products of the higher sulphonation degree were not isolated from such mixture.

At the SO<sub>3</sub>/TPP ratio above 6 mol/mol, sodium salts of both phenyl(di(m-sulphophenyl))phosphine (NaTPPDS) and tri(m-sulphophenyl)phosphine (NaTPPTS) were isolated. The maximum yield of NaTPPDS was about 70% and 75% for crystallisation and extraction-crystallisation procedure, respectively at the SO<sub>3</sub>/TPP ratio equal to 6 mol/mol and it monotonously decreased to 4% at the SO<sub>3</sub>/TPP ratio equal to 48 mol/mol. The yield of the separated NaTPPTS increased from 5 to 33 and 43% % for crystallisation and extraction-crystallisation procedure, respectively, when the SO<sub>3</sub>/TPP ratio increased from 6 to 30 mol/mol. However, at higher SO<sub>3</sub>/TPP ratio the post-reaction mixture became brown and lower amounts of sulphonated phenylphosphines (about 5 and 20% of NaTPPDS and NaTPPTS ) were separated.

*Figure 1. Effect of the SO<sub>3</sub>/TPP ratio on the yield of the separated sodium salts of phenyl(di(m-sulphophenyl))phosphine (NaTPPDS) and tri(m-sulphophenyl)phosphine (NaTPPTS) (crystallisation technique, time of sulphonation 20 h, full and empty symbols denote crystallisation and extraction-crystallisation, respectively).*

Besides higher yields the products isolated by extraction had the purity higher by about 5% in respect to those isolated only by crystallisation. Thus, the undesired oxidation of phosphines to phosphine oxides was significantly retarded.

## FORMATION OF MICROEMULSION

Two phase hydrocarbon-water system exhibited a high interfacial tension, e.g., 51.2 and 50.8 mN m<sup>-1</sup> for hexene and hexane, respectively. An addition of sodium dodecylsulphate to the aqueous phase permitted to decrease the interfacial tension only to few mN m<sup>-1</sup> and typical emulsions could be formed. An addition of butanol up to 25% had relatively a small effect on the interfacial tension although some decrease of the interfacial tension was observed. Ultralow values, characteristic for microemulsions, were first observed for systems containing

above 25% butanol and above 7% SDS. They varied in the range of few  $\mu\text{N m}^{-1}$ . Only in the case of 2-ethylhexanol higher values of the interfacial tension were registered. 60-120 minutes were necessary to achieve these low values. The interfacial tension changed in the order: heptanal < hexane < hexene < 2-ethylhexanol. Somewhat lower values were observed at 50°C in comparison to those registered at 20°C.

The solubilisation of hexene in the aqueous phase depended both on the content of butanol and SDS (Figure 2). The concentration of SDS in the aqueous phase should exceed 7% to make the butanol containing solution homogeneous. The solubility of hexene in pure water was negligible, while the solubility of butanol amounted to 6.4% at 20°C. Thus, an addition of surfactant was needed to obtain homogeneous solutions. A further solubilisation of hexene was very specifically related to butanol content. In the range of 10-40% butanol in the aqueous phase, solubilisation increased monotonically with increased SDS concentration and also with increased butanol content. In the range of 43-47% butanol in the aqueous phase, the hexene solubilisation increased very slowly with SDS concentration up to 18-21 g SDS/100 g of the aqueous phase. In such system an abrupt increase of solubilisation was observed up to the values over 130-150 g/100 g of the aqueous phase. The formed transparent system, as being a true bicontinuous microemulsion, accepted not only large quantities of hexene, but also small quantities of water, without any phase separation. It was interesting to note that the solubilisation was not observed for aqueous solutions containing 50% of butanol, even for a high SDS concentration of 26 g/100 g aqueous phase. It meant that the bicontinuous microemulsion region was strictly limited to butanol content of 43-47%.

The solubilisation efficiency of the examined system depended on the polarity of solubilised species and the content of sodium tri(m-sulphophenyl)phosphine (Figure 3). The following order of solubilisation was observed: hexane > hexene > heptanal = benzene. 16-18% and 25% SDS were needed to solubilize nonpolar hydrocarbons and polar heptanal and benzene, respectively. An addition of sodium tri(m-sulphophenyl)phosphine caused a decrease of solubilisation and shifted the curves towards higher quantities of SDS (26 and 32%, respectively). The microemulsion was homogeneous when heated to 60°C (a heating to higher temperatures needed a pressure system) but separated after addition of 1% NaCl.

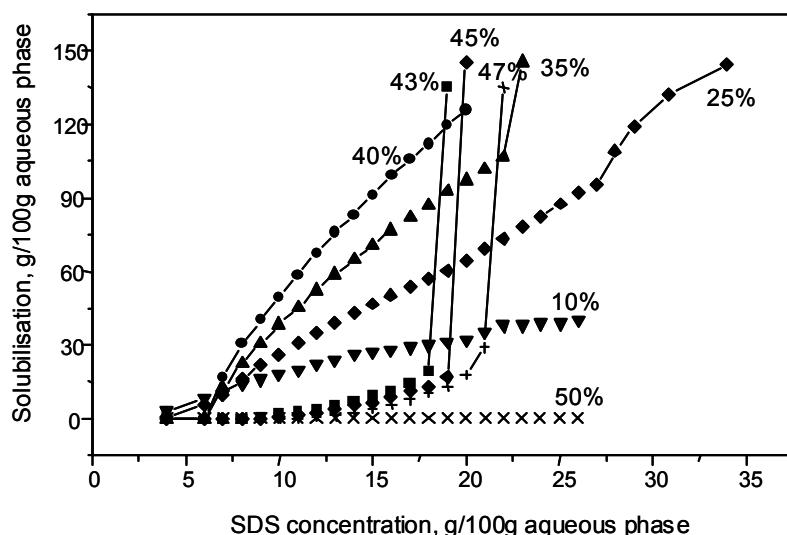

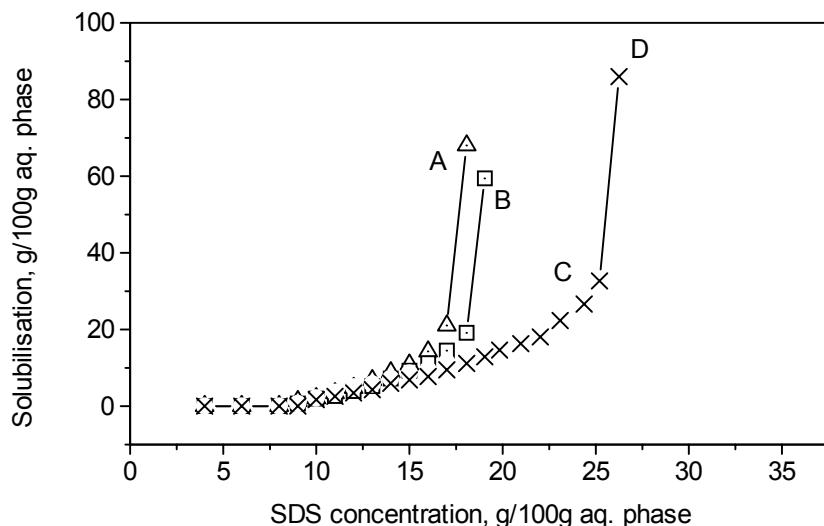

Figure 2. Solubilisation of hexene in sodium dodecylsulphate-butanol-water system for various concentrations of butanol (percents given on curves denote the concentration of butanol in aqueous phase without SDS).

## HYDROFORMYLATION AND SEPARATION OF MICROEMULSION

The separation of the post-reaction mixture (after hexene hydroformylation) was achieved by the addition of butanol (43%)-water solution to decrease the concentration of SDS to about 13 and 14-17.5% in systems without and with Na-TPPTS, respectively (Table 2). Aldehydes were transferred into the organic phase with the distribution coefficient equal to 1.6 and 2.5 in the systems without and with 3% Na-TPPTS, respectively. SDS remained in the aqueous phase together with the whole amount of catalyst used.

*Figure 3. Solubilisation of various components in sodium dodecylsulphate-butanol (43%)-water system (A, hexane; B, hexene; C, heptanal, D, benzene).*

*Table 2. Separation of the post-reaction mixture after hydroformylation (43% butanol and 57% water).*

Content of SDS (%)	Content of Na-TPPTS (%)	SDS conc. in aqueous phase (%)	O/W phase ratio	Distribution coefficient
20	0.0	12.5	1 : 1.8	1.6
30	0.0	12.8	1 : 2.6	1.5
20	3.0	14.0	1 : 1.2	2.5
30	3.0	17.5	1 : 1.6	2.4

The use of microemulsion for hydroformylation of hexene permitted to achieve a high conversion of hexene equal to about 97% and the yield of heptanals above 94%, in the reaction time below 40 minutes (Table 3). 50% conversion of hexene was obtained already after 11-13 minutes. It was the main advantage of the microemulsion use in comparison to the heterogeneous micellar systems applied for hydroformylation. However, the ratio of isomers (n/iso) having straight and branched alkyl chain was not enough high and changed in the range of 2.2-2.5.

An addition of 3% Na-TPPTS to the aqueous medium had a small but positive effect on the olefin total conversion. A small increase in n/iso isomer ratio was also observed. It was accompanied by a little decrease in kinetics as regards the increasing values of half-conversion time. Evidently, an increase of ligand (or electrolyte) concentration improved reaction selectivity expressed as n/iso ratio equal to 2.8-2.9.

*Table 3. Hydroformylation of hexene in sodium dodecylsulphate-butanol-water system.*

SDS (%)	Content Na-TPPTS (%)	n/iso ratio (mol/mol)	Reaction time (min)	Half conversion time (min)	Total conversion (%)	Aldehyde yield (%)
0.0	0.0	-	60.0	-	0.0	0.0
20	0.0	2.2	37.0	11.0	96.7	94.6
30	0.0	2.5	37.5	11.3	96.9	94.2
20	3.0	2.9	30.0	12.6	98.0	95.8
30	3.0	2.8	33.0	13.0	99.2	96.8

Experimental conditions: pressure, 2 MPa; temperature, 100°C; catalyst 500 ppm Rh as RhH(CO)(Na-TPPTS)<sub>3</sub>; hexene 0.02 mol; contact liquid 10 g; synthetic gas H<sub>2</sub>:CO=1:1 mol/mol, 43% butanol in respect to water.

## CONCLUSIONS

Solvent extraction was a suitable technique to separate sulphonated triphenylphosphines from oleum with the purity and yield higher than that obtained by crystallisation from various solvents. Tributyl phosphate was a suitable extractant. Sodium salts could be then recovered as precipitates by treating the organic phase with sodium hydroxide solution. The solvent extraction simplified the separation process. About 90% of sulphate ions remained in the aqueous phase after extraction with TBP. As a result, an increase of the yield (5-10%) and purity (3-6%) was observed in comparison to the separation only by crystallisation. The separation could be obtained more quickly using less chemicals and producing less wastes.

Microemulsions could be easily obtained in the systems containing hydrocarbons, water, butanol, sodium dodecylsulphate and tri(m-sulphophenyl)phosphine and could be separated in organic and aqueous phases by addition of aqueous butanol solution. SDS remained in the aqueous phase together with the whole amount of catalyst used and could be recycled.

The hydroformylation carried out in microemulsion occurred rapidly in comparison to the classical system and high yields of reaction were obtained. However, the selectivity of reaction was lower.

## DEVELOPMENT OF A NOVEL PROCESS FOR PURIFICATION OF PHENOLIC DERIVATIVE

Oldrich Mikus and Bridget M. Hutton\*

AECI Ltd., Modderfontein, South Africa

\*CSIR, Bio/Chemtech, Modderfontein, South Africa

A novel process for purification of a phenolic derivative using liquid-liquid extraction was developed as an alternative to a three-stage re-crystallisation. The extraction process operates at a high aqueous to organic ratio and at elevated temperature. The process development was performed on two different scales. Initially, a bench-scale study was conducted on 1:133 scale. This gave an indication of the process characteristics and provided engineering data for design of the commercial process. Subsequently, the commercial-scale process was specified and the equipment was designed. This was followed by a pilot-plant study on the system at a scale-down ratio of 1:9. The process was successfully commercialised using a compact mixer-settler unit with a capacity of 8 m<sup>3</sup>/h. This novel process enables the product to be effectively purified using fewer unit operations and features higher product recovery, shorter batch cycle and less solvent consumption than the original crystallisation purification process.

### INTRODUCTION

Recent experience in the development of fine chemical processes has shown that the isolation of products from crude post reaction mixtures to the required purity typically represents about 80% of the overall effort. This purification typically requires a complex set of unit operations, some of which have to be performed under very specific conditions.

Catalytic alkylation of an aromatic hydrocarbon yields a post-reaction product containing both *mono-* and *di*-alkyl derivatives, where the *mono*-alkyl derivative is the required product and the *di*-alkyl derivative is an undesirable impurity to be removed in the purification process. Even after optimisation of the reaction conditions, the concentration of the *di*-alkyl derivative in the crude product is still approximately 10% by mass. The final product specification, however, requires that the concentration of the *di*-alkyl derivative should not exceed 0.03% by mass. The original process to achieve a final product with less than 0.03% impurities was *via* a three-stage re-crystallisation. The three stage re-crystallisation entailed complete dissolving of the crude product firstly in water, filtering the hot solution followed by crystallisation of an intermediate, which contained about 0.3% of impurities. Further reduction of the impurities was achieved by another re-crystallisation from an organic solvent, followed by re-crystallisation of the product from water. The final re-crystallisation from water was used to remove the organic solvent from the product, since the solvent would contaminate the product.

Another possible purification method considered was distillation under high vacuum, however, the relative volatility of the components to be separated indicated that a rectification column with many stages and high reflux ratio would be required. Another problem would be that operation under high vacuum and high temperature could allow oxygen to enter the distillation column, which would cause oxidation of the product.

The application of solvent extraction as a possible purification process was investigated. It was found that despite the similar solubility of the both *mono*- and *di*-derivative in an organic solvent, the partition coefficients of both species differed by two orders of magnitude in favour of the component to be removed. This phenomenon, which was previously employed only as an analytical technique [1], facilitated an opportunity for replacement of multiple crystallisation with solvent extraction. Figure 1 compares the original three stage re-crystallisation process with the newly developed extraction process.

### **INITIAL EVALUATION OF THE NOVEL PROCESS**

Initial evaluation of the system on a laboratory scale indicated that the organic solvent could effectively remove the impurities using a single stage extraction operated at elevated temperature. However, it was also evident, that should the quantity of solvent remain the same as or similar to that used for re-crystallisation, a large percentage of the required product would be extracted along with the impurities. The ratio of solvent to feed required for the extraction was found to range between 1: 60 and 1:120. Further tests on a laboratory scale indicated that at these extreme ratios, the system was not operable, due to problems both with mixing and settling of the two phases. Another problem encountered was that it was impossible to effectively replicate the continuous extraction system. In addition, the concentrations of impurities monitored in the raffinate were ppm levels and the actual success of the novel process could only be evaluated as per the quality of the final product crystallised from sufficient quantity of raffinate. The laboratory tests also showed that due to the small amount of material used and the accuracy of the analytical technique employed, it was impossible to achieve mass balance closure. Consequently the decision was made to conduct the next development stage on a bench scale, operating the process continuously.

### **BENCH-SCALE INVESTIGATION (1:133)**

Two options were considered for the bench-scale investigation, namely application of an extraction column or a single-stage mixer settler. The latter option was employed due to equipment availability and in-house experience with mixer-settler extraction.

A rectangular, polypropylene mixer-settler with a total volume of 10 litres was used for the bench-scale development. The unit comprised four compartments, a mixer, a settler, an extract compartment and a raffinate compartment. The volume of the mixer was 1.8 litres. The mixer was furnished with a pumping agitator connected to a variable speed drive. All the compartments were furnished with stainless steel heating coils to enable the required temperature to be maintained. Equipment was furnished with a glass lid in order to minimise losses of solvent by evaporation and to allow visual inspection of the behaviour of the phases in the individual compartments. To achieve the required high aqueous to organic ratio and yet to allow a reasonable phase ratio in the mixer the extract was recycled from the extract compartment to the mixer in external tubing *via* a peristaltic pump. In terms of throughput, the bench-scale unit operated at a 1:133 scale-down ratio as compared to the commercial equipment. The unit was installed and operated at a pilot plant facility since large vessels were required to support the extraction operation on a continuous basis, for the duration of at least 10 hours.

During the bench-scale experiments, the effect of feed to solvent ratio on the extraction efficiency of both the impurities and the product was studied, at a predetermined temperature and hydrodynamic conditions. In addition, the effect of changing the temperature was tested. Large samples of raffinate were collected and crystallised to allow evaluation of the product quality. Several bench-scale experiments were performed which allowed determination of the system characteristics and facilitated identification of possible operability and scale-up problems. The results produced mass balance data for the novel process design and enabled integration of the design into the original flow-sheet. Of greater importance was the fact that the bench-scale process demonstrated that the required quality of the product was achievable on a consistent basis. A complete component mass balance was performed which allowed calculation of the extraction efficiencies of both the product and impurities. The effect of the phase ratio on the extraction efficiency of both species is shown in Figure 2.

Because of the limited solubility of the product in water, an attempt was made to maximise the concentration of the product in the feed by operating at as high a temperature as possible. Continuous extraction trials have, however, revealed that the organic phase in equilibrium to the feed composition represents a supersaturated solution, which solidifies on cooling and thus accurate temperature control is essential. Because of solidification, the handling of extract at low flow rates was identified as a major operability problem and it was found that standard extraction equipment readily available was not suitable for the novel process. Consequently specialised equipment was designed, specifically for the novel process.

Figure 3 illustrates an example of the liquid-liquid equilibrium of the product and the effect of different feed to solvent ratios on the operability of the process.

The bench-scale study confirmed that a single-stage continuous extraction was an effective alternative to the three-stage re-crystallisation. Dissolved solvent was flashed off from the raffinate, which was then cooled and crystallised to produce product that was of the required specification. Furthermore, it was found that an optimum mass ratio of solvent to feed of 1:100 was required in order to achieve the lowest possible extraction efficiency (loss) of the product (preferably <15%), while simultaneously maintaining an extraction efficiency on impurities greater than 94%. It was also found that the extract represents a supersaturated solution and that even a small temperature drop resulted in immediate solidification.

### PILOT-PLANT STUDY (1:9)

Based on the results of the bench-scale study the commercial extraction unit was conceptually designed. A geometrically similar pilot plant unit was fabricated on a scale-down ratio of 1:9. The unit was a horizontal cylinder of an internal diameter of 0.3 m and length of 2.5 m. It was fabricated from stainless steel and glass segments to enable visual monitoring of the process. The internal space comprised five compartments, namely a mixer, a settler, an extract recycle compartment, an extract accumulation compartment and a raffinate compartment. The extract was circulated from the extract recycle compartment to the mixer via an internal pipe using the pumping effect of the agitator. Fresh solvent was injected directly into the recycle line. The mixer was furnished with two baffles and a straight-blade pump turbine impeller.

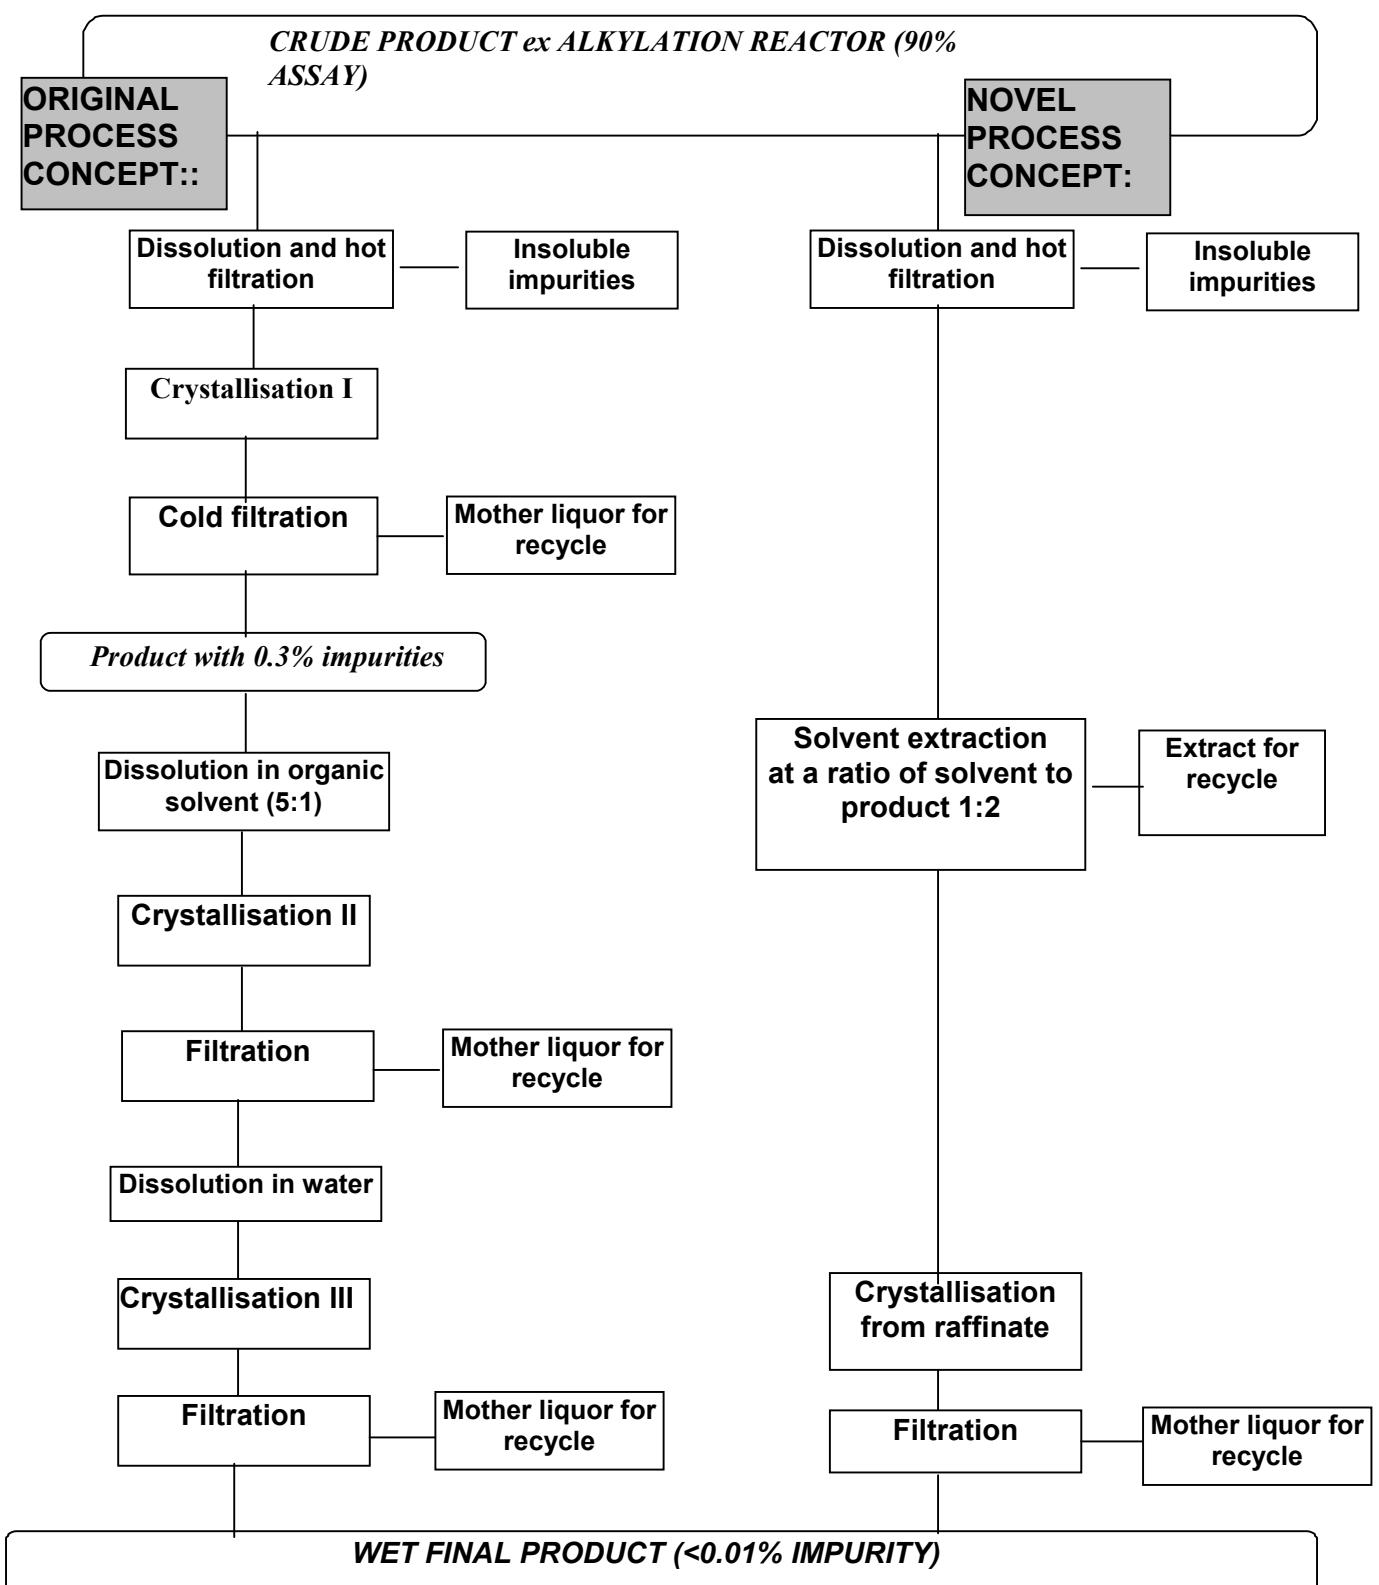

Figure 1. Comparison of the original and the novel process.

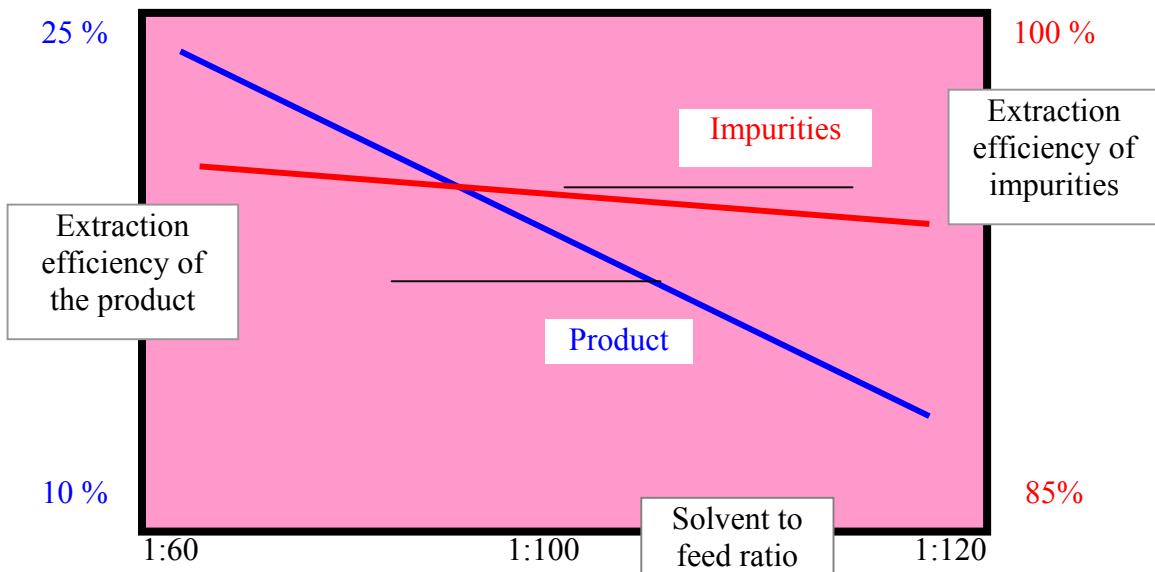

Figure 2. Effect of solvent to feed ratio on the extraction efficiency of product and impurities.

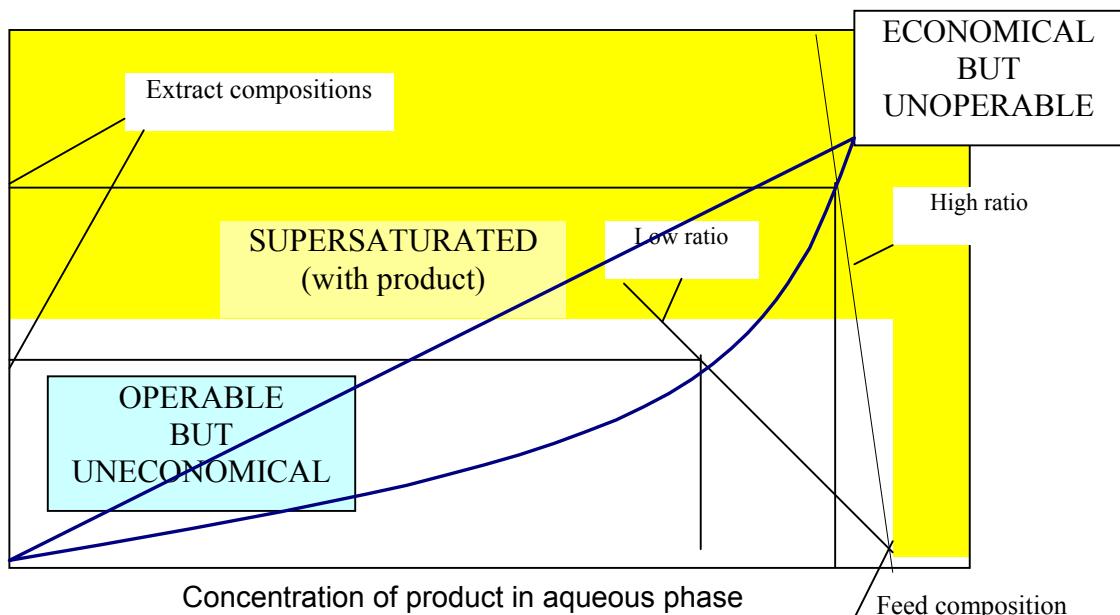

Figure 3. Partitioning of the product between phases at elevated temperature.

The pilot-plant unit was installed at the commercial plant and operated. In terms of performance, the extraction efficiency results obtained compared favourably with those obtained from the bench-scale studies. Additional information was obtained for modification of the commercial unit design in terms of the hydrodynamic condition in the mixer, settling characteristics, temperature control, start-up and shut-down, as well as sizes of the individual compartments.

## NOVEL PROCESS COMMERCIALISATION

Based on the results obtained from the pilot-plant study the original design of the commercial unit was modified and the recommended changes implemented. The unit was then fabricated, installed and integrated into the existing process.

Because of the non-standard geometry of the mixer, very little information was available to scale-up the mixing, namely the agitator speed. The factor used to adjust the small-scale (1:9) speed to the commercial-scale operation was a scale ratio as defined in Eq. (1), raised to an exponent,  $n$ :

$$N_2 = N_1 (1/R)^n = N_1(D_1/D_2)^n \quad (1)$$

The value of the exponent,  $n$  generally depends on the type of agitation problem and typically ranges between  $n = 2/3$  and  $n = 1$  [2]. The mixing problem in this case was actually three fold. Firstly, reasonably equal liquid motion was required in order to prevent emulsification (recommended  $n = 1$ ). Secondly, equal mass transfer between the liquid phases was required (recommended  $n = 2/3$ ). In addition, the agitator needed to provide a sufficient pumping effect, in order to recycle the extract. Based on experimental observation of the mixing and settling characteristics, as well as the volumetric mass transfer coefficient, a value of  $n \sim 0.8$  was found to be a reasonable compromise for scale-up [3].

Performance tests were completed using the commercial unit which proved that product complying with the specification was produced on a consist basis. A comparison of the novel process with the original purification process is summarised in Table 1.

*Table 1. Comparison of major features of original and novel process.*

	Original process	Novel process
Number of process steps	10	5
Number of recycle stream	3	2
Batch cycle time	40 hours	16 hours
Consumption of solvent	5 kg /kg of product	0.5 kg/kg of product
Product recovery	66%	71%
Product quality	complies with specification	complies with specification

## CONCLUSION

Application of the scale-up/scale-down approach to commercialisation of the novel process was found to be very beneficial despite the increased total development time and costs. It allowed identification of the process problems affecting the design of the equipment and facilitated changes prior to the fabrication and commissioning of the commercial-scale unit. The pilot-plant study using 1:9 geometrically similar unit, installed and operated at the commercial plant, gave engineering information on the process hydrodynamics, settling characteristics, process operability and instrumentation required. It also enabled the full-scale process to be accurately replicated and the proposed operating procedures tested including the start-up and shut-down. Furthermore operation of the pilot-plant unit contributed to better understanding of the novel process by the plant operating staff, which made a valuable contribution to the novel process commercialisation.

## THE SEPARATION OF PHENOLIC COMPOUNDS FROM NEUTRAL OILS AND NITROGEN BASES

Denise L. Venter and Izak Nieuwoudt

Department of Chemical Engineering, University of Stellenbosch, Stellenbosch, South Africa

Liquid-liquid extraction with a solvent system consisting of triethylene glycol as selective solvent, water as co-solvent and hexane as countercosolvent is proposed for the separation of phenolic compounds from neutral oils and nitrogen bases. Solvent selection was by means of computer-aided molecular design. Liquid-liquid equilibria for the solvent system plus phenolic compounds, neutral oils and nitrogen bases were determined. The effect of solvent ratios on the desired separation are illustrated on the basis of separation factors and percentage recoveries of phenolic compounds. The three-parameter NRTL model was fitted to the equilibrium data and was used in the optimisation of a multistage countercurrent extraction process. Pilot-plant tests performed on an industrial heavy naphtha stream yielded a final phenolic product purity of 99.75% and phenolic recovery in excess of 91%.

### INTRODUCTION

Coal pyrolysis liquors are a major source of valuable phenolic compounds. The separation of phenolic compounds from the neutral oils and nitrogen bases also present in the pyrolysis liquors is difficult due to low relative volatilities and the formation of azeotropes and eutectics [1]. The desired high phenolic recovery and phenolic product purity of 99.5% cannot be achieved by means of conventional distillation processes.

Alternative processes such as liquid-liquid extraction with various low-boiling solvents [2-5], mixtures of high-boiling solvents [5-7] and extractive distillation [8] have been extensively investigated. Disadvantages of these processes include the high solvent ratios required, low recovery of the higher substituted phenolic compounds, inability to treat a wide-boiling feedstock in one process step and complex post-purification of the phenolic product. A solvent system consisting of a selective solvent, water as a co-solvent, and hexane as a countercosolvent, is proposed as an alternative.

A computer-aided molecular design program identified glycols as suitable commercial selective solvents. The suitability of the proposed solvent system for the separation of phenolic compounds from neutral oils and nitrogen bases was evaluated by means of batch extraction and pilot plant tests.

## SOLVENT SELECTION

Three synthetic feed streams were compiled to represent a typical industrial coal pyrolysis liquor namely:

- phenol (71 wt%) + benzonitrile (6.67 wt%) + aniline (6.67 wt%) + mesitylene (9 wt%) + 5-et-2-me-pyridine (6.67 wt%)
- m-cresol (53.33 wt%) + o-tolunitrile (6.67 wt%) + o-toluidine (6.67 wt%) + pseudocumene (6.67 wt%) + undecane (6.67 wt%) + indene (20 wt%)
- 2,4-xlenol (13.33 wt %) + 3,5-xlenol (6.67 wt%) + 3,4-xlenol (6.67 wt%) + indane (6.67 wt%) + dodecane (26.67 wt %) + naphthalene (40 wt%)

Solvent selection was based on the phenol containing feed stream. Of the neutral oils and nitrogen bases present in the pyrolysis liquor, benzonitrile was identified as the neutral oil potentially most difficult to separate from phenol. A computer aided molecular design program based on a genetic algorithm, using the modified Unifac model, was used to predict a suitable solvent for the separation of phenol from benzonitrile [9]. Favourable phenol-benzonitrile separation factors were predicted for ethylene glycol as well as for a variety of high molecular weight molecules containing ether, carbonyl and hydroxyl functional groups. Of the commercially available solvents tested on batch extraction scale, triethylene glycol achieved the highest phenol-benzonitrile, phenol-aniline and phenol-5-et-2-me-pyridine separation factors as well as the highest phenol recovery.

From the solvent selection process it was concluded that effective solvents for the separation under investigation were those containing hydroxyl groups positioned on the molecule backbone in such a way as to facilitate hydrogen bonding with more than one phenolic molecule at a time. Two commercially unavailable solvents, 1,3-(ethoxy-2-hydroxy)-propane-2-ol and 1,3-(diethoxy-4-hydroxy)-propane-2-ol were therefore synthesised from ethylene glycol and diethylene glycol respectively [10].

The performance of the synthesised and commercially available solvents with respect to phenolic recoveries as well as m-cresol-o-tolunitrile, 2,4-xlenol-o-tolunitrile, and 2,4-xlenol-o-toluidine separation factors was tested in batch extraction experiments. The results obtained are listed in Table 1.

*Table 1. Batch extraction test results for the comparison of synthesised and commercial solvent performance at constant solvent molar ratios.*

Solvent	Functional groups		$\beta_{m\text{-Cresol-o-Toluonitrile}}$	$\beta_{2,4\text{-Xlenol-o-Toluonitrile}}$	$\beta_{2,4\text{-Xlenol-o-Toluidine}}$	Recovery (%)		$n_{m\text{-Cresol}} / n_{\text{Solvent}}$	$n_{2,4\text{-Xlenol}} / n_{\text{Solvent}}$
	-C-O-C-	-O-H				m-Cresol	2,4-Xlenol		
EGd*	2	2	8.9	n/a	n/a	88.2	n/a	1.2	n/a
DiEGd**	4	4	19.1	12.5	3.5	95.1	86.7	1.2	0.4
TEG	2	2	13.1	9.6	3.5	93.9	90.8	1.6	0.6
Tetra EG	3	3	16.5	11.1	3.6	95.3	90.7	1.3	0.5
Glycerol	0	3	3.8	10.1	1.1	60.1	2.1	0.7	0.02
Tetraglyme	4	1	3.3	n/a	n/a	83.2	n/a	1.3	n/a

\*1,3-(ethoxy-2-hydroxy)-propane-2-ol    \*\*1,3-(diethoxy-4-hydroxy)-propane-2-ol

As can be seen from Table 1, 1,3-(diethoxy-4-hydroxy)-propane-2-ol yielded higher phenolic recoveries and separation factors than triethylene glycol. However, the difference in solvent performance is small and triethylene glycol is relatively inexpensive and readily available. Triethylene glycol was therefore selected for further process development.

## EXPERIMENTAL

Batch extraction tests were executed on each of the three synthetic feed streams in order to determine the effect of solvent ratios on separation efficiency. Ratios of solvent (triethylene glycol) to feed, water to solvent (triethylene glycol) and countercosolvent (hexane) to feed were varied from 0.5 to 3.0, 0.0 to 0.7 and 0.5 to 5.0, respectively. The concentrations of the components in each resulting liquid phase, with the exception of water, were determined by means of capillary gas chromatography with an FID detector. The water concentrations were determined by means of Karl-Fischer titrations.

The separation factor  $\beta_{ij}$  for a phenolic compound  $i$  relative to a neutral oil or nitrogen base  $j$  is defined as follows :

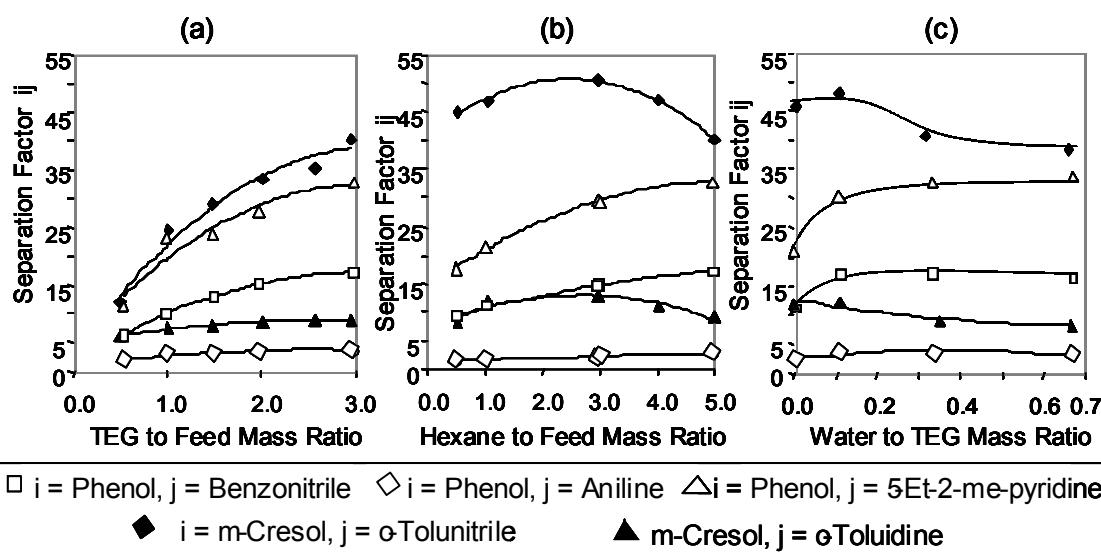

$$\beta_{ij} = (x_i^E / x_i^R) / (x_j^E / x_j^R) \quad (1)$$

where  $x_i^E$  and  $x_i^R$  are the molar concentrations of component  $i$  and  $x_j^E$  and  $x_j^R$  are the molar concentrations of component  $j$  in the extract and raffinate phases respectively.

Separation factors obtained for phenolic compounds relative to paraffins, alkyl-substituted benzenes, indane, indene and naphthalene are listed in Table 2. Figure 1 illustrates the effect of the solvent (TEG) to feed, water to solvent (TEG) and hexane to feed ratios on the separation factors obtained for phenolic compounds relative to aromatic amines, nitriles and 5-*et*-2-me-pyridine. Figure 2 illustrates the effect of the various solvent ratios on the phenolic recoveries. The mass compositions of the resulting phases and corresponding separation factors and phenolic recoveries are reported elsewhere [11].

*Table 2. Separation Factors,  $\beta_{ij}$ , for phenolic compounds,  $i$ , relative to neutral oils,  $j$ .*

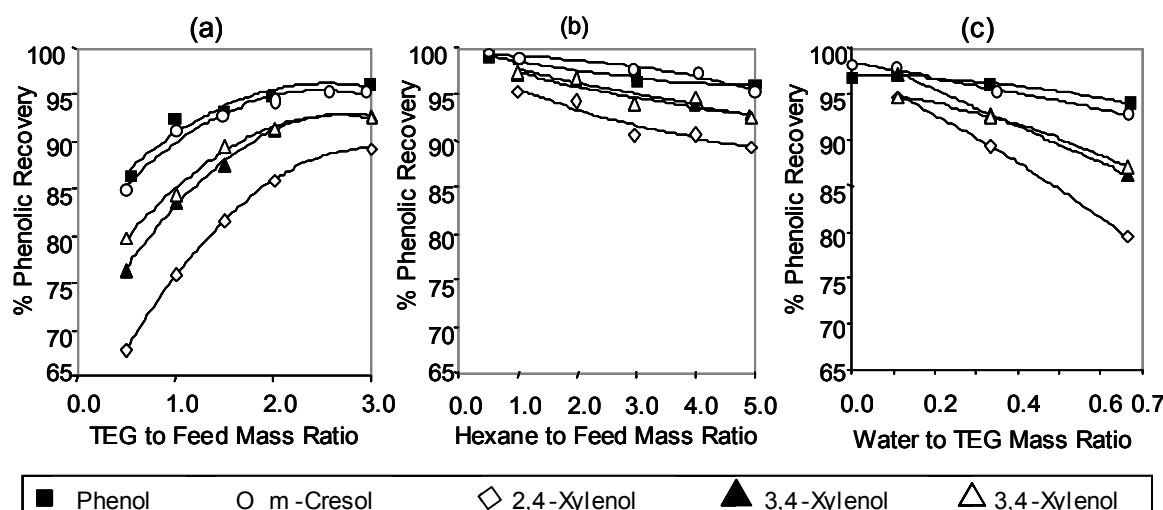

$i$	$j$	$\beta_{ij}$ (minimum)	$\beta_{ij}$ (maximum)
Phenol	Mesitylene	81	1600
m-Cresol	Pseudocumene	34	3100
m-Cresol	Undecane	79	4600
m-Cresol	Indene	20	172
Xylenol	Dodecane	204	6300
Xylenol	Indane	50	2950
Xylenol	Naphthalene	36	170

*Figure 1. Effect on the separation factor  $\beta_{ij}$  of the (a) solvent to feed mass ratio at a constant water to solvent mass ratio of 0.3 and a constant hexane to feed mass ratio of 5.0; (b) hexane to feed mass ratio at a constant solvent to feed ratio 3.0 and a constant water to solvent mass ratio of 0.3. (c) water to solvent mass ratio at a constant solvent to feed ratio 3.0 and a constant hexane to feed ratio of 5.0.*

It is clear from Table 2 that the separation of phenolic compounds from paraffins, naphthalene, indene, indane and the alkyl-substituted benzenes is trivial using the proposed solvent system. Figure 1 shows that excellent separation factors are obtained for phenolic compounds relative to aromatic nitriles and 5-et-2-me-pyridine. The separation factors obtained for phenol relative to aniline are satisfactory.

It can further be seen from Figure 2 that excellent phenol and m-cresol recoveries are obtained for all solvent ratios tested. For phenol and m-cresol, recoveries in excess of 99% may be obtained in a single stage. Recoveries in excess of 98% may be obtained for the xylenol isomers at solvent ratios in excess of 2 and water to solvent ratios smaller than 0.25.

*Figure 2. Effect on the percentage recovery of phenolic compounds of (a) the solvent to feed mass ratio at a constant water to solvent mass ratio of 0.3 and a constant hexane to feed mass ratio of 5.0; (b) the hexane to feed mass ratio at a constant water to solvent mass ratio of 0.3 and a constant solvent to feed mass ratio of 3.0; (c) the water to solvent mass ratio at a constant solvent to feed ratio 3.0 and a constant hexane to feed ratio of 5.0.*

It is clear from Figures 1a and 2a that while an increase in the solvent to feed ratio from 0.5 to 3.0 results in an increase in both the phenolic recoveries and the separation factors, a further increase will have a negligible effect on either separation efficiency or recovery.

It can be seen from Figure 1b that an increase in the hexane to feed ratio from 1.0 to 3.0 results in an increase in all the separation factors. As the hexane to feed ratio is increased further, the separation factors of phenol relative to benzonitrile, aniline and 5-et-2-me-pyridine increase while those of m-cresol relative to o-tolunitrile and o-toluidine decrease. It can be concluded from Figure 1 that, using the proposed solvent system, the most difficult separation is that of phenol from aniline. It can further be seen from Figure 2b that the effect of the hexane to feed ratio on phenolic recovery is small. The optimum hexane to feed ratio is therefore determined as that at which the separation of phenol from aniline is optimum.

From Figure 1c it can be seen that an increase in the water to solvent ratio from 0.0 to 0.2 results in an increase in the separation factors of phenol relative to aniline, benzonitrile and 5-et-2-me-pyridine and a decrease in those of m-cresol relative to o-toluidine and o-tolunitrile. A further increase in the water to solvent ratio results in a decrease in the all the separation factors. It can further be seen from Figure 2 that an increase in the water to solvent ratio results in a decrease in the phenolic recovery. The effect of the water to solvent ratio becomes more significant with a progression in the phenolic homologous series.

It is concluded that the optimum solvent to feed, water to solvent and hexane to feed ratios, with respect to phenolic recovery and separation efficiency, are 3.0, 5.0 and 0.2 respectively.

## THERMODYNAMIC MODELLING

For a multicomponent two-phase liquid-liquid extraction system at equilibrium, the distribution coefficient may be expressed in terms of either the activity coefficients or equilibrium molar concentrations of component  $i$  in both phases:

$$K_i = x_i^E / x_i^R = \gamma_i^R / \gamma_i^E \quad (2)$$

where  $\gamma_i^E$  and  $\gamma_i^R$  are the activity coefficients of component  $i$  in the extract and raffinate phases respectively.

The activity coefficients for a two-phase liquid-liquid extraction system may be modeled with the three-parameter Non-Random Two-Liquid (NRTL) model [12] using an appropriate set of binary interaction parameters,  $b_{ij}$  and  $\alpha_{ij}$ .

Each batch extraction was simulated with the process simulator, PRO/II version 5.11, (Simulation Sciences Inc. 1999), using the sets of binary parameters obtained through regression of the equilibrium data [10]. The root-mean-square deviation (RMSD) for each multicomponent system was calculated from the experimental and simulated equilibrium molar fractions of each component in the two resulting liquid phases according to the following equation:

$$\text{RMSD} = \left[ \sum_n \frac{\sum_i (x_{i,\text{exp}}^E - x_{i,\text{sim}}^E)^2 + \sum_i (x_{i,\text{exp}}^R - x_{i,\text{sim}}^R)^2}{2kn} \right]^{1/2} \quad (3)$$

where  $n$  is the number of data points,  $k$  is the number of components,  $x_{i,\text{exp}}^E$  and  $x_{i,\text{sim}}^E$  are the experimental and simulated molar fractions of component  $i$  in the extract phase and  $x_{i,\text{exp}}^R$  and  $x_{i,\text{sim}}^R$  are the experimental and simulated molar fractions of component  $i$  in the raffinate.

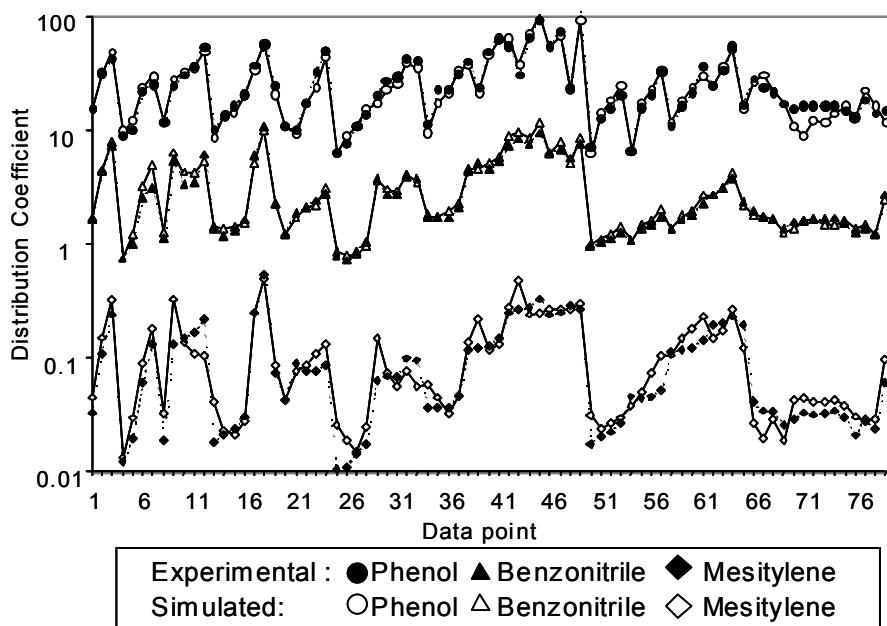

The experimental and simulated distribution coefficients for the system hexane + water + triethylene glycol + mesitylene + 5-et-2-me-pyridine + aniline + benzonitrile + phenol are shown in Figures 3 and 4. The RMSD value calculated for the system is 0.0037. The experimental and simulated distribution coefficients for the systems hexane + water + triethylene glycol + pseudocumene + undecane + indene + o-tolunitrile + o-toluidine + m-cresol and hexane + water + triethylene glycol + indane + dodecane + 2,4-xylenol + 3,4-xylenol + 3,5-xylenol are reported elsewhere [11]. The RMSD values calculated for the two systems are 0.010 and 0.0058 respectively.

From Figures 3 and 4 and it can be concluded that the equilibrium data can accurately be correlated with the NRTL model.

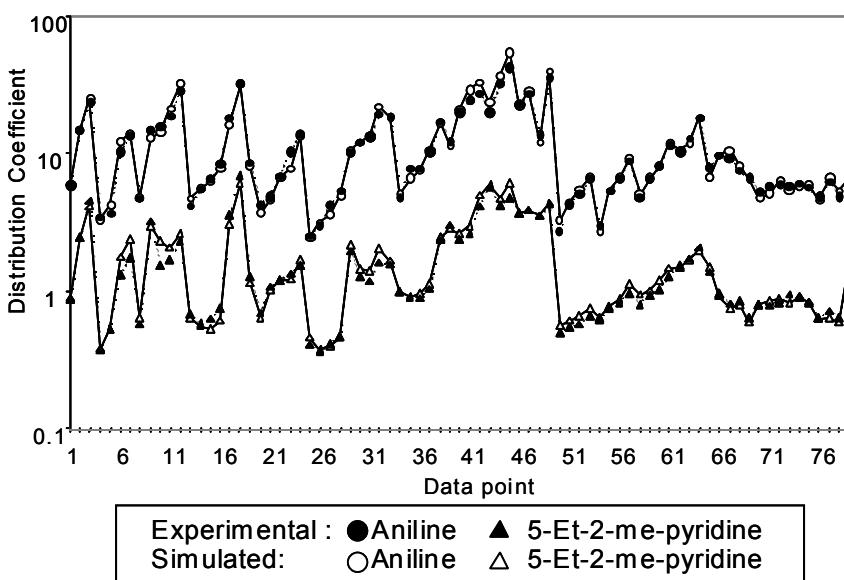

## MULTISTAGE EXRACTION

The proposed solvent system was tested in an agitated glass column containing 28 mixing stages. Mixing was by means of six-blade Rushton turbines. Two perforated stator plates with a free cross-sectional area of 36% separated each mixing stage. Knitted wire mesh was installed between the stator plates to induce coalescence and settling of the dispersed phase liquid droplets. The pilot plant extraction column was configured for countercurrent extraction with the light countercurrent phase as the continuous phase and the heavy solvent phase as the dispersed phase.

Pilot-plant tests using a synthetic feed stream consisting of aniline, o-tolunitrile, m-cresol and p-cresol were performed in order to determine the impeller rotation speed, feed entry point position and solvent ratios required to obtain the highest possible phenolic product purity and recovery.

*Figure 3. Experimental and simulated distribution coefficients obtained for phenol, benzonitrile and mesitylene for the system phenol + benzonitrile + aniline + 5-ethyl-2-methyl pyridine + mesitylene + triethylene glycol + water + hexane at 313.15 K and 101.3 kPa.*

*Figure 4. Experimental and simulated distribution coefficients obtained for aniline and 5-ethyl-2-methyl pyridine for the system phenol + benzonitrile + aniline + 5-ethyl-2-methyl pyridine + mesitylene + triethylene glycol + water + hexane at 313.15 K and 101.3 kPa.*

The optimum solvent to feed, hexane to feed and water to solvent ratios with respect to product purity and phenolic recovery were determined as being 3.0, 5.0 and 0.25 respectively. The optimum phenolic product purity and recovery were yielded using a feed point at the top of the extraction column and an impeller speed of 250 rpm.

Implementation of these optimum operating conditions on an industrial heavy naphtha stream yielded a phenolic product purity of 99.75% after solvent recovery. The corresponding phenolic recovery was in excess of 91 %. Under these conditions, seven equilibrium stages were obtained in the extraction column.

The proposed separation process, including solvent recovery, was simulated with using the NRTL model with the experimentally determined interaction parameters. A single stream consisting of all the components used in the batch extraction tests was specified as the feed stream to the simulated process. A final simulated phenolic product purity of 99.5% and recovery in excess of 94% was obtained after solvent recovery. The optimum simulated solvent ratios were identical to those obtained for the pilot-plant tests.

## CONCLUSIONS

Liquid-liquid equilibria for the solvent system triethylene glycol, hexane and water plus phenolic compounds plus neutral oils and nitrogen bases were determined at 313.15 K in order to evaluate its suitability in separating phenolic compounds from neutral oils and nitrogen bases.

The separation of phenolic compounds from paraffins, indane, indene, naphthalene and trimethylbenzene isomers is trivial using the proposed solvent system. The selectivities obtained for phenol with regards to benzonitrile, aniline and 5-et-2-me-pyridine as well as those obtained for m-cresol with regards to o-tolunitrile and o-toluidine are highly satisfactory. The proposed solvent system was implemented in a multistage countercurrent extraction column with an industrial heavy naphtha stream as feed. The final phenolic product purity after solvent recovery was 99.75% and the phenolic recovery in excess of 91%.

It can therefore be concluded that the triethylene glycol, hexane and water are effective solvents for the separation of phenolic compounds from neutral oils and nitrogen bases.

## NOMENCLATURE

x	equilibrium molar fraction	<i>Subscripts</i>
K	distribution coefficient (defined in eq. 1)	i component i
$\beta$	separation factor (defined in eq. 2)	j component j
$\gamma$	liquid phase activity coefficient	
k	number of components	<i>Superscripts</i>
n	number of data points	E extract (water-rich) phase
		R raffinate (hexane-rich) phase

## WAX FRACTIONATION WITH SUPERCRITICAL FLUID EXTRACTION

I. Nieuwoudt, J. C. Crause, M. du Rand and C. E. Schwarz

The University of Stellenbosch, Stellenbosch, South Africa

Supercritical fluid processing offers an attractive alternative for the processing of paraffin waxes. Supercritical fluid phase equilibria for wax systems were experimentally determined and equations of state models were fitted to the data. These models were used to optimise the supercritical fluid fractionation process. Pilot-plant experiments were done to confirm the model predictions. It was shown that superior wax products could be produced with supercritical fluid fractionation and that the processing costs are comparable with that of competing processes.

### INTRODUCTION

Supercritical fluid extraction has been around for almost a century and has several times been hailed as a miracle cure for several problems. However, it often looks like an elegant solution looking for a suitable problem. In 1935 Van Dijck [1] alluded to the use of supercritical solvents in the fractionation of oligomers. Although he used thermal instability as the reason for doing the work, no technical or economic comparison with other methods was presented.

A systematic study was made to identify the wax products for which supercritical fluid extraction is the technically and economically superior fractionation method.

In order to cut down on R&D time and costs, the following route was followed. Accurate phase equilibrium data was measured and equation of state models fitted to the data. The models were used to explore the possibilities of the process. Models were also developed for the competing processes namely short path distillation and fractional crystallization. Pilot plant experiments were done to confirm the model predictions. Conceptual designs were done to compare the economics of the various processes.

### PHASE EQUILIBRIUM MEASUREMENTS

Although several papers have been published on the phase equilibria of supercritical solvents and high molecular weight n-alkanes[2], several of the data sets are incomplete in the mixture critical region whilst some other data sets are highly unreliable. High pressure static equilibrium cells were constructed with which it was possible to measure accurate phase equilibrium data that encompasses the mixture critical region [2,3]. Some of the data sets are shown in Figures 1 and 2. To keep the operating pressures in a comfortable range, ethane is recommended for waxes with carbon numbers of up to 35 whereas propane is recommended for higher molecular weight waxes.

From Figures 1 and 2 it is evident that the solvents can be loaded to approximately 10 % wax. This is important since it determines the solvent:feed ratio which in turn has a dramatic effect on the operating and capital costs. It is also clear that the solubilities of the wax components (at constant pressure and temperature) are a strong function of the chain length. This is important to get good selectivity.

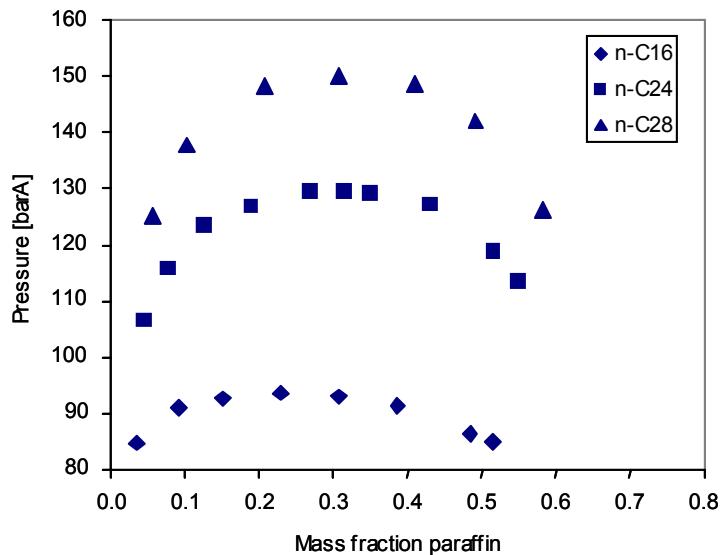

Figure 1. Phase equilibrium data for ethane binaries at 69.7 °C [2].

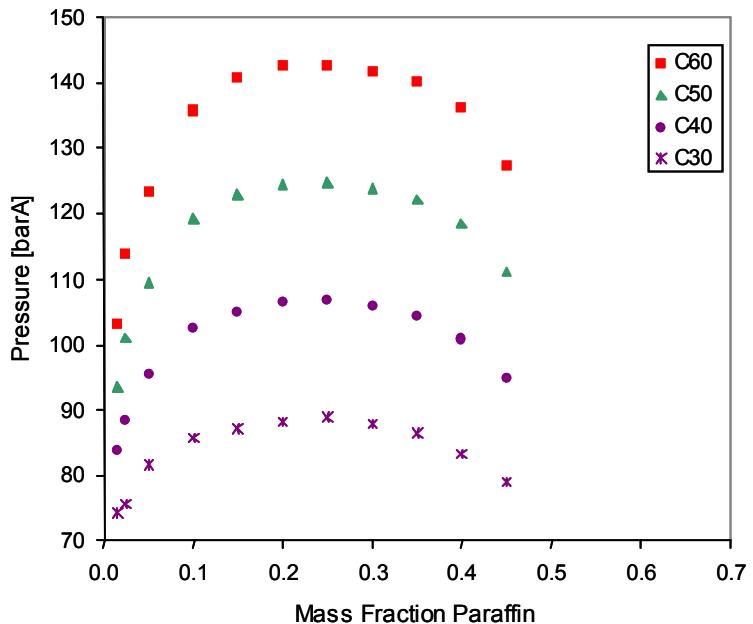

Figure 2. Phase equilibrium data for propane binaries at 135 °C [3].

Equations of state are fitted to the equilibrium data. An example is given in Figure 3. It was found that by using multiple interaction parameters, the cubic equations of state better reproduced the phase diagrams than the more complex equations of state based on statistical mechanics.

These cubic equation of state models were used to optimise the conceptual design of a supercritical fluid wax fractionation unit.

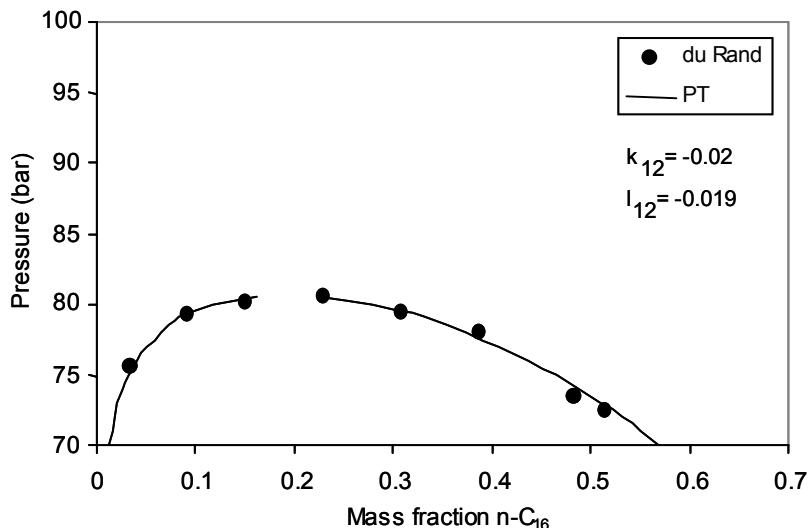

Figure 3. Ethane-hexadecane phase equilibria fitted with Patel-Teja EOS at 59.7°C [2].

### MEDIUM WAX FRACTIONATION

The Patel-Teja model was used to find the optimal conditions for fractionating medium wax ( $C_{16} - C_{36}$ ) with ethane. Supercritical fluid extraction experiments (with ethane as solvent) were conducted at the conditions predicted by the model [4]. The same fractionation was also experimentally done with short path distillation [4]. From Figure 4 it can be concluded that the fractionation in an optimised supercritical fluid extraction column is much better than in a single short path distillation unit.

Based on the experimental results, a conceptual design was done for a supercritical fluid extraction unit and a series of short path distillation units. The final product specifications of the units were identical. A model was also developed to model a wax crystallization unit [5]. A conceptual design of a crystallization unit, with the same product specifications, was also done. Whilst keeping an eye on the capital costs, energy integration was used to minimize the operating costs.

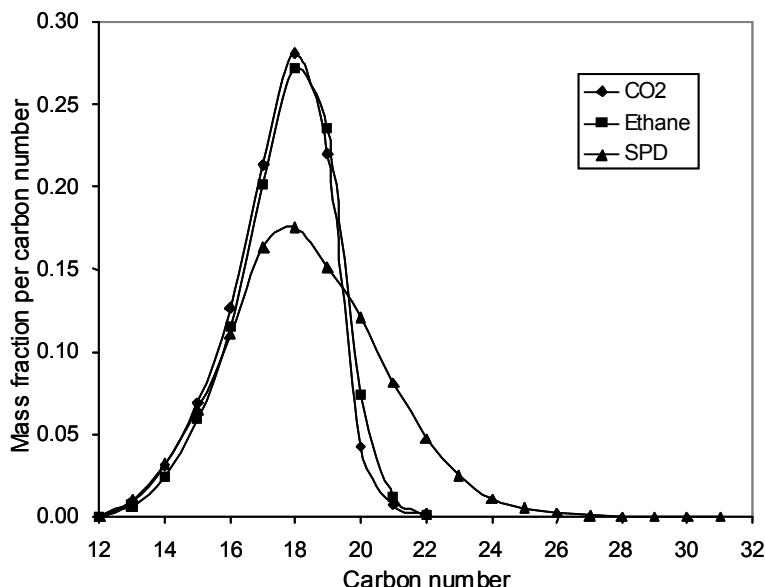

Figure 4. Comparison between the distillate cut sharpness of SCF with ethane or  $CO_2$  and Short Path Distillation.

The following results were obtained for a plant that fractionates 60 000 tons/a of medium wax into two products.

*Table 1. Cash Flow Analysis of Medium Wax Fractionation Conceptual Plant Designs.*

	SCFE	Crystallization	SPD
No of stages(units)	45	5	5
Feed Position	Mid. Column	3	2
Reflux Ratio	10.5	2	0.27
Capital Cost (million \$)	8.7	22.0	13.6
Utilities Cost (\$/ton product)	19	13	10
Internal Rate of Return	32.1	15.7	24.8
Pay Back Period	3.2	5.0	3.8

Both the supercritical fluid extraction and crystallization units are operated at approximately the melting point of the wax, which means that no thermal degradation takes place. The short path distillation unit is operated at approximately 160 °C (and a pressure of 40 Pa abs.). However, due to the high heat capacity of the ethane and the high ethane:feed ratio, the energy consumption of the supercritical extraction process is rather high. The energy consumption of the crystallization process is high as a result of the high heat of fusion and the limited opportunities for heat integration in a solids handling plant.

It is clear that the economics of the supercritical fluid extraction process is sound. The crystallization process has the advantage that it can preferentially remove the oily iso-paraffins from medium wax. However, if the aim is to fractionate n-paraffins, supercritical extraction must certainly be a contender.

## HARD WAX FRACTIONATION

As the molecular weight of the waxes become higher, the iso-paraffin content becomes less, which takes away the advantages of the crystallization process. In this case a comparison between supercritical fluid extraction and short path distillation is required. Models were fitted to equilibrium data, as well as to experimental supercritical fluid extraction and short path distillation data. These models were used to do a conceptual design of the two processes. The products from a single short path distillation unit and from a single supercritical fluid extraction column are shown in Figure 5. The supercritical extraction unit uses propane at 125°C (just above melting point) and 95 bar whereas the short path distillation unit uses a heat transfer fluid at 330°C and operates at a pressure of 20 Pa abs.

It is evident that the products from the supercritical extraction unit are superior to that of a single short path distillation unit. The high temperatures in the SPD unit may also cause degradation of the wax. The high temperature also has a negative impact on the utility consumption of the SPD unit. The economics of supercritical extraction of hard waxes will thus even be more favourable compared to that of short path distillation than is the case with medium wax (Table 1).

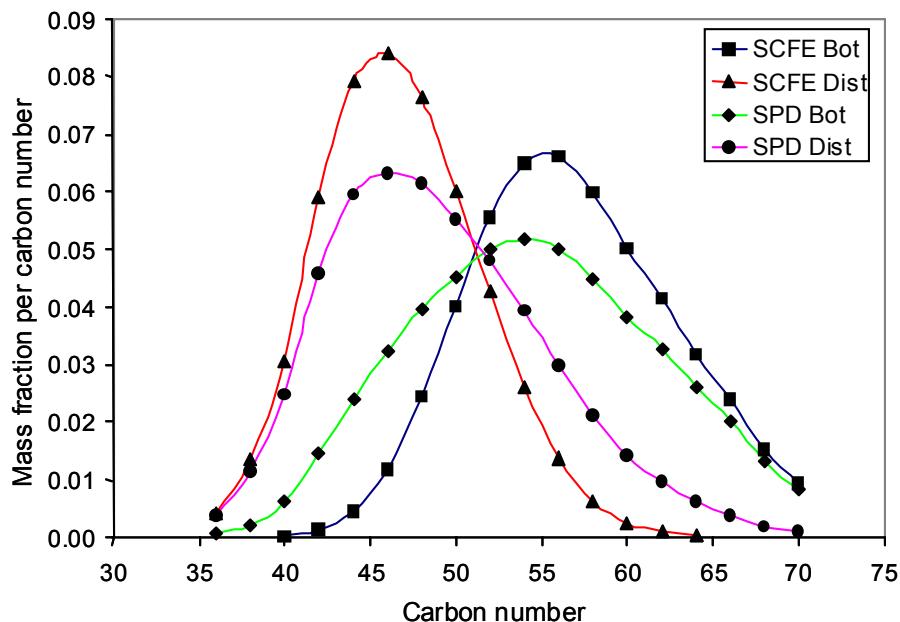

Figure 5. Comparison between the cut sharpness of SCF with propane and Short Path Distillation.

## CONCLUSIONS

The following conclusions can be drawn from this study:

- Several short path distillation or crystallization units are needed to give the same fractionation as a single supercritical extraction column.
- Crystallizations have an edge in waxes with a high iso-paraffin content since it fractionates based on melting points.
- The profitability of supercritical fluid wax fractionation units improve relative to that of the competing processes as the carbon number of the wax increases.
- For high molecular weight waxes supercritical fluid extraction should be the fractionation method of choice based on technical and economic considerations.

## NOVEL APPLICATION PERSPECTIVES FOR METAL EXTRACTANTS: OLEFIN SEPARATIONS

Bart A.E. Wentink, Patrick W.T. Krooshof, Norbert J.M. Kuipers,  
André B. de Haan and Harko Mulder\*

University of Twente, Enschede, The Netherlands  
\*Sasol Technology, Sasolburg, South Africa

Olefin separations are industrially important but energy intensive separations. Application of metal ligand complexes, based on ligands developed for the hydrometallurgy industry, can reduce the energy consumption of such separations. This concept is investigated experimentally by gravimetical measurement of the ethylene solubility. Silver complexed with the commercial ligand di(2-ethylhexyl)phosphoric acid diluted in dodecane, more than triples the ethylene solubility, compared to the situation without silver. However, the ethane solubility remained unaffected. Commercially viable separation factors are around 1.2, so the achieved selectivity of 2.4 is sufficient. Another ligand, Cyanex 301, diluted in dodecane and complexed with either copper(I) or silver(I) did not enhance the ethylene solubility.

### INTRODUCTION

The recovery and purification of olefins (e.g., ethylene, propylene or 1-butene) from hydrocarbon streams is a difficult and expensive operation. Selective and reversible olefin complexation by (transition) metal ions has been put forward as a possible alternative for conventional separations. In most cases, aqueous silver salt or organic copper(I) solutions are employed [1]. Disadvantages of these are the high vapour pressure of the applied solvent, the low metal solubility in hydrocarbons and an insufficient metal ion stability. This restrains the application on an industrial scale. These disadvantages can be overcome by complexation of the metal ion with an organic ligand. In this way the solubility in organic solutions and metal ion stability are increased, whereas the vapour pressure is reduced by application of a low boiling solvent.

In hydrometallurgy many complexing ligands have been developed for the recovery of metal ions from aqueous streams. These ligands are commercially available, widely applied, diverse and have a low vapour pressure. The right combination of metal ion, diluent and ligand is expected to yield a new range of olefin complexing media.

The feasibility of the proposed concept will be demonstrated in this paper by measurement of the ethylene solubility in dodecane containing the metal ion ligand complex. The investigated ligands are Cyanex 301 [di(2,2,4-trimethylpentyl)dithiophosphinic acid,  $(C_8H_{17})_2P(S)SH$ ] and D2EHPA [di(2-ethylhexyl)phosphoric acid,  $(C_8H_{17}O)_2P(O)OH$ ]. The metal ions used in this investigation are silver(I) and copper(I).

## $\pi$ -COMPLEXATION BETWEEN METAL IONS AND OLEFINS

The complexation of olefins by transition metal ions is described by the Dewarr-Chatt-Duncanson or  $\pi$ -complex model. A  $\pi$ -complex is composed out of two bonds, a  $\sigma$  and  $\pi$ -bond. The  $\sigma$ -bond is formed between the vacant  $s$ -orbital of the metal ion and the  $\pi$ -molecular orbital of the olefin, as illustrated in Figure 1. The empty metal ion  $s$ -orbital acts as a Lewis acid by accepting an electron from the olefin. The metal ion also acts as a Lewis base by back-donating electrons from its full  $d$ -orbital in the empty  $\pi^*$ -orbital of the olefin [1]. In principle, all transition metal ions can be used, but copper(I) and silver(I) ions exhibit a strong but reversible reaction.

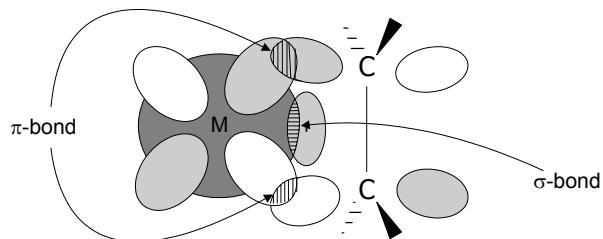

Figure 1.  $\pi$ -Complex formation between transition metal ion (M) and olefin [1].

## GAS ABSORPTION

The overall ethylene ( $C_2^-$ ) solubility ( $S_{C_2^-}$ ) in solvents containing metal ion ligand complexes that are capable of  $\pi$ -complexation is equal to the sum of the physical solubility and the solubility as a result of the  $\pi$ -complexation reaction. The physical solubility of ethylene is described by means of a Henry coefficient ( $H_{C_2^-}$ ). The  $\pi$ -complexation of ethylene with the metal ion ligand complex is described as a equilibrium reaction ( $K_r^{C_2^-}$ ), as indicated in Figure 2.

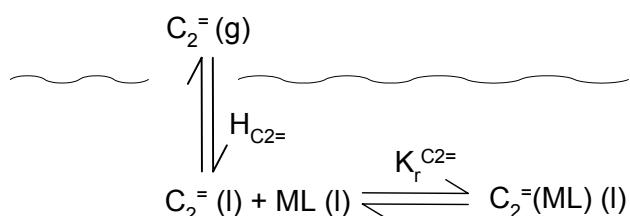

Figure 2. Ethylene solubility in liquids with  $\pi$ -complexation with metal ligand complexes.

Based on the processes shown in Figure 2, Equation (1) has been derived, describing the ethylene solubility as a function of the ethylene pressure ( $P_{C_2^-}$ ) and initial metal ion complex concentration  $[\text{ML}]_0$ . It is assumed that the reaction stoichiometry between ethylene and metal ion-ligand complex is 1:1.

$$S_{C_2^-} = \frac{P_{C_2^-}}{H_{C_2^-}} \left( 1 + \frac{K_r^{C_2^-} [\text{ML}]_0}{1 + (K_r^{C_2^-} P_{C_2^-}) / H_{C_2^-}} \right) \quad (1)$$

The model parameters were determined from the experimentally observed ethylene solubilities of two experiments. Henry's coefficient was estimated using a solution of metal free ligand in dodecane. From the determined Henry coefficient, the equilibrium constant was determined by fitting equation (1) to the experimental solubilities.

## EQUIPMENT AND PROCEDURES

All silver complexes were synthesised by liquid-liquid extraction. In the liquid-liquid extraction, equal volumes of the organic ligand (in dodecane) and aqueous silver nitrate solution were mixed for approximately 1 h using a magnetic stirrer. The equilibration time differed from ligand to ligand, but is well below the time used. Samples of the organic phase were taken ( $\pm 5$  ml) for analysis of the metal content by atomic absorption spectrophotometry (AAS).

The copper complexes were synthesised by liquid-liquid extraction or by reacting an (acidic) ligand with solid copper(I) oxide. The liquid-liquid extraction for copper is similar to the method described for silver. In the oxide method, a molar excess of cuprous oxide ( $Cu_2O$ ) was reacted with an acidic ligand in dodecane under continuous flowing nitrogen. After the reaction, the excess oxide settled and liquid samples were taken to determine the metal content.

The ethylene ( $C_2H_4$ ) solubility was determined with an Intelligent Gravimetric Analyser (IGA, model 003, Hiden Analytical). The IGA was originally designed to measure the gas uptake by solids, but was adapted to study gas absorption (for more details on the IGA, see [2, 3]). Typically a sample of 0.5 g metal ion ligand complex (in dodecane) was used, held in a Pyrex-glass sample holder. Pressure steps of approximately 0.6 bar were used at a constant temperature ( $25^\circ C$ ) to determine the absorption isotherms. The temperature was controlled by a Julabo (F32 MP) water bath to within  $\pm 0.2^\circ C$ . A typical IGA run lasted around 4000 min.

Ethylene (99.95%) was acquired from Praxair,  $AgNO_3$ ,  $Cu_2O$ ,  $CuSO_4$  and dodecane ( $C_{12}H_{26}$ ) from Aldrich, and D2EHPA (95%) from Merck. Cyanex 301 (77.2%) was a gift from Cytec Industries Europe. All chemicals were reagent grade, except when noted, and used as received. In the reported Cyanex 301 concentration the impurities were neglected.

## SELECTION OF ORGANIC EXTRACTANTS (LIGANDS)

In hydrometallurgy many complexing ligands have been developed that have the potential to be used in olefin complexation. The main criterion for a first selection was that the organic ligand must be able to complex either copper(I) or silver(I). Additional criteria were that the organic ligand must be thermally stable and if possible form a strong bond with the metal. The selected ligands are shown in Figure 3.

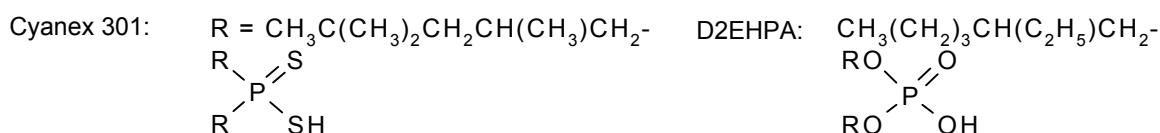

Figure 3. Selected ligands.

Cyanex 301 exists in the organic phase as a monomer, forms strong bonds with copper and silver and reacts with a metal:ligand ratio of 1 [5, 6]. It is claimed that Cyanex 301 reduces copper(II) to copper(I) upon extraction [5]. This is advantageous, because copper(I) complexes olefins and copper(II) does not. Furthermore, Cyanex 301 easily extracts copper(II) or silver(I) at a pH below 2, that facilitates the synthesis of complexes with these metals. D2EHPA forms dimers in the organic phase because of hydrogen bonding [10]. Therefore the metal:ligand molar ratio is 1:2 [10]. D2EHPA extracts silver(I) at a pH of approximately 5, due to its higher  $pK_a$  value. This complicates the synthesis of these complexes. The bond between metal and oxygen is weaker compared to the metal-sulphur bond, possibly resulting in a lower metal ion-ligand complex stability. The extraction of Cu(I) by D2EHPA or Cyanex 301 is not described in the literature.

## RESULTS

### IGA Method Verification

Figure 4 presents the ethylene solubility in pure dodecane as a function of pressure. The results from the IGA accurately correspond with the literature results. The calculated Henry coefficient for both the literature and IGA solubility data is reported in Table 1 and deviates approximately 1%.

### Oxygen-Containing Ligands

The effects of  $\pi$ -complexation on the ethylene solubility are illustrated in Figure 4. The silver/D2EHPA-complex almost triples the ethylene solubility, compared to the situation of only D2EHPA in dodecane, and more than doubles the solubility compared to pure dodecane. The ethane solubility, however, remained unaffected by the silver complex. The curved nature of the ethylene solubility isotherm is indicative for the  $\pi$ -interaction between silver and ethylene and is typical for a system with a combination of chemical complexation and physical solubility [9]. The addition of D2EHPA to dodecane reduced the ethylene solubility. It is believed that this is due to the enlarged liquid polarity, as a result of the functional group of the D2EHPA. The absorption curves of ethylene and ethane in D2EHPA/dodecane are straight, typical for only physical solubility and in accordance with Henry's law [8]. The selectivity of ethylene over ethane varied with pressure and was between 1.9 and 1.4.

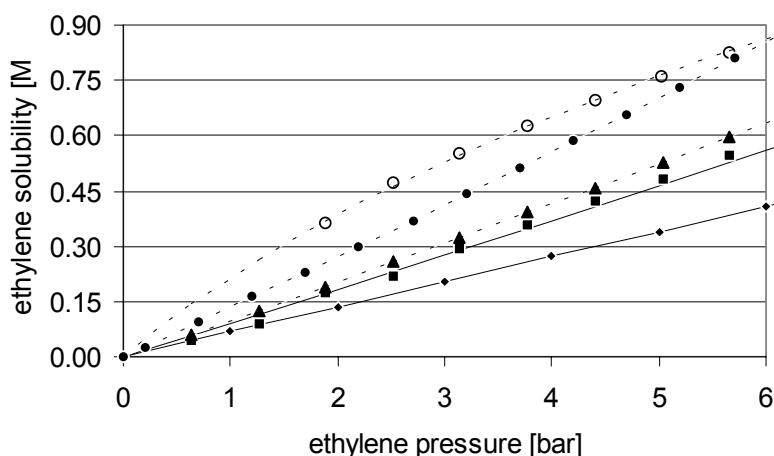

Figure 4. Ethylene and ethane solubility isotherm at 298 K. Ethylene in: (■) pure dodecane; (—) pure dodecane literature [4]; (—◆—) 2 M D2EHPA/dodecane; (○), (···) 0.79 M Ag/2 M D2EHPA/dodecane experimental & model. Ethane in: (··●··) pure dodecane literature [11]; (··▲··) 0.79 M Ag/2 M D2EHPA/dodecane.

### Model Results

The model can accurately describe the ethylene solubility, for the reactive and non-reactive situation, as displayed in Figure 4. The corresponding parameters are given in Table 1.

Table 1. Henry coefficients and equilibrium constant of ethylene and ethane.

	$H_{C_2^=}$ [bar·M <sup>-1</sup> ]	$K_r^{C_2^=}$ [M <sup>-1</sup> ]
ethylene dodecane [4]	10.8	--
ethylene dodecane	10.7	--
ethylene 2 M D2EHPA/dodecane	14.7	--
ethylene 0.79 M Ag/2 M D2EHPA/dodecane	14.7	3.4
ethane 2 M D2EHPA/dodecane	9.6	--

## Sulphur-Containing Ligands

Figure 5 presents the ethylene solubility in solutions of Cyanex 301 complexed with or without copper or silver in dodecane. Two copper-containing solutions were measured, a solution with 0.44 M copper synthesised by liquid-liquid extraction and a solution with 0.88 M copper synthesised by the oxide method.

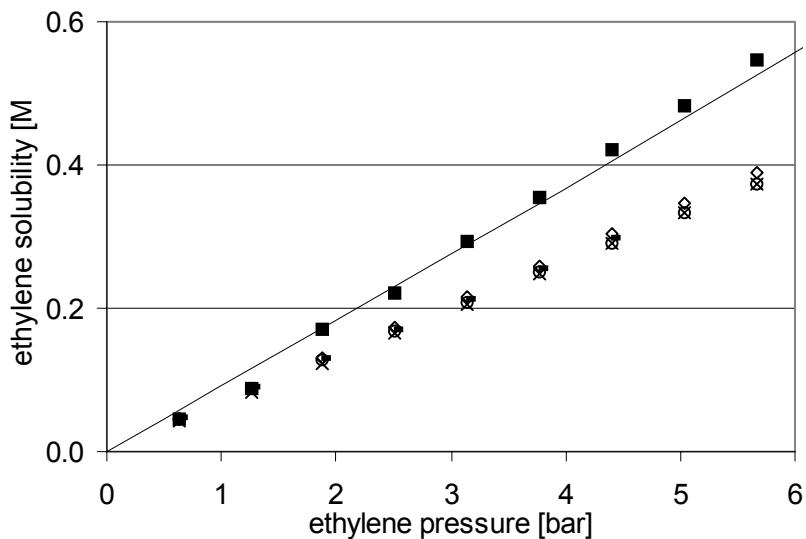

Figure 5. Ethylene solubility at 298 K in: (■) pure dodecane; (—) pure dodecane literature [4]; (◊) 1 M Cyanex 301/dodecane; (×) 0.44 M Cu/1 M Cyanex 301/dodecane; (○) 1.0 M Ag/1 M Cyanex 301/dodecane; (∗) 0.88 M Cu/1 M Cyanex 301/dodecane.

Again, the solubility of ethylene is reduced by the presence of the organic ligand. However, in contrast to the silver/D2EHPA-complex, the introduction of copper(I) or silver(I) complexed with Cyanex 301 does not enhance the ethylene solubility. Apparently, the metal ion is inhibited by Cyanex 301 from forming a  $\pi$ -bond with the olefin. The reasons for this could be the redistribution of electrons around the metal ion, steric hindrance of the ligand or a combination of both.

The complexation of copper(I) involves  $\pi$ -bonding of metal *d*-orbitals and sulphur atom orbitals that alter the electron structure of copper(I) [7]. It is claimed, however, that for silver(I),  $\pi$ -bonding does not play a significant role [7]. So, in case of copper the electron delocalisation might lead to a reduced affinity towards ethylene, but for silver it can be expected that this is of less importance. Another possibility is the formation of multinuclear complexes of Cyanex 301 with copper or silver [5, 6], as shown in Figure 6.

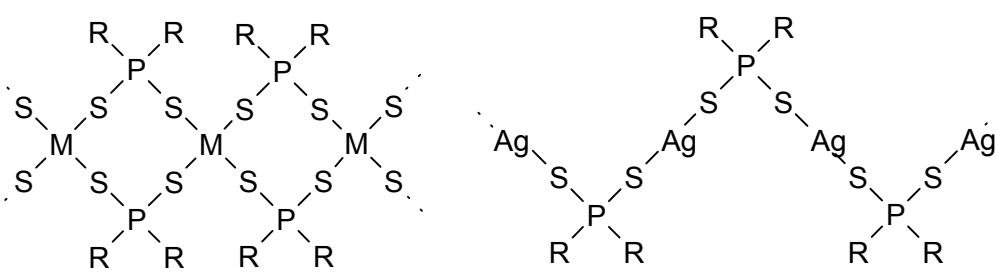

Figure 6. Metal-Cyanex 301 complex structure ( $M = \text{Cu}(\text{I})$  or  $\text{Ag}(\text{I})$ ) [5,6].

Copper(I) forms tetrahedral complexes, as is shown in the left part of Figure 6. Opposite to copper(I), silver(I) forms four-coordinate tetrahedral complexes less readily than two-coordinate linear ones [12]. Consequently, the linear complex structure as shown in the right

part of Figure 6 was suggested [6]. However, the formation of a four-coordinated complex with silver can not be excluded. The formation of these multinuclear complexes could result in steric hindrance of the metal ion that inhibits the formation of  $\pi$ -complexes between metal ion and ethylene. It is a phenomenon that occurs for both metals, which is in accordance with the observed ethylene solubility. Further investigation of sulphur-containing complexes that do not form multinuclear complexes might clarify this.

## CONCLUSIONS

It has been demonstrated that olefin/paraffin separations are a novel application for ligands that were developed for extractive hydrometallurgy. If the ligand is complexed with a suitable metal ion, the olefin solubility can be increased by selective  $\pi$ -complexation. The metal ion is stabilised by the ligand and can be solvated in a useful (high) concentration. The effects of such complexes on the ethylene solubility were investigated experimentally, using a gravimetical method.

Pure dodecane already has an intrinsic selectivity for ethane over ethylene, due to differences in polarity. The achieved selectivity is approximately 0.7, based on the ratio of the physical solubility of ethylene over ethane. The addition of the silver/D2EHPA complex, however, raises the solubility of ethylene by a factor of almost three without affecting the ethane solubility. The increase in selectivity between the presence and absence of the complex is more then three. The achieved selectivity of ethylene over ethane is 2.4, which is sufficient for the separation of ethylene from ethane with the developed metal ligand complex.

The use of ligands is not always beneficial, as is the case with Cyanex 301 that is complexed with copper(I) or silver(I). The ligand inhibits the metal ion from forming  $\pi$ -complexes with silver and consequently the ethylene solubility is not enhanced. Metal complexes with this ligand are therefore unsuitable for the separation of ethylene from ethane.

## ACKNOWLEDGEMENTS

Sasol Technology is thanked for their financial support of the project and permission to publish this paper. Cyanex 301 was a gift from Cytec Industries.

# HYDRODYNAMIC BEHAVIOUR IN PACKED COUNTERCURRENT COLUMNS FOR SUPERCRITICAL FLUID EXTRACTION

Gerd Brunner and Ron Stockfleth

Technische Universität Hamburg-Harburg, Hamburg, Germany

The hydrodynamic behavior, *i.e.*, flooding, liquid holdup, and pressure drop of countercurrent columns with two random packings, Raschig Rings and Berl Saddles, and two gauze packings, Sulzer CY and Sulzer EX, is scrutinized at temperatures between 313 K and 373 K and pressures between 8 MPa and 30 MPa using carbon dioxide as supercritical solvent and water and olive oil deodorizer distillate as liquid phases. The behaviour of falling films at high pressures is examined. A general predictive approach to flooding based on sophisticated mechanistic models is developed. Parameters in this correlation have to be fitted for each packing. Therefore, a more general empirical approach has been employed. The resulting correlation represents measured flooding point data for a variety of packings, fluid substances and mixtures within a standard deviation of 19%.

## INTRODUCTION

In recent years supercritical fluids have been introduced as a mass-separating agent for various separation processes. For liquid feeds, supercritical fluid extraction can most effectively be carried out using a continuous countercurrent process. For the design of countercurrent columns knowledge about the hydraulic capacity and the flow regimes of the packed column is required. Correlations would enable the reduction in number of experiments. The objective was the examination of the hydrodynamic behaviour, that is, flooding, liquid holdup, and pressure drop of columns with random and regular packing. The falling film on the packing is of major importance and was therefore investigated in true liquid-fluid countercurrent flow. The influence of mass transfer was eliminated by equilibrating the phases before contacting them countercurrently. Knowledge about the hydraulic capacity of the packed column is important to determine the inner diameter that will be needed for the countercurrent throughput of the required amounts of solvent and feed without flooding the column.

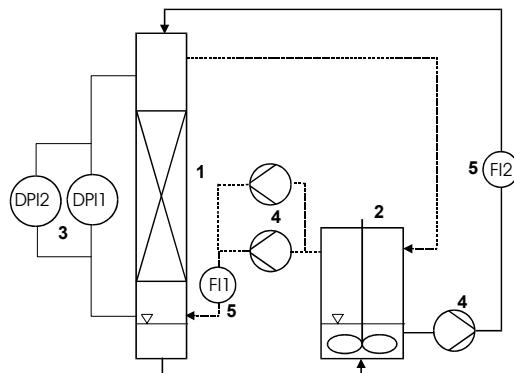

## EXPERIMENTAL

### Apparatus

The apparatus shown in Figure 1 is operated at pressures between 8 and 30 MPa and temperatures between 313 and 373 K. It consists of two main parts: the 1.89 m high column with four long windows filled with up to 0.9 m packing and an equilibrium autoclave, equipped with a stirrer. The bottom segment of the column is also equipped with a long window to allow the continuous monitoring of the liquid level [1].

## Methods, Substances And Experimental Conditions

The coexisting phases are brought into equilibrium by circulating and stirring to observe the hydrodynamic phenomena independently of mass transfer phenomena. Three high-pressure gear pumps (two for the supercritical phase and one for the liquid phase) convey the two phases from the autoclave to the column and back into the autoclave after passing through the packing [2].

*Figure 1. Flowsheet of the experimental apparatus. 1, column; 2, autoclave; 3, differential pressure transducers; 4, gear pumps; 5, flow meters; full line, liquid cycle; dashed line, supercritical fluid cycle.*

The hydrodynamic behaviour, *i.e.*, flooding, liquid holdup, and pressure drop of countercurrent flow in the column was investigated for two random packings, Raschig Rings and Berl Saddles, and two gauze packings, Sulzer CY and Sulzer EX, at temperatures between 313 K and 373 K and pressures between 8 MPa and 30 MPa using carbon dioxide as supercritical solvent and water and olive oil deodorizer distillate as liquid phases.

With respect to the behaviour of falling films at high pressures, film thickness, flow regimes, and flooding points for countercurrent annular flow of corn oil (Mazola<sup>TM</sup>) and carbon dioxide at 338 K and pressures between 7.6 and 20.6 MPa were examined experimentally. The film flows down a stainless steel rod with a diameter of 10 mm and a length of 1000 mm that is inserted in a glass tube with an internal diameter of 15 mm yielding an annulus of 2.5 mm. The glass tube is placed within the high-pressure column.

## A UNIVERSAL PREDICTIVE APPROACH TO FLOODING

At constant gas velocity the pressure drop as a function of the superficial liquid velocity first rises slightly and then abruptly with increasing liquid velocity. This abrupt change in pressure drop is a typical indicator for flooding. Liquid holdup as a function of the superficial liquid velocity exhibits the same behavior.

There are numerous possible definitions and criteria for the flooding point of a countercurrent column. Throughout this paper a liquid layer of 50 mm height on the uppermost packing element is the indicator for a flooding point. Most sophisticated semi-mechanistic models for the hydraulic capacity use the interdependence of liquid holdup and pressure drop to quantify the flooding point. These models follow a modular approach. First, the dry pressure drop and the holdup below the loading point are described. That means the interaction of a single phase with the packing is modeled. Then, the holdup beyond the loading point and the pressure drop of the irrigated packing are specified. These two phenomena are coupled, *i.e.*, pressure drop depends on holdup since this determines the free area available to the gas flow and the holdup depends on the pressure drop because this is a measure for the shear

force the gas flow exerts on the liquid. A consequence of the coupled equations is, that the solution is cumbersome because it involves iterations. With these equations the flooding point can be determined as the point where the derivative of the holdup with respect to the dry pressure drop, which is a measure for the gas velocity, becomes infinity.

### Dry Pressure Drop

Experimental studies [3] of the single-phase flow through fixed beds of varying porosity (0.3 – 0.75) suggest that the friction factor  $\psi$  is proportional to  $\varepsilon^{4.55}/(1-\varepsilon)$ . This is slightly different from Ergun's result [4] stating that  $\psi \sim \varepsilon^3/(1-\varepsilon)$ . Since the latter did not vary the porosity to the extent of the former, the following friction factor as suggested by Stichlmair *et al.* [5] according to Rumpf is used.

$$\psi = \frac{4}{3} \frac{\Delta P_0 \varepsilon^{4.65} d_p}{H(1-\varepsilon) \rho_G u_G^2} = f \left( \text{Re}_G = \frac{u_G d_p \rho_G}{\eta_G} \right) = \frac{K_1}{\text{Re}_G} + K_2, \quad (1)$$

with  $\Delta P$  as the pressure drop,  $H$  the height of the packing,  $\rho_G$  the density of the gas,  $\eta_G$  its viscosity, and  $u_G$  its velocity. Due to the limited accuracy and quantity of the experimental data a simple function of the Ergun-type was chosen to describe the dependence of the friction factor on the Reynolds number of the gaseous phase. The correlations obtained are:

$$EX : \psi = \frac{155}{\text{Re}_G} + 3.4, \quad Raschig, Berl : \psi = \frac{23}{\text{Re}_G} + 1.2, \quad CY : \psi = \frac{23}{\text{Re}_G} + 0.2 \quad (2)$$

### Holdup below the Loading Point

The loading point is the point at which the two phases flowing through the packing start to interact. Below the loading point the liquid flows through the packed bed as if there was no other phase flowing countercurrently. So, the holdup below the loading point describes the sole interaction of the liquid with the packing in the same way as the dry pressure drop describes the sole interaction of the gas with the packing. The total liquid holdup consists of two contributions: the dynamic or operating holdup and the static holdup. The static holdup is liquid trapped in gussets and attached to the packing by adhesive forces. It will not drain from the packing and remain there until removed by some other means. The dynamic or operating holdup is the liquid that will drain if the liquid pump is shut off. The following function was used to correlate the holdup to  $\text{Re}_L$  and  $Fr_L$ :

$$h_0 = C_1 \left( \frac{Fr_L^2}{\text{Re}_L} \right)^{C_2}, \quad Fr_L := Fr_L^* \frac{\rho_L}{\Delta \rho} = \frac{u_L^2 a \rho_L}{g \Delta \rho} \quad (3)$$

where  $h_0$  denotes the dynamic liquid holdup below the loading point. The Reynolds number relates the inertial force to the viscous force and the Froude number rates the inertial force to the gravitational force.  $C_1$  and  $C_2$  are parameters obtained by fitting calculated to measured data. This approach contains already a simplification; the more general approach would raise each dimensionless number to a different unknown power. The holdup below the loading point correlated with the modified Froude number  $Fr_L$  taking the buoyancy into account results in an absolute standard deviation of 1.8 % with  $C_1 = 1.6$  and  $C_2 = 0.23$  for Raschig rings, Berl saddles and Sulzer EX. The Sulzer CY packing requires a correlation different from the one valid for the other packings:  $C_1 = 1.1$  and  $C_2 = 0.25$  with an absolute standard deviation of 0.5 %.

### Holdup and Pressure Drop beyond the Loading Point

Above the loading point the holdup and pressure drop are no longer independent of each other. The liquid holdup decreases the available free cross-sectional area available for the gas flow thereby increasing the local gas velocity and the pressure drop. The pressure drop is a measure for the interfacial shear force the gas exerts on the liquid – the higher this force the higher the liquid holdup. In this paper the authors follow the suggestion of Stichlmair *et al.* [5] for the interdependence of holdup and pressure drop.

$$h = h_0 \left[ 1 + C_3 \left( \frac{\Delta P}{H \Delta \rho g} \right)^{C_4} \right] \quad (4)$$

$$\frac{\Delta P}{\Delta P_0} = \frac{\left\{ \left[ 1 - \varepsilon \left( 1 - \frac{h}{\varepsilon} \right) \right] / (1 - \varepsilon) \right\}^{2+c}}{\left( 1 - \frac{\varepsilon}{h} \right)^{4,65}} \quad (5)$$

$$c := \frac{-K_1}{\psi} \quad (6)$$

$K_1$  is the constant from equation 1 and  $\psi$  the friction factor that would result if there were no liquid flow, *i.e.*, the dry friction factor. Equation 6 relates the holdup beyond the loading point to the holdup below the loading point and the reduced pressure drop. The reduced pressure drop is the ratio of the force the gas flow exerts on the liquid to the total static head of the liquid. In analogy to fluidized beds a force balance yields that the upper limit for the reduced pressure drop is the liquid holdup, because this would mean that the force the gas flow exerts on the liquid suspends the entire liquid in the column. As already pointed out earlier, the difference of the densities has to be used instead of the liquid density to account for the significant buoyancy force exerted on the liquid by the dense gas.  $C_3$  and  $C_4$  are parameters obtained by fitting calculated to experimental data. Since pressure drop and holdup have also been measured above the loading point,  $C_3$  and  $C_4$  can be obtained directly. The fitting procedure yielded a relative standard deviation of 17.15 % for  $C_3 = 4.1$  and  $C_4=2.0$  with constant  $C_4$  and a relative standard deviation of 17.05 % for  $C_3 = 5.5$  and  $C_4=2.3$  with variable  $C_4$ . However, since these parameters have a significant impact on the calculation of the flooding point, it was also tried to fit  $C_3$  and  $C_4$  to the measured flooding points, as described in the following.

### Flooding

The flooding point is reached if a finite change in gas or liquid velocity leads to an infinite change in pressure drop or holdup. The dry pressure drop is a measure for the gas velocity and the flooding criterion can be formulated as [5]:

$$\frac{\partial \Delta P}{\partial \Delta P_0} = \infty \quad \Leftrightarrow \quad \frac{\partial \Delta P_0}{\partial \Delta P} = 0 \quad (7)$$

Substituting equation 6 for the holdup into equation 7 then inverting it and taking the derivative, yields:

$$\left(\frac{\Delta P}{H\Delta\rho g}\right)^{-C_4} - \frac{4,65C_3C_4h_0}{\varepsilon - h_0 \left[1 + C_3 \left(\frac{\Delta P}{H\Delta\rho g}\right)^{C_4}\right]} - \frac{\frac{2+c}{3}C_3C_4h_0}{1 - \varepsilon + h_0 \left[1 + C_3 \left(\frac{\Delta P}{H\Delta\rho g}\right)^{C_4}\right]} = 0 \quad (8)$$

Equation 8 has to be solved iteratively. The flowsheet for the calculation of a flooding point is displayed in Figure 2. Considering the limited success of the universal predictive approach outlined in the previous paragraphs, an alternative empirical approach is presented as well.

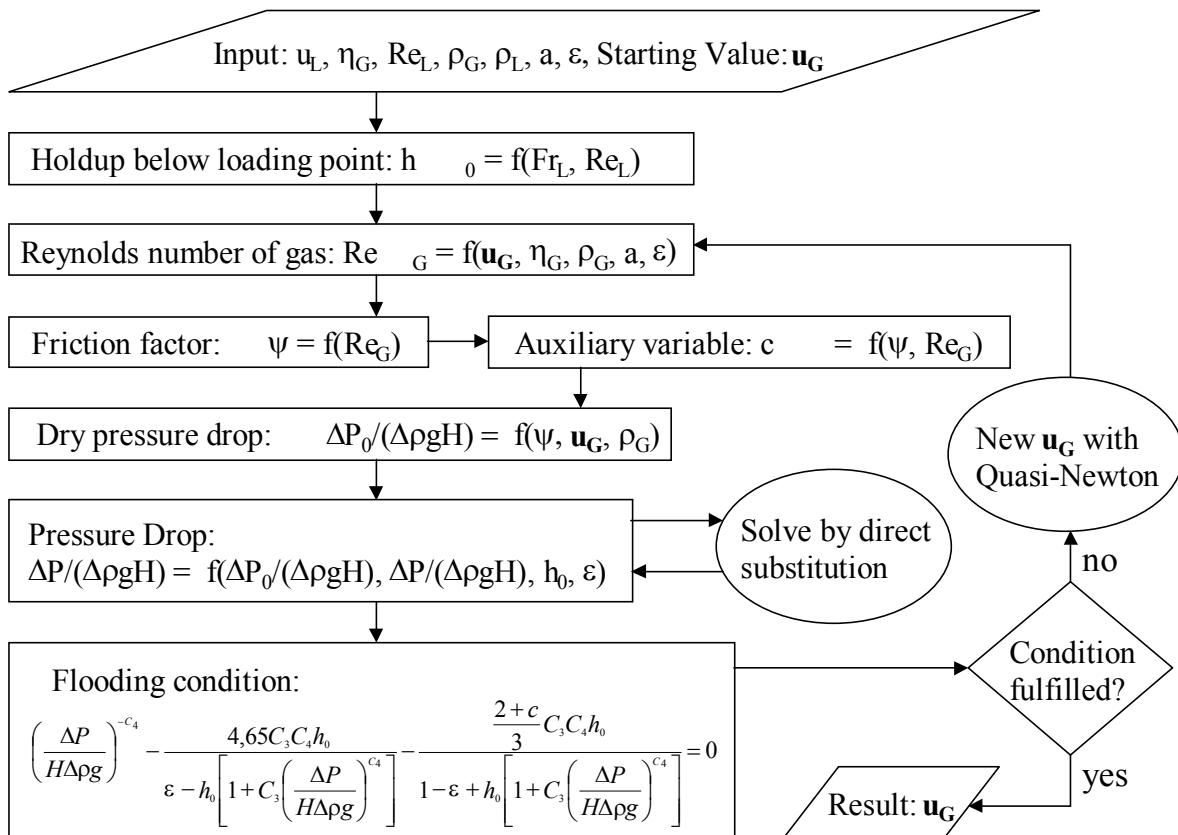

Figure 2. Flowsheet for the calculation of the flooding point.

## A UNIVERSAL EMPIRICAL APPROACH TO FLOODING

### A Falling Film At High Pressures

The flow regime of a falling film is an important asset for the design of gas-liquid contacting devices, because it determines the interfacial area, the rate of its renewal, and the mixing and backmixing of the liquid phase. In countercurrent annular flow the liquid flows downwards in different flow regimes: smooth, waves, crests, or droplets. The gas flows upwards and exerts a shear force on the liquid. The magnitude of this force depends on the momentum of the gas flow, its physical properties and the topology of the interfacial area. Both phases interact and this may lead to flooding if the annular area is too small to allow the countercurrent flow of both phases.

Film thickness, flow regimes, and flooding points for countercurrent annular flow of corn oil (Mazola<sup>TM</sup>) and carbon dioxide at 338 K and pressures between 7.6 and 20.6 MPa are examined experimentally. The film flows down a stainless steel rod with a diameter of 10 mm and a length of 1000 mm that is inserted in a glass tube with an internal diameter of 15 mm yielding an annulus of 2.5 mm. The film thickness adheres to Nusselt's equation [6] for smooth water films. With increasing liquid flow rate the falling film exhibits the following flow regimes: wavy film, troughs/crests on the film, drop formation, and flooding. The countercurrent gas flow affects the flow regime of the liquid film. The flooding points for the falling film column can be correlated with the same equation as the flooding points for packed columns with various packings and fluids at different states (high and ambient pressure).

### Film Thickness And Transition Between Different Flow Regimes

Nusselt's equation [6]  $\psi_L = \frac{6}{Re_L}$  describes the measured film thickness with acceptable accuracy. The borderlines between the flow regimes waves - troughs/crests and troughs/crests - drops can be shown in a  $Re_L$ - $K_F$ -diagram as suggested by Grimley [7]. The data for the crest-drop-transition can be described with decent accuracy using Moser's correlation [8]:

$$Re_L = 0.84 K_F^{0.18} \quad . \quad (9)$$

It is obvious that the gas flow has a significant impact on the flow regime of the liquid film. The gas flow exerts a shear force on the liquid film and this affects the shape of the interface, i.e., the flow regime.  $F_{shear} \approx \tau H d_H$ , where  $\tau$  is the shear stress,  $H$  the height of the film and  $d_H$  its hydraulic diameter, in this case the difference between rod diameter and inner diameter of the glass tube (5 mm). The gas flow exerts the following force on the liquid surface:

$F_{gas} \approx \Delta P d_H^2$ , where  $\Delta P$  is the pressure drop. If the shear force the gas exerts on the inner wall of the glass tube is neglected, a force balance yields:  $F_{gas} = F_{shear} \Rightarrow \tau \approx \Delta P \frac{d_H}{H}$ .

The shear stress in the liquid surface is proportional to the pressure drop. Rating the pressure drop to the impact pressure of the gas flow gives the dimensionless gas resistance

factor  $\psi_G$ :  $\psi_G = \frac{\Delta P d_H}{\rho_G (u_G - u_L)^2 H}$ , where  $u_G - u_L$  is the slip velocity. The influence of the gas

flow on the flow regime was taken into account by using the property  $Re_L(1+\psi_G)^n$  instead of  $Re_L$  as in Figure 3. For the exponent the value of  $n = 1/3$  yielded the best coincidence between transition points with and without countercurrent gas flow. The newly introduced ordinate appropriately accounts for the impact of the gas flow on the transition of the flow regimes.

### Flooding

For the correlation of the flooding points an approach dating back to Wallis [10] was employed.

$$j_G^* = f(j_L^*); \quad j_G^* = \frac{u_G}{\varepsilon} \sqrt{\frac{\rho_G}{g d_H (\rho_L - \rho_G)}}; \quad j_L^* = \frac{u_L}{\varepsilon} \sqrt{\frac{\rho_L}{g d_H (\rho_L - \rho_G)}} \quad (10)$$

With  $u_L$  for the superficial liquid velocity and  $\varepsilon$  the fractional void volume which is unity for a falling film column but smaller than unity for packed columns.  $j_G^*$  and  $j_L^*$  are modified Froude numbers rating the respective impact pressure to the difference between liquid head and buoyancy. Figure 6 shows that flooding diagram, which is only marginally different to that proposed by Sherwood *et al.* [9] where  $j_G^*$  is a function of  $\phi$ . Figure 4 displays various flooding data for packed columns for a variety of packings (Sulzer CY, Sulzer EX, Sulzer Mellapak, 5 x 5 x 0.5 mm Raschig rings, and 4 mm Berl saddles) and substances (water, air, carbon dioxide, olive oil deodorizer distillate, soybean oil deodorizer distillate, fatty acid methyl esters, and tocopherols) and the flooding data of the falling film column. A flooding point correlation as suggested by Wallis [10] was employed.

$$\sqrt{j_G^*} + K_1 \sqrt{j_L^*} = \sqrt{K_2} \Leftrightarrow j_G^* = \frac{K_2}{(1 + K_1 \sqrt{\Phi})^2} \quad (11)$$

with  $K_1$  and  $K_2$  as dimensionless parameters.

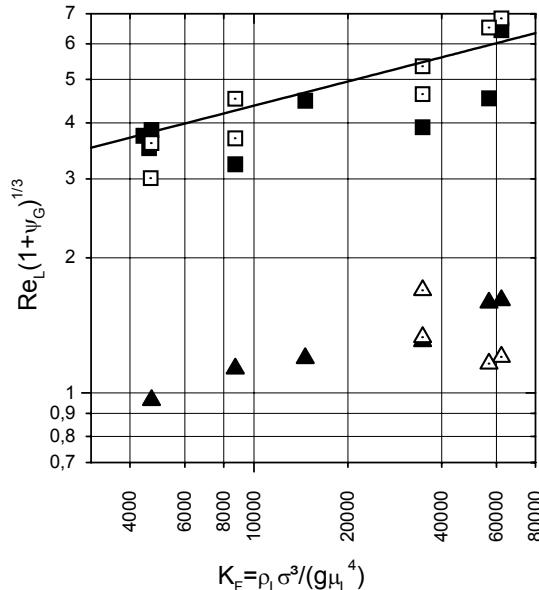

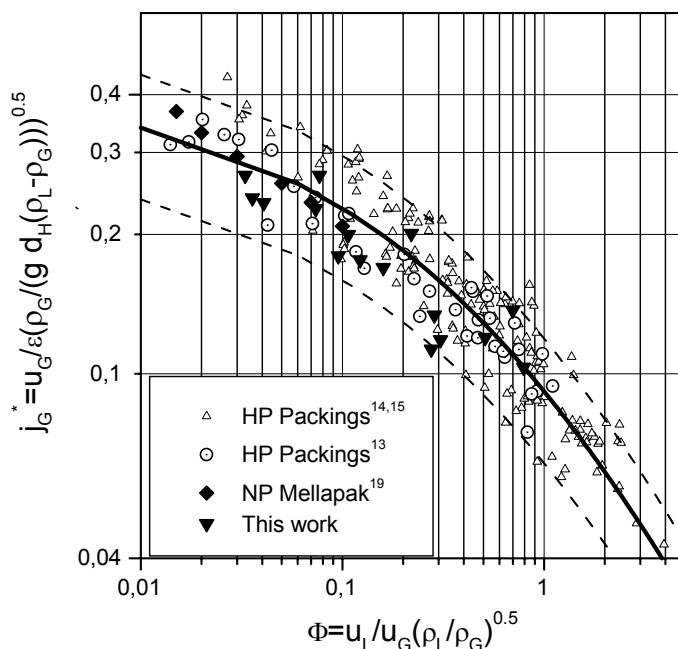

Figure 3. Flow regimes: New diagram accounting for shear stress. ■, drop formation without gas flow; □, drop formation with gas flow; ▲, crest formation without gas flow; △, crest formation with gas flow; line, Moser's correlation [8].

For the correlation of the data displayed in Figure 4, the values  $K_1 = 0,4222$  and  $K_2 = 1,1457$  resulted in a relative standard deviation of 19 %. This is an acceptable value, especially if considering that only one set of parameters for Equation 11 correlates the flooding points for a wide variety of geometries (structured packings, random packings and falling film columns), substances and states (temperature, pressure).

## CONCLUSIONS

Hydrodynamic behaviour of countercurrent columns at high pressure can be described with models developed for normal pressure if density of the gaseous phase is taken into account. This phase produces significant buoyancy that reduces the static head of the liquid. Dry pressure drop can be modeled with an Ergun-type equation. Liquid holdup below the loading point is correlated with one set of parameters of a two-parameter expression using the Reynolds and Froude numbers of the liquid phase. Falling film thickness can be described with the Nusselt's equation. Flooding points could not be predicted in general with a mechanistic model of solid physical background. A modified empirical flooding diagram from Sherwood, Shipley and Holloway and the flooding equation proposed by Wallis for vertical pipes are suitable to correlate the measured flooding points with sufficient accuracy.

*Figure 4. Flooding diagram. Thick line, correlation; dashed lines,  $\pm 30\%$  interval;  $\Delta$ , structured and random packings at high pressures;  $\circ$ , structured packings at high pressures;  $\blacklozenge$ , Mellapak<sup>TM</sup> at normal pressure;  $\blacktriangle$ , falling film flooding at high pressures.*

## A CASE STUDY OF AN INDUSTRIAL PACKED COLUMN DESIGN USING SINGLE DROP MASS TRANSFER DATA

P. Barnard, M. J. Slater\* and X.-P. Wu

A.H. Marks and Company Ltd., Bradford, United Kingdom  
\*University of Bradford, Bradford, United Kingdom

Drop mass transfer coefficients have been measured for an industrial extraction system in a rising drop column and a counter-current packed bed of 150 mm diameter, 1.8 m packing height. The drop interaction, break-up and coalescence in a packed column can all be expected to enhance the mass transfer coefficients by virtue of mixing of drop contents and because of shortening of drop life-times. However in this case drop mass transfer coefficients for the packed column had values corresponding to those for drops with long life-time with no evidence of enhancement. A marked sensitivity of calculations of coefficients to assumed average drop size is demonstrated. A model for mass transfer coefficients allowing for interfacial contamination suggested that rigid drop conditions were suffered. The design of a large diameter column was made more certain by the results obtained.

### INTRODUCTION

An industrial process has previously been successfully operated using several mixer-settlers. It was required to determine the possibility of using a packed column to reduce ground space requirements and to contain solvent safely. A programme of work on single drop mass transfer measurements and preliminary column design calculations to assess feasibility and costs was undertaken. This led to further limited pilot work on a counter-flow packed column.

### PRELIMINARY WORK

Equilibrium data were obtained at 32 and 50°C and were found to be favourable and independent of temperature. The distribution coefficient for the component to be recovered (solute concentration in solvent/concentration in aqueous, in g/L) was about 16 at low solute concentrations but much less at higher concentrations.

In order to carry out performance calculations various physical properties were measured – densities and viscosities at the two temperatures and interfacial tension at 30°C (Table 1). There was no reason to believe that any problems were posed by these properties.

Table 1. Physical properties.

Temperature	32°C	50°C
Aqueous density kg/m <sup>3</sup>	1168	
Solvent density kg/m <sup>3</sup>	874	
Aqueous viscosity, g/m.s	1.56	1.02
Solvent viscosity, g/m.s	0.53	0.45
Interfacial tension, mN/m	8.4	

Drop sizes were then estimated for the packed column using [1]

$$d_{32} = 1.0 (\gamma / g \Delta\rho)^{0.5} \quad (1)$$

giving a value of 1.7mm (at 32°C) with an uncertainty of about ± 20%. There will of course be a size distribution – the largest drops are not expected to exceed twice d<sub>32</sub>.

Drops of about this size were produced from glass needles at the base of an empty rising drop column. Drop terminal velocities were measured and for a drop of 1.9 mm the velocity was 67 mm/s. Using the correlation [2]

$$V_T = 0.249 d_{32} (g^2 \Delta\rho^2 / \rho_c \mu_c)^{0.33} \quad (2)$$

this value was adjusted to 60 mm/s for a drop of 1.7 mm. The characteristic velocity is less than the terminal velocity due to hindrance and was obtained using [3]

$$V_K = V_T [ 1 - (d_{32}/d_p)^{0.7} ]^{1.5} \quad (3)$$

assuming 25 mm Raschig ring packing, hence V<sub>K</sub> = 47 mm/s. Using the simplest possible slip velocity relationship [4]

$$V_{\text{slip}} = V_K (1 - x) \quad (4)$$

and a suitable flow ratio V<sub>d</sub> / V<sub>c</sub> = 0.33, a flooding hold-up of x<sub>f</sub> = 0.25 was determined. At 60% approach to flooding superficial velocities of V<sub>c</sub> = 8.2 mm/s and V<sub>d</sub> = 2.7 mm/s can be used. The full-scale column diameter calculated using the expected flow rate of aqueous phase was 0.6 m which was acceptable. Under these conditions the actual dispersed phase hold-up, x, would be 0.075 and the specific interfacial area 200 m<sup>2</sup>/m<sup>3</sup>.

The calculation of column height depends on having realistic kinetic data and specification of degree of extraction.

### SINGLE DROP MASS TRANSFER COEFFICIENTS

An empty jacketted column was set up for single drop rise mass transfer experiments. The column had three different rise heights, (305, 450 and 1200 mm) and a collection point 20 mm above the drop formation needle so that drop formation mass transfer was excluded. Several heights are needed to establish the time-dependency of the mass transfer coefficient. Two solvent drop sizes of 1.9 and 2.5 mm were used (it being difficult to produce small drops of exactly the right size, especially when small). Data were obtained at 32 and

50°C (Figure 1). The feed composition was altered from 8.3 wt% down to 1.5 wt% for some runs; a small reduction in the overall solvent-based mass transfer coefficient  $K_{os}$  was apparent as feed concentration decreased. Higher temperature gave significantly higher  $K_{os}$  values. The strong variation of  $K_{os}$  with contact time indicated that circulation conditions inside the drop dominate the mass transfer process since diffusion in spheres is an unsteady-state process. There was little dependence on drop size. The small degree of scatter is an indication of the reliability of the data.

Assuming a worst case and using  $K_{os}$  values expected for long contact times (> 20 s); the overall solvent-based transfer unit height  $H_{os}$  was estimated to be about 2.4 m at 32°C and 1.6 m at 50°C. (The drop contact time per transfer unit height is far longer than 20 s). If repeated drop break-up and coalescence were obtained in a packed column much smaller transfer unit heights would be anticipated but this effect cannot be predicted.

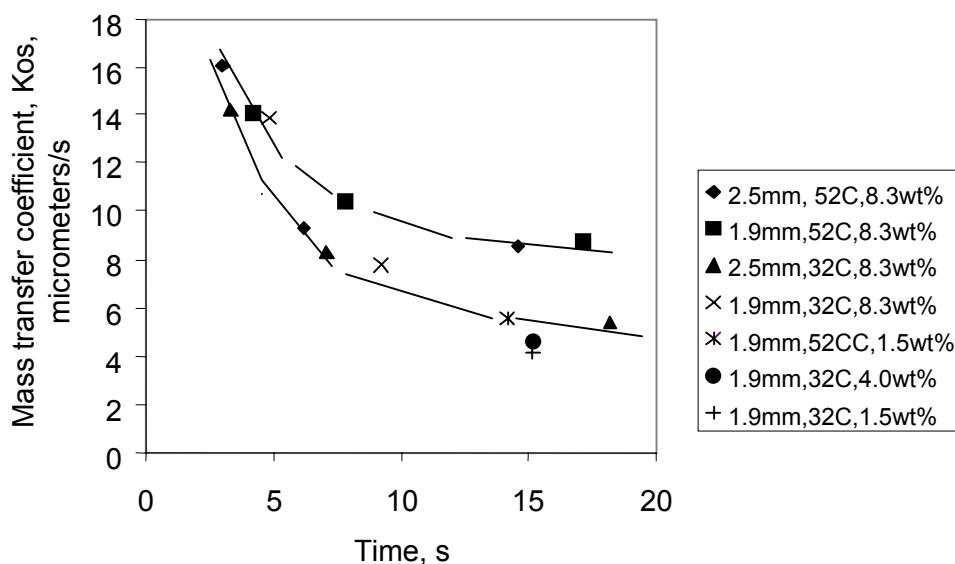

Figure 1. Rising drop mass transfer coefficients.

## NUMBER OF TRANSFER UNITS

For a feed of 8.3 wt% and a solvent/aqueous flow ratio of 1/3 the number of transfer units based on the solvent phase was calculated by graphical integration. For 98% extraction  $N_{os} = 2.25$  and for 99% extraction  $N_{os} = 3.24$ . The column heights estimated on the basis of single drop results ( $H_{os}$  values) were acceptable and gave reasonable column height/diameter ratios.

## PILOT COLUMN RESULTS

The packed column of 150 mm diameter, 1.8 m packed height initially contained stainless steel Mini-rings. The feedstock was taken from the production plant but cooling during transport caused solutes to crystallize out of solution. The feed was therefore reheated to 32°C prior to extraction. The first few trials at lower than the required flow rate showed sensible degrees of extraction with  $H_{os}$  of 3 to 4 m and calculated  $K_{os}$  values of 2 to 4  $\mu\text{m/s}$ . These  $K_{os}$  values were however lower than those indicated for single drops. There was also an unexpected problem with phase separation.

The phases disengaged at the top interface with a normal thickness of dispersion band of a few centimetres but above that a foam developed, carrying aqueous feed into the solvent product stream. Mild agitation with a simple paddle broke this foam. Foam formation was presumed to be due to the presence of interfacially active contaminants or solutes in the feed.

A further four runs at higher flow rate using ceramic packing were then carried out with better control over the feed condition and excellent mass balances. Transfer unit heights ranged from 3.6 to 4.6 m for different flow rates and ratios (Table 2). The derived overall mass transfer coefficients are shown in Table 3. Again it was found that values of  $K_{os}$  were much lower than for single drops when using the average drop size of 1.7 mm in calculations.

*Table 2. Mass transfer results for packed column  
1.8m ceramic packing, 32°C.*

Run	Aqueous flowrate L/min	Solvent flowrate L/min	$N_{os}$	$H_{os}$ m
1	3.3	1.00	0.46	3.9
2	5.5	3.25	0.39	4.6
3	10.4	3.89	0.50	3.6
4	8.3	3.09	0.50	3.6

## DISCUSSION

In view of the uncertainty over drop size estimation, calculations were also made using physical property data that were more accurately determined for liquids at each end of the column. Densities and viscosities varied slightly with composition and interfacial tension had dropped to 6.8 mN/m from 8.4 mN/m. Visually drops appeared to be in the 1 to 3 mm size range; average drop sizes of 1.4 and 2.0 mm were arbitrarily assumed (with adjustments to  $V_T$  and  $V_K$ ) and column  $K_{os}$  values recalculated. The values are rather sensitive to average drop size and for an assumed value of 2 mm they were close to single drop values for long contact time (Table 3 and Figure 1).

*Table 3. Mass transfer coefficients for packed bed.*

Run	$V_c$ , mm/s	$V_d$ , mm/s	$K_{os}$ , $\mu\text{m}/\text{s}$		
			$d = 1.4 \text{ mm}$	$d = 1.7 \text{ mm}$	$d = 2.00 \text{ mm}$
1	3.06	0.92	2.0	3.0	5.5
2	5.06	3.00	1.5	2.4	4.3
3	9.58	3.58	1.5	2.4	4.7
4	7.64	2.85	1.9	2.8	5.1

The prediction of drop size is clearly an important issue in estimating performance of the column. The data for this case suggested that little internal drop mixing was present and that drop life-time was long enough to allow the assumption that any break-up / coalescence that occurred did not enhance the mass transfer coefficients.

Arbitrary variation of an index on the term  $(1-x)$  in the slip velocity relationship as proposed by Godfrey and Slater [4] has no impact on calculations since the hold-up  $x$  is less than 0.15.

Axial mixing in both phases has been neglected since in a column of 150 mm diameter the effects are small and other uncertainties noted above are more significant. Correction for the adverse effects of axial mixing should be made in designing a large diameter column, particularly if a very high degree of extraction is to be specified.

Fitting of a combined mass transfer coefficient model [5] to the data indicated that there was a high degree of "contamination" with near-stagnant drops in the size range used. This could explain the observed lack of extensive coalescence between drops.

## CONCLUSIONS

From the data obtained prediction of column height for 98% and 99% extraction can be made with confidence. However, the prediction of a packed column performance depends sensitively on average drop size estimation. To make better predictions study of the drop breakage rate in packed columns is desirable and feasible; measurement of coalescence rate is also needed but is not easily done. The comparison of single drop mass transfer coefficients and those in a packed bed is perhaps the best, if pragmatic, approach to understanding the exceedingly complex role of drop break-up and coalescence processes. In the particular case studied there seemed to be no evidence of mass transfer enhancement by packing; modelling of the single drop mass transfer coefficient data suggests that drops are rigid in condition and so not amenable to coalescence.

The combination of limited work on single drops and a pilot column is very helpful in giving confidence in design and the use of the column can reveal unsuspected operating problems. In future similar work the replacement of pilot column tests with two-phase counter-flow tests with batch circulation of phases to equilibrium using a short section of column is advocated as a sensible approach so that relevant data can be obtained and problem-resolving can be achieved at low cost.

## ACKNOWLEDGEMENTS

## INDUSTRIAL APPLICATIONS OF CENTREK CENTRIFUGAL EXTRACTORS

Kuznetsov G.I., Pushkov A.A. and Kosogorov A.V.

Research and Development Institute of Construction Technology (NIKIMT), Moscow, Russia

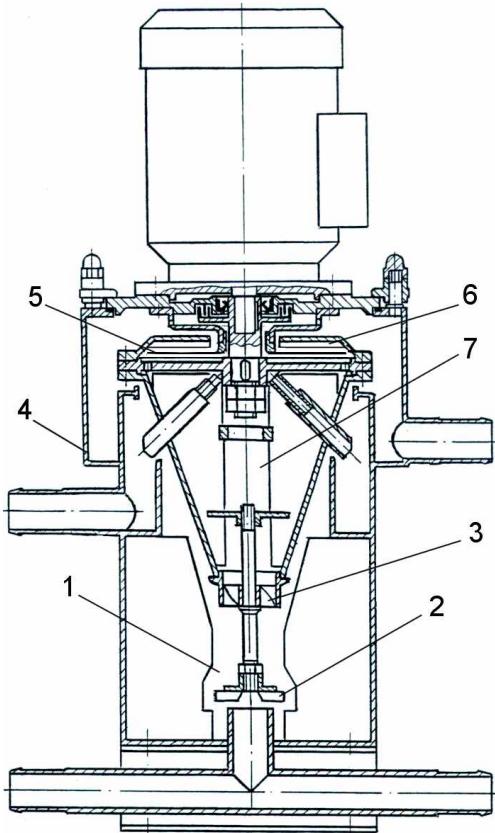

This paper describes the design and technical characteristics of CENTREK centrifugal extractors and their industrial applications. These include enriched uranium purification, natural uranium, Zr, Hf, Sm, Re production, copper electrolyte purification, copper extraction from ammonical etching solutions and medicine production. The processes tested on pilot scale are also discussed.

### CENTREK CENTRIFUGAL EXTRACTORS

In centrifugal extractors intense mixing is combined with subsequent separation of the emulsions under the action of centrifugal forces hundred times that of gravity to make it possible to achieve a high capacity with a relatively small piece of equipment. Therefore they are applied in industry for processes requiring short residence time of solutions because of radiolytic solvent decomposition or changing product properties with time, for processes requiring the restriction of the solvent volume (for reasons of nuclear safety, expense and fire hazard), for processes which use viscous liquids with small difference in density that are prone to emulsification and for processes where it is possible to use the difference in the extraction rate of components to improve their separation.

The NIKIMT have developed various modifications of CENTREK centrifugal extractors for fast and slow mass transfer rate processes (EC type), in single-stage and blocks, with phase recirculation, for radiochemical processes remotely controlled by manipulators or robots (ECR type), and for operation with solutions containing solid contaminants (ECK type) [1]. The units most extensively used in industry are centrifugal extractors with a conical rotor (Figure 1). The technical characteristics of these ECK type extractors are given in Table 1.

The extractor operates as follows: feed solutions are fed to the mixing chamber (1) where they are mixed by stirrer (2). The emulsion thus formed is transferred by screw conveyer (3) to a rotor (7) where it is separated under the action of centrifugal forces. Separated liquids are directed into circular collectors (5) of the fixed body (4) and then gravitate out of the extractor. The conical shape of the rotor and special design hydrolock (6) with activator (5) promote the continuous removal of solid contaminants from the rotor together with heavy phase. The apparatus design allows the change of phase contact time by changing the volume of the mixing chamber. Engineering design of extraction processes requires the combination of single stage centrifugal extractors in multistage cascades with commutating tubes.

\*D- rotor diameter; N-rotation speed; Q-capacity for system of 1 M TBP in kerosene – 2 M HNO<sub>3</sub>, for the ratio of flow rate equal to 1 and emulsion type – “oil in the aqueous phase”; V<sub>s</sub>, V<sub>m</sub>-volume of the separation and mixing chambers, respectively; P-drive output; I,b,h-length, width, height, respectively; m-mass of the extractor; \*\* - made of titanium.

To assemble the cascades easier the modules of three and more single stage extractors were developed. The block design was also developed [1]. Commutating channels between stages and mixing chambers are integrated into the apparatus body. The block extractor is designated for processes with slow mass transfer rates.

CENTREK centrifugal extractors are simple in service and reliable in operation. This is achieved making use of vibroinsulators, the application of conical shape of rotor and the related location of the center of the rotating mass in the zone of the bearing support.

### PURIFICATION OF ENRICHED URANIUM FOR FUEL ELEMENT FABRICATION [2,3]

For more than 30 years enriched uranium purification, especially for high grade, has been carried out with centrifugal extractors. They are also used for the recovery and purification of enriched uranium from scrap and residue of fuel element fabrication. A process flow sheet with EC100 extractors is shown on Figure 2. Presently, more than 200 extractors are in operation at several plants. An automated process control system is used in their operation. The use of centrifugal extractors together with the process control system allows a reduction to one tenth of the normal solution volume inventory and thereby to improve nuclear safety.

*Figure 2. Flow sheet of enriched uranium purification: [1] – concentration detector, [2] - flowmeter, (>) – pneumatic valve.*

### PROCESSING URANIUM ORE SOLUTIONS [1]

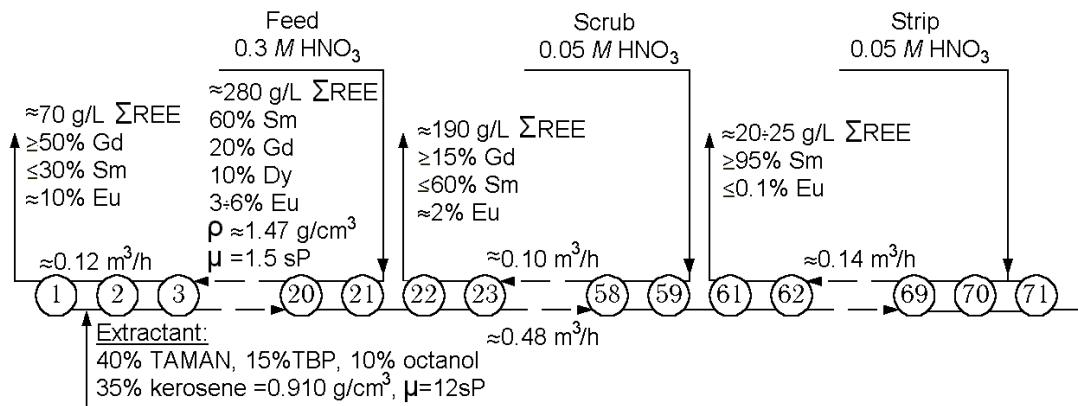

The four-stage block type extractor with a 400 mm rotor diameter is used for this process. During the commercial tests 10 000 m<sup>3</sup> sulfuric acid desorption solutions were processed. They contained 4 000 kg solid contaminants and an average flowrate was 22 m<sup>3</sup>/h. Extractant: Di(2-ethylhexyl)phosphoric acid (DEHPA) – 50 g/l, TBP – 25 g/l, Trialkylamine (TAA) – 12 g/l.

During the operation dynamic equilibrium is established in the apparatus. The quantity of contaminants in solutions on entrance to the apparatus is equal to their quantity on exiting. The use of centrifugal extractors allows the reduction of the working area, volume of solutions in the process as well as to considerably improve fire safety.

### RARE-EARTH ELEMENTS PRODUCTION [2,4]

The technology is complicated by the difficult conditions of separation of the emulsions because of the high viscosity (up to 0.04 Pa·s) and a small difference in the densities (not over 0.02 g·cm<sup>-3</sup>) of the solutions, as well as the low separation coefficients of adjacent rare-earth (RE) elements (about 1.5-2.0), which necessitates a large number of stages (up to

100). For example, a cascade of EC125 type centrifugal extractors have been used for more than 15 years for samarium production from a middle-group RE-concentrate (Figure 3). It was necessary to take into account the effect of phase entrainments on process performance. Increasing entrainments are observed in the parts of the cascade where the difference in phase densities is smallest. Admissible entrance on extraction should not exceed 1%, but on strip stage entrainments more than 1% have no effect on technological performances of the process, as samarium purification is ended on the scrub stage.

*Figure 3. Flow sheet of samarium production from RE concentrate.*

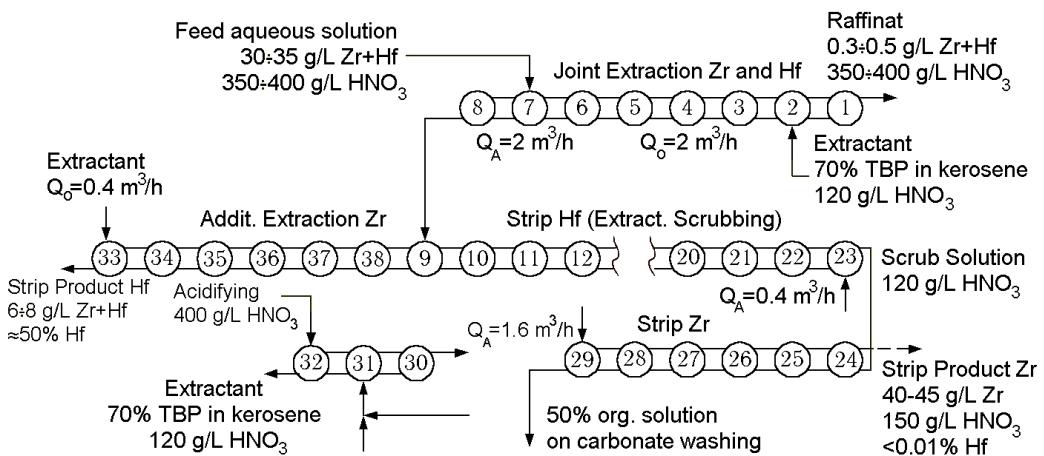

Fifteen-year experience of industrial operation showed high reliability of centrifugal extractors and their stable operation in very complicated conditions of given technological processes.

## ZIRCONIUM AND HAFNIUM PRODUCTION [2,5]

A flow sheet for nuclear-grade zirconium production that has been used for more than 25 years is shown as Figure 4. The primary removal of Zr and Hf from bulk impurities is achieved in their co-extraction (stages 1-8) and the removal of Hf and a number of limiting contaminants (Al, Cr, Cu, Ti, Fe, Si and others) is achieved with scrubbing (stages 9-23). EC250 extractors are used in all operations except stages 33-38 where EC125 extractors are used for complete Zr extraction. The Zr decontamination factor in the scrubbing operation notably depends on the flow ratio of organic to scrubbing solutions, as well as on the entrainments of aqueous phase. For example, decreasing flow ratio O/A from 5 to 4 increases the decontamination factor from 200 to 1 800, and increasing the entrance of aqueous phase to organic one from 0.005 to 0.5% decreases the decontamination coefficient from 1 600 to 300, when O/A=4. The proper choice of value and direction of entrainments allows the capacity of the extractors to be increased without deterioration of overall performance. The flow sheet of Hf production differs negligibly from the Zr one. Hf strip product solution is used as feed solution and ECK160 extractors are used.

## RHENIUM EXTRACTION [6]

For the extraction and concentration of rhenium three EC250 units are used for extraction and one EC125 unit is used for stripping. Extractant: 30% TAA, 10% octanol and kerosene. Ammonium hydroxide solution is used for stripping. A concentrating ratio of more than 100 is achieved. Extraction from sulfuric acid solutions has also been successfully tested [7].

*Figure 4. Flow sheet of production of nuclear grade zirconium.*

### ARSENIC REMOVAL FROM COPPER ELECTROLYTE [8]

For this process 6 centrifugal extractors (4 on extraction and 2 on stripping) are used for arsenic removal to purify copper electrolyte. Electrolyte after correction of  $\text{H}_2\text{SO}_4$  concentration to 170-180 g/l is decontaminated by 100% TBP. Water is used for stripping. TBP is periodically scrubbed from its hydrolysis products with soda solution. Fine electrolytic copper is prepared from the strip product solution.

### COPPER EXTRACTION FROM AMMONIACAL ETCHING SOLUTIONS (MECER-PROCESS) [9]

Copper extraction and keeping its concentration in etching solutions up to optimal limits of 100-130 g/l is carried out by the MECER-process in which the expensive extractant LIX-54 is used. The replacement of mixer-settlers with CENTREK centrifugal extractors of type ECK140 (titanium construction) allows a ten-fold decrease in the extractant volume and improves the compactness of the MECER unit. Six MECER units with CENTREK centrifugal extractors have been in operation in France, Slovenia and Norway since 2000.

### MEDICINE PRODUCTION [10,11]

In antibiotic production a number of problems have to be overcome concerning the formation of poorly separating emulsions, the use of extractant easily dissolved in water, the decomposition of products in time, and, the presence of solid contaminants in solutions. These problems have been successfully solved by employing CENTREK centrifugal extractors. In these solid contaminants are removed together with the aqueous phase, and emulsification and phase contact time are kept to a minimum. Besides considerably improved working conditions of the operation staff due to the hermetic nature of the apparatus and the decreased frequency of their cleaning from precipitates. Compared with the existing process the use of the cascade of 6 CENTREK centrifugal extractors allows a decrease of the consumption of extractant by half and an increase of the antibiotic concentration by 6 times (to 30 000 mg/l). Therefore the evaporation stage has been eliminated. The product yield increased, its quality improved and technological time shortened by half. Similar positive results have been obtained in the extraction and purification of flaminium and kaleflonium from vegetable sources [12]. The industrial production of amino acids was started in July 2001 [13].

## PILOT-SCALE INVESTIGATIONS

The industrial applications of CENTREK centrifugal extractors are testimony to the success of this technology. Pilot-scale tests that have been conducted show that there is a good potential for further applications of CENTREK centrifugal extractors in industry. The processes tested include: reprocessing fast breeder reactor spent fuels [14,15], UNEX process for long-lived fission products, cesium, strontium, transplutonium elements from liquid radioactive wastes [16], sewage purification [17] and nickel and cobalt separation [18,19].

## SIEVE TRAY EXTRACTORS: A CLOSER LOOK AT CAPACITY LIMITATIONS

Frank Seibert, James R. Fair and Jose L. Bravo\*

Separations Research Program (SRP), The University of Texas at Austin, TX, USA

\*Shell Global Solutions International, Amsterdam, The Netherlands

Sieve tray extractors continue to be highly utilized in the chemical and petrochemical industries. The trays are inexpensive, simple and have demonstrated the ability to handle very high throughputs. Their mass transfer efficiency, while somewhat limited, is often adequate and may be compensated for by a modest increase in the solvent to feed ratio. However, the tray hydrodynamics are very complex and not well understood, especially in large diameter columns. As a result, expected throughputs may not be realized. Unfortunately, use of a single model or correlation developed from laboratory-scale equipment to predict sieve tray flooding velocities would likely be unreliable. A close look reveals that there are six significant and distinct mechanisms that limit capacity. These mechanisms have been observed in the Separations Research Program (SRP) 10.2- and 42.8-cm diameter extractors and have also been reported by SRP industrial sponsors. The objective of this paper is to address briefly the important mechanisms that limit capacity of sieve tray extractors. A collateral objective is to familiarize process engineers with these mechanisms.

### INTRODUCTION

Sieve trays are often used for continuous extraction processes in the chemical and petrochemical industries. The sieve tray extractor is simple in design, requires no moving parts, reforms drops at every tray, reduces backmixing and can handle some slurries. The extraction column consists of a series of perforated plates that are connected by downcomers (or upcomers). The perforations are designed to pass the dispersed phase and the downcomers (or upcomers) are to pass the continuous phase. A completely coalesced layer is supposed to exist underneath the tray (light-phase dispersed) for the purpose of reforming drops and preventing backmixing of the continuous phase.

The hydraulic mechanisms involved in flooding of sieve tray extractors are not clearly understood, especially for larger diameter columns. While very little has been reported on the hydraulic performance of large-scale sieve tray extractors, three studies using larger equipment have been reported by Ololidi *et al.* [1], Seibert and Fair [2] and Eldridge and Fair [3]. An example of sieve tray flooding data is illustrated in Figure 1. Sieve tray flooding studies have been carried out at the SRP using 10.2- and 42.8-cm diameter columns, often with mixtures of industrial importance, indicate that there are six distinct mechanisms that can limit tray capacity:

- Spray column flood (ultimate capacity);
- Large height of coalesced layer at one or more trays (from high orifice and/or downcomer pressure drop, or entrainment into downcomer);
- Inadequate drop coalescence at main operating interface;
- Cross-flow velocity of the continuous phase/length of flow path;
- Poor interface control.

This paper addresses briefly each of the flooding mechanisms.

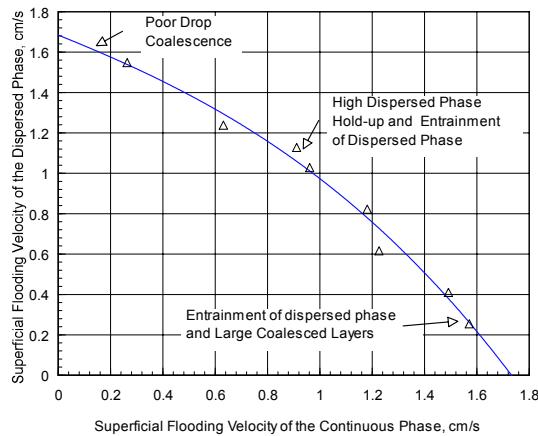

Figure 1. Sieve tray flooding data. System: toluene (d) / water (c). Tray spacing = 30.5 cm. Column diameter = 42.8 cm.

## FLOODING MECHANISMS

### Spray Column Flood

The ultimate capacity of a tray extractor will approach that of a spray column. A flooding model developed at the SRP with supporting experimental data is provided in a previous publication [2]. The capacity of the spray column is generally limited by entrainment of dispersed phase by the continuous phase, or vice versa. As a result of a distribution in drop sizes, entrainment of smaller drops is the most common mechanism of flooding in a spray column. In larger diameter columns, tray capacity may exceed that of a large diameter spray column depending on the phase flow ratio and the degree of continuous phase recirculation. Spray column axial mixing experiments at the SRP have indicated that the actual velocity of the continuous phase can be increased by backmixing [4]. These experimental studies indicate that the interstitial continuous phase velocity can be increased by a factor of 25 for  $U_c/U_d$  of 0.05. Nevertheless one would expect the maximum capacity of a sieve tray extractor to approach that of a spray column free of backmixing.

### Large Height of the Coalesced Layer

The performance of a sieve tray extractor is strongly influenced by the height of the coalesced layer below (light-phase dispersed) or above (heavy-phase dispersed) the tray. The height will depend on the pressure drop through the sieve holes and downcomer along with the density difference. As discussed in the paper by Mewes and Kunkel [5], the height also depends on the dispersed phase hold-up in the drop rise region, downcomer length, and possible dispersed phase hold-up in the downcomer. Their generalized model assuming no dispersed phase in the downcomer is given in Equation 1.

$$h = \frac{(\Delta P_o + \Delta P_{dow})}{(\rho_c - \rho_d)g(1-\phi_d)} - \frac{\phi_d}{(1-\phi_d)} Z_d \quad (1)$$

The pressure drop through the sieve holes may be estimated using the model of Pilhofer [6]. The downcomer (or upcomer) pressure drop may be estimated using the model of Major and Hertzog [7]. In addition, the rigorous model developed by the SRP, which not only accounts for expansion and compression but also for frictional losses, may be used. Experimental verification of the coalesced height model is provided in an SRP Technical Report [8]. The two downcomer pressure drop models are very similar except the SRP model includes frictional losses that are important for viscous systems and with trays having long downcomers (upcomers). The SRP downcomer pressure drop model is also applicable when the inlet and outlet areas are different.

$$\Delta P_{dow} = \rho_c \left[ 0.75U_1^2 + U_2^2 + 0.5 \left( \frac{f_1 L_1 U_1^2}{d_1} + \frac{f_2 L_2 U_2^2}{d_2} \right) \right] \quad (2)$$

$$Z_d = L_1 + L_2 \quad (3)$$

$$Re \left( \frac{\rho_c U_{dow} d}{\mu_c} \right) < 3,000 \quad (\text{laminar flow}) \quad f = \frac{64}{Re} \quad (4)$$

$$Re \left( \frac{\rho_c U_c d}{\mu_c} \right) > 3,000 \quad f = -0.0071 \ln\{Re\} + 0.1 \quad (5)$$

Large coalesced layer heights will result in reduced mass transfer and control of the main operating interface. Ideally, for commercial-scale columns, the design height should be limited to approximately 2.5 cm. In addition, the designer should be careful to include an allowance for flow variations in the column and their effect on coalesced layer height fluctuations and on interface control.

### Inadequate Drop Coalescence

The capacity of a tray extractor may be limited by insufficient drop coalescence at the main operating interface, which results in significant carryover of continuous phase. Generally, an uncoalesced layer will cause problems for the interface sensor and will likely exit the column carrying with it a significant quantity of continuous phase trapped between the uncoalesced drops. This method of flooding has become common with columns having high dispersed-to-continuous phase flow ratios and whose rates have increased significantly beyond their original design point. The presence of surface-active contaminants can also promote the formation of an uncoalesced layer. Studies at the SRP show that the critical superficial dispersed phase velocity ( $U_{df,uncoal}$ ), which may result in the formation of a large uncoalesced layer, can be estimated from the characteristic drop velocity ( $U_{so}$ ) obtained using the model of Grace and co-workers [9].

$$U_{df,uncoal} \approx 0.12 \bullet U_{so} \quad (6)$$

The formation of the uncoalesced layer is a result of the rate of drop coalescence being slower than the rate of drop arrival at the interface. One method of eliminating or minimizing the height of the this layer is to use a larger column diameter section in the region of the main operating interface, to create additional interface area for coalescence. A more cost-

effective remedy may be to add structured packing to the interface region. However, to promote coalescence the packing must be preferentially wetted by the dispersed phase and should be relatively open to allow counterflow of the coalescing phases. In a hydrocarbon/water system, hydrocarbon will generally preferentially wet a hydrophobic surface like Teflon while water will generally preferentially wet a less-hydrophobic material such as stainless steel. The effectiveness of a Type 2 Teflon structured packing to reduce the height of uncoalesced layer and extend column capacity is shown in Figure 2 [10]. Additional experimental data may be found in the study of Schober [10]. In the example, n-hexane is dispersed into a continuous water phase.

### High Cross Flow of the Continuous Phase

Pilot tests of sieve tray extractors are often performed prior to final design of the commercial-scale column. The design is often scaled-up based on superficial velocities of the dispersed and continuous phases calculated from the volumetric flow rates and the column cross-sectional area. However, in scaling up one must be careful about the cross-flow velocity ( $U_{c\text{flow}}$ ) of the continuous phase, the value of which may be estimated by Equation 7.

$$U_{c\text{flow}} \approx \frac{D_{\text{col}}}{Z - h} U_c \quad (7)$$

With regard to scale-up, larger diameter extractors will exhibit a greater amount of internal circulation within a tray. A high degree of continuous phase circulation was observed and reported in the larger-scale study of Eldridge and Fair (3). These effects were especially pronounced at high dispersed-to-continuous phase flow ratios. The high cross-flow continuous phase velocity will lead to a velocity vector associated with the drop as shown in Figure 3.

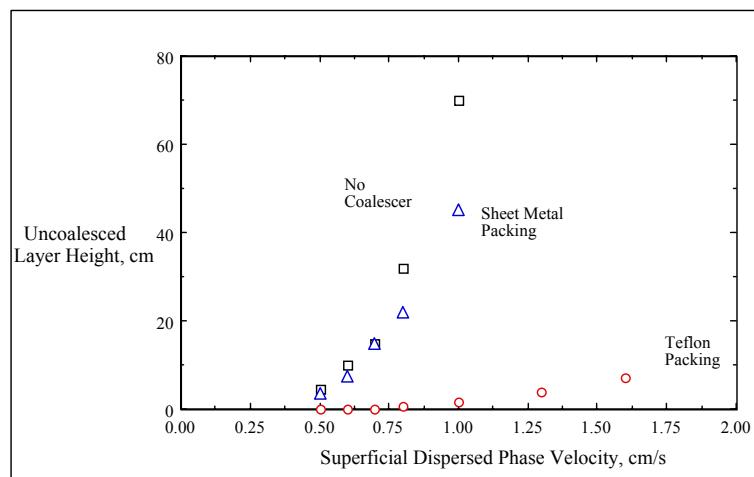

Figure 2. Effects of a teflon coalescer [10]. System: hexane (d) / water (c).

The cross flow velocity and the additional drag reduce the  $j$  component of the characteristic drop velocity. As a result the capacity will likely be equivalently reduced.

$$U_{so} = U_{so,i} + U_{so,j} \quad (8)$$

The characteristic drop velocity in the  $j$  direction may be calculated implicitly from

$$U_{so,j}^2 = U_{so}^2 \frac{1}{\sqrt{1 + \left(\frac{U_{so,i}}{U_{so,j}}\right)^2}} - U_{so,i}^2 \quad (9)$$

where:  $U_{so,i}$  = cross-flow velocity, cm/s

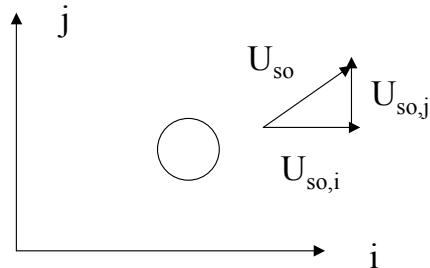

Figure 3. Characteristic drop velocity vector.

The effect of the flow path length phenomenon has been observed empirically in large-scale industrial extractors where more hydraulic capacity is achieved by shortening the flow path of sieve trays and increasing the number of passes. The use of multiple upcomers or downcomers will result in a lower cross-flow velocity and therefore reduce the overall drag force on the drop. Large diameter multiple upcomer trays have been shown to provide 10-15% greater capacity relative to the single pass tray.

#### Poor Interface Control

Poor control of the main operating interface is another cause of flooding. As shown in Figure 4, the position of this interface is often controlled by adjusting the heavy phase outlet flow from the extractor. If an adjustment of the interface level is required, the valve will open to lower the level or close to raise the level. As the valve changes, the internal flows change with resulting change in the coalesced layer height. Unfortunately, depending on the relative pressure drops (orifice versus downcomer), the height may increase or decrease until reaching a steady value. This results in a response lag which in many cases will cause the interface to move initially in the wrong direction. Such an inverse response may cause the operator to over-react and re-adjust the valve, which in turn can cause a coalesced layer flood as discussed earlier. The ability to measure the heavy phase outlet flow rate can be extremely beneficial in controlling the interface position and preventing an accidental flood.

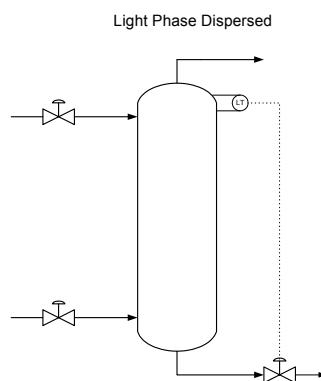

Figure 4. Typical interface control of a sieve tray extractor.

## CONCLUSIONS

There are many mechanisms that can limit the capacity of a sieve tray extractor. Six of the most common are addressed in this paper. While it may comprise complex hydrodynamics, the sieve tray extractor still provides reliable and cost effective efficiency for a large number of chemical and petrochemical applications. Trays such as UOP's multiple upcomer/downcomer or Shell's new Hi-Fi tray are modified versions of the conventional sieve tray that have demonstrated reliable performance and 10-15% higher capacities.

## NOMENCLATURE

d	Downcomer diameter, cm
$d_1$	Inlet diameter of downcomer, cm
$d_2$	Outlet diameter of downcomer, cm
$f_1$	Friction factor associated with downcomer diameter $d_1$
$f_2$	Friction factor associated with downcomer diameter $d_2$
g	Gravitational constant, cm/s <sup>2</sup>
h	Height of the coalesced layer, cm
$L_1$	Length of downcomer having Velocity $U_1$ and Diameter $d_1$
$L_2$	Length of downcomer having Velocity $U_2$ and Diameter $d_2$
$\Delta P_o$	Pressure drop through sieve hole, g/cm-s <sup>2</sup>
$\Delta P_{dow}$	Pressure drop through downcomer, g/cm-s <sup>2</sup>
$U_c$	Superficial continuous phase velocity based on cross-sectional area, cm/s
$U_{cflow}$	Superficial crossflow velocity of the continuous phase based on the average projected area, cm/s
$U_1$	Inlet velocity in downcomer, cm/s
$U_2$	Outlet velocity in downcomer, cm/s
$U_{dow}$	Downcomer velocity, cm/s
$U_{so}$	Characteristic drop velocity calculated by the method of Grace et al., cm/s
$Z_d$	Length of the downcomer, cm
$\phi_d$	Dispersed phase hold-up
$\rho_c$	Density of the continuous phase, g/cm <sup>3</sup>
$\rho_d$	Density of the dispersed phase, , g/cm <sup>3</sup>
$\mu_c$	Viscosity of the continuous phase, g/cm-s

## HYDRODYNAMICS AND MASS TRANSFER OF A ROTATING DISC COLUMN

Manabu Yamaguchi, Haruo Yamashita and Hideo Noda

Department of Mechanical Engineering, Himeji Institute of Technology, Himeji, Japan

Characteristics of hydrodynamics and mass transfer in a rotating disc column, consisting of six stages separated by stator rings equipped with stainless steel mesh coated with teflon, has been investigated experimentally. Hydrodynamics: effects of the impeller speed, the flow rates of the continuous and dispersed phases on the drop size, the hold-up fraction and the flooding flow rate of the dispersed phase are examined using the system of toluene drops in water phase. Mass transfer: column performance for mass transfer is also examined using the system of toluene/acetone/water under various operating conditions and evaluated by the number of theoretical stages per unit column height.

### INTRODUCTION

A large number of contactors for liquid-liquid extraction have been developed and their characteristics have been reported [1]. Recently, we developed a multistage mixer-settler column with a novel impeller [2]. The impeller consisted of a special structure of static-mixers inside channels fixed on a disc and was named an active turbine impeller. When the dispersed and continuous phases flow with twist-shear force through the channels rotating together with the disc, the one phase is dispersed into the other phase and both phases are discharged from the channel into the column stage [3]. Consequently, it was shown that the column had excellent characteristics for the hydrodynamics as well as mass transfer in the lower revolution of the impeller [2].

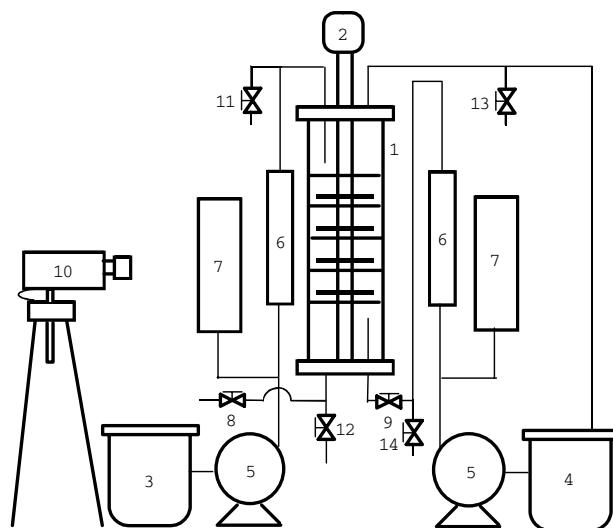

The aims of the present study were to examine the hydrodynamic and mass transfer characteristics of a rotating disc column and to compare the column performance with the novel impeller in the previous study [2] and that with disc impeller in the present study, which was taken off the channel with the static-mixer elements.

### EXPERIMENTAL

#### Experimental Apparatus

A schematic diagram of an experimental apparatus is shown in the Figure 1. The column consisted of a 150 mm diameter, 570 mm high glass column divided into 6 compartments; the top of the column 100 mm high, 4 stages each 70 mm high, and the bottom of the column 185 mm high (hereafter called the top stage, 1st stage, 2nd stage..., and bottom stage). The diameter of the disc, located 15 mm above the lower stator ring in each stage, was 110 mm and that of the stator opening was 110 mm. Each stator ring was equipped with a drop

coalescer made of a stainless steel mesh coated with teflon and with two downcomers of stainless steel bent into a U shape. Thus, the space in each stage was divided into a mixing zone and a coalescence zone except for the top and bottom of the column. In the experiment, fine droplets formed in the column were carried down with the continuous phase and accumulated at the bottom stage and, in the extreme case, they flowed out with the continuous phase as entrainment. Therefore, at the bottom stage, a stainless steel-like sponge layer was inserted to prevent these entrainments. Each stage in the column was equipped with probes to sample the liquid phases. The probes were set at a suitable position above the impeller.

*Figure 1. Schematic of experimental apparatus.*

### **Experimental Procedure**

In the hydrodynamic experiment, the system of toluene drop in water phase was used. In the mass transfer experiment, the system of water/acetone/toluene recommended by European Federation of Chemical Engineering Working Party (EFChE) was used.

### **Drop size**

Drops in the 2nd stage were recorded on a personal computer through a CCD camera and later they were measured by reproducing their images. Drop size was determined as the Sauter mean diameter.

### **Hold-up fraction of dispersed phase**

The column was filled to a given level with water as the continuous phase, which was fed at a given flow rate through the flowmeter from the top of the column. The impellers were rotated at a given speed, and the air in the column was perfectly exhausted by rotating the impeller intermittently. Toluene as the dispersed phase was fed at a given flow rate through the flowmeter from the bottom of the column. Each of the phases flowed countercurrently at a constant flow rate. After steady-state flow of both phases was maintained, the hold-up was measured by the following two methods. For the first method, the liquid phase in each stage was sampled using a syringe from each sampling probe, and the volume of both phases was measured using a volumetric cylinder. The hold-up fraction was defined as the ratio of dispersed phase volume to total volume of both phases. For the second method, after the

feeding of both phases was simultaneously stopped, the dispersed phase was collected by intermittently rotating the impeller. A position of the dispersed phase/continuous phase interface was measured and the total volume of dispersed phase in each stage was obtained. In this way the ratio of dispersed phase volume to total volume of the 4 stage compartments was determined.

#### ***Flooding flow rate of dispersed phase***

When the feeding rate of the dispersed phase attained a critical value under a constant flow rate of the continuous phase and a constant impeller speed, the volume of the uncoalesced drops in the top stage increased and forced the dispersed phase/continuous phase interface down, and finally the interface entered into the 1st stage from the top one. This behavior made a steady state flow for both phases in the column impossible. Flooding was defined by this behavior.

#### ***Mass transfer***

Mass transfer experiments were carried out for different flow rates for both phases and different revolutions of the impeller. A specific operating condition was chosen to compare the mass transfer performance in the present column with those of conventional contactors in the literature; a constant throughput ratio of 1 to 1.5 (water to toluene phase) was used. The experimental procedures were essentially the same as those in the hold-up experiment except for the liquid-liquid system used. After a steady-state flow for both phases was achieved, the liquid phases at each stage were sampled using a syringe from each sampling probe. After both sampled phases were separated into the dispersed and continuous phases, they were rapidly moved by syringe into the covered sample bottles. Also, simultaneously the dispersed and continuous phases at the inlet and the outlet of the column were sampled. The acetone concentration in each phase was measured using a gas chromatograph with a packing of 1.2.3-Tris(2 cyanoethoxy) propane/Uniporto B.

## **RESULTS AND DISCUSSION**

#### **Drop Size**

Experimental drop sizes obtained under various operating conditions are shown in Figure 2. In the figure, RDC means a column with rotating disc impellers and ATC means a column with active turbine impellers. In the RDC, the dispersed phase (toluene phase) trapped by a disc impeller was discharged into the stage space as dispersed drops due to centrifugal force of the rotating disc. Therefore, it is considered that drop size is greatly influenced by impeller speed and the flow rate of the dispersed phase. In fact, in the case of low speed of the impeller, dispersed phase trapped widely by the disc moved about unsteadily together with rotation of the impeller. This was especially true in the case of around 100 rpm where bigger drops were formed irregularly as well as intermittently, and drop size could not be determined. The drops were formed regularly with increasing impeller speed and their sizes decreased, but effect of flow rates of the dispersed and continuous phases on their size was very small. At greater than 400 rpm impeller speed, drop size decreased significantly with flow rate of the dispersed phase. On the other hand, in the ATC, the drop sizes were small and nearly constant as shown in the Figure 2.

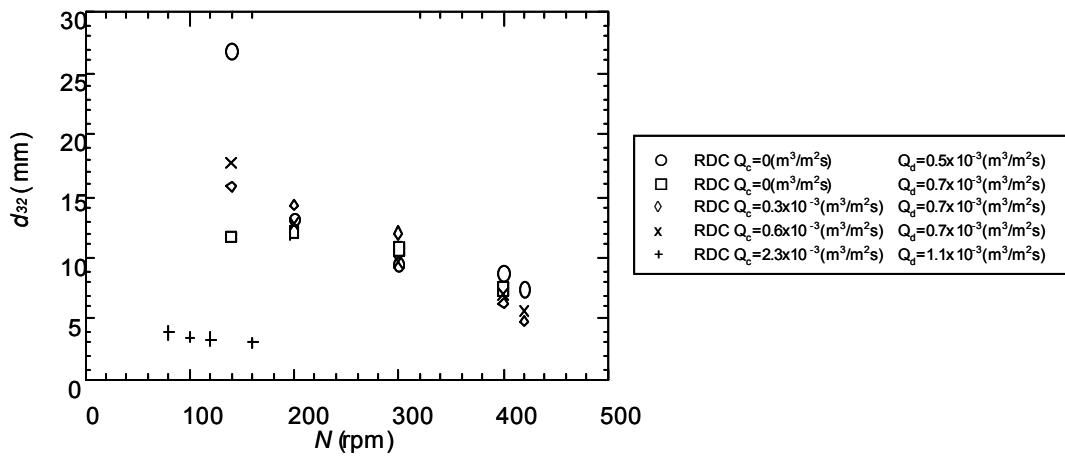

Figure 2. Relation between drop size and impeller speed.  
(RDC – Rotating Disc Impellers, ATC – Active Turbine Impellers).

### Hold-up Fraction of Dispersed Phase

A typical result of the experimental hold-up fraction for constant flow rates of both the phases is shown in Figure 3. The hold-up in the RDC were nearly constant values in the region of less than 400 rpm of impeller speed, but increased abruptly in the region of higher speed than 400 rpm. This was considered to be due to the marked decrease in the drop size for speeds of higher than 400 rpm that caused the rise velocity of the drops to decrease. Although the effect of the flow rate of the dispersed phase on the hold-up is not shown in the figure, the hold-up increased with increased flow rate of the dispersed phase. Their curves of the hold-up vs. impeller speed were similar to the circle symbols in Figure 3. On the other hand, the hold-up in the ATC was higher than in the RDC. As a result, the ATC predominates over the RDC in respect of operating conditions, e.g., lower impeller speed, easier operations etc.

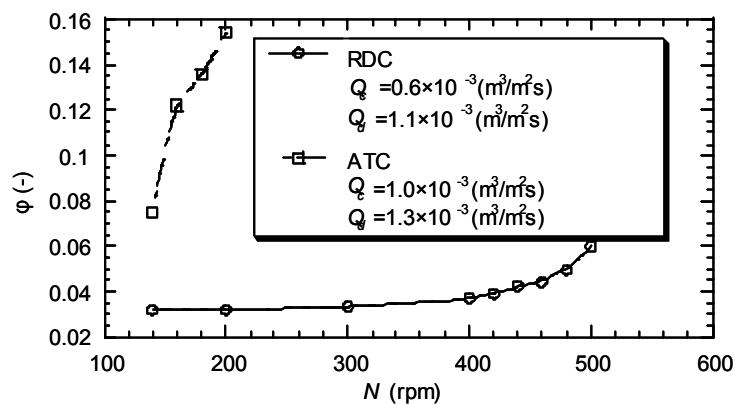

Figure 3. Relation between hold-up fraction and impeller speed.

## Mass Transfer

The stage efficiency for the system of water/acetone/toluene was close to 100% irrespectively of the impeller speed and flow rate of both phases. This is because the equilibrium constant of the test liquid system used is large. The column performance was evaluated using the Number of Theoretical Stages per Column Height which is often cited in the literature. NTS/H value was obtained by graphical stepwise construction using the concentration equilibrium line and column operating one. Figure 4 shows typical experimental results between NTS/H and impeller speed in the RDC. NTS/H values increased with impeller speed and significantly in the region of higher speed than 400 rpm. In the figure, the values of NTS/H in the ATC are also shown to compare with those in the RDC. NTS/H values in the ATC result in much higher than those in the RDC.

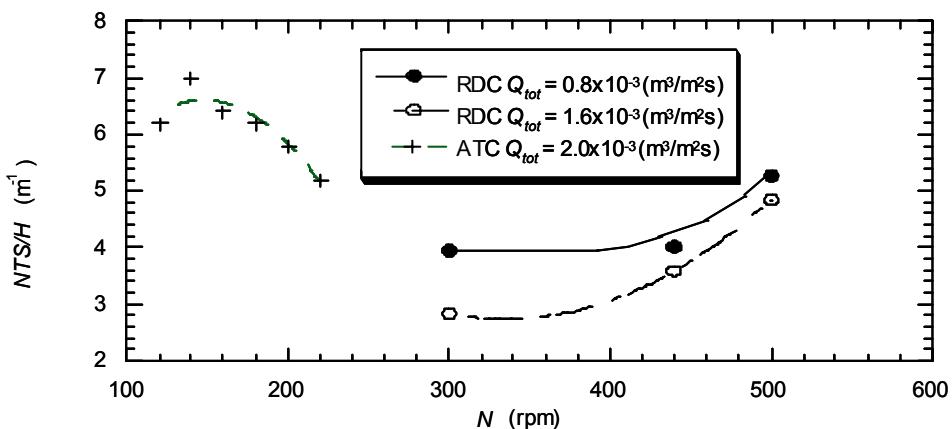

Figure 4. Relation between NTS/H and impeller speed.

## CONCLUSIONS

Droplet sizes in the present column (RDC) decreased with increasing rotating speed of the disc impeller and the flow rate of the dispersed phase, but were larger than those in the previous column (ATC). The Hold-up fractions of the dispersed phase were lower than those in the previous one. Mass transfer performance in the previous column was much better than that in the present one.

In recent years effort has been focussed on developing alternative experimental procedures to generate reliable design data for extraction columns at reduced costs. The study of single drop behaviour has been very fruitful but the problem remains of accounting for drop interaction, affecting hydrodynamics and mass transfer by drops coalescing and breaking up. An alternative technique is proposed in this work concerning the study of a 4-stage Kühni column with circulation of aqueous and organic phases until chemical equilibrium is reached. The hydrodynamic conditions in the column are realistic because normal flow rates are used. A model has been developed to describe the transient process of concentration changes in both phases assuming fixed hydrodynamic conditions and constant flow rates. Start-up results for the extraction and stripping of zinc with D2EHPA are presented. The procedure yields data immediately useful for column design at minimal cost.

### INTRODUCTION

In recent years, much work on single drops has been done in order to develop cheaper alternative experimental procedures with short columns [1-3]. The complex effects in a swarm of drops whose interaction affect hydrodynamics and mass transfer by drops coalescing and breaking up are not measured. Axial and radial mixing effects also arise in operation of industrial-scale columns, so direct application of single drop data is therefore of limited value [4,5]. The use of short columns with circulation of both phases at normal flow rates until equilibrium is reached is an alternative method. A drawback concerns the generation of a swarm of drops with sizes appropriate to a longer column. Several start-up procedures applied to reactive systems have been discussed by Mansur *et al.* [6]. Mathematical modelling complexities depend on the start-up strategy chosen to perform the experiments. The simplest cases involve fixed hydrodynamic conditions, for example, when one or both solute-free phases are fed to the column until hydrodynamic equilibrium is reached, then the pure phase(s) is(are) replaced at initial time by the real stream(s) containing the reactive species. A similar idea is a  $\delta$ -injection of solute as proposed by Wichterlova and Rod [7] to investigate mixer-settler performance.

In this paper, the transient start-up behaviour of a 4-stage Kühni column of 150mm diameter with circulation of both phases is investigated. Results for extraction and stripping of zinc with D2EHPA are presented. A stagewise model is proposed to describe the transient process of concentration changes in both phases assuming fixed hydrodynamic conditions and constant flow rates. Parameters have been estimated by data fitting.

## COLUMN MODELLING AND NUMERICAL SOLUTION

The stagewise backflow model [8] has been widely used to describe the non-ideal flow in extraction columns since the late 1960s. According to this model, both phases are assumed to behave as continua. In other words, this assumption presupposes that drops split and coalesce so frequently that any change in concentration spreads rapidly into neighbouring drops resulting in no differences in concentration in drops of different sizes. The model assumes an extractor with N perfectly mixed cells; circulating streams are characterised by a backmixing coefficient. Additional stages assuming no mass transfer are added to the extremes of the column to represent settling ( $i = 1$ ) and coalescence ( $i = N+2$ ) zones. The model has been evaluated using the reactive possible test system  $ZnSO_4/D2EHPA/n$ -heptane. Equilibrium and kinetics descriptions valid for extraction and stripping conditions have recently been proposed by Mansur *et al.* [9,10] assuming two consecutive reactions with all activity coefficients equal to unity with equilibrium constants as follows:

$$K_D = \frac{[ZnR_2RH][H^+]^2}{[Zn^{2+}][RH]^2} = 9.436(\text{mol}/\text{m}^3)^{0.5} \quad (1)$$

$$K_C = \frac{[ZnR_2][RH]^2}{[ZnR_2RH]} = 0.212(\text{mol}/\text{m}^3)^{0.5} \quad (2)$$

According to the equilibrium model, zinc ions and dimeric-D2EHPA molecules react reversibly at the liquid-liquid interface producing a  $ZnR_2RH$  complex and protons. However, at high loading conditions, part of the zinc-complex breaks down in the organic bulk solution [Equation (2)] producing  $ZnR_2$  and free dimeric-D2EHPA that reacts again with zinc [Equation (1)]. Therefore, the transient mass balances of the five reactive species in the stage  $i$  of the column are:

$$\frac{(1-\phi)V_i}{Q_c} \frac{dC_{A,i}}{dt} - (1+\alpha)C_{A,i+1} - \alpha C_{A,i-1} + (1+2\alpha)C_{A,i} + \frac{aV_i}{Q_c} R_i = 0 \quad (3)$$

$$\frac{(1-\phi)V_i}{Q_c} \frac{dC_{H,i}}{dt} - (1+\alpha)C_{H,i+1} - \alpha C_{H,i-1} + (1+2\alpha)C_{H,i} - \frac{2aV_i}{Q_c} R_i = 0 \quad (4)$$

$$\frac{\phi V_i}{Q_d} \frac{dC_{BD,i}}{dt} - (1+\beta)C_{BD,i-1} - \beta C_{BD,i+1} + (1+2\beta)C_{BD,i} + \frac{aV_i}{Q_d} \left( \frac{3R_i - S_i}{2} \right) = 0 \quad (5)$$

$$\frac{\phi V_i}{Q_d} \frac{dC_{CD,i}}{dt} - (1+\beta)C_{CD,i-1} - \beta C_{CD,i+1} + (1+2\beta)C_{CD,i} + \frac{aV_i}{Q_d} (R_i - S_i) = 0 \quad (6)$$

$$\frac{\phi V_i}{Q_d} \frac{dC_{CM,i}}{dt} - (1+\beta)C_{CM,i-1} - \beta C_{CM,i+1} + (1+2\beta)C_{CM,i} - \frac{aV_i}{Q_d} S_i = 0 \quad (7)$$

where  $R_i$  and  $S_i$  are reaction rate fluxes according to Equations (1) and (2), respectively. Assuming no significant effect on the diffusion of dimer-D2EHPA and protons [10]:

$$R_i = \frac{\frac{C_{A,i}C_{BD,i}}{C_{H,i}} - \frac{C_{CD,i}C_{H,i}}{K_D C_{BD,i}^{0.5}}}{\frac{C_{BD,i}}{k_A C_{H,i}} + \frac{1}{k_{F,i}} + \frac{C_{H,i}}{k_{CD} K_D C_{BD,i}^{0.5}}} \quad (8)$$

$$S_i = K_C C_{CD,i} - C_{CM,i} C_{BD,i}^{0.5} \quad (9)$$

so the balance between diffusional and chemical reaction control is determined not only by hydrodynamic conditions affecting the mass transfer coefficients but also by the concentrations of the reacting species and equilibrium considerations. The chemical reaction contribution depends on the ionic strength of aqueous phase with  $k_{F,i}$  given by [10]:

$$\log(k_{F,i}) = -5.597 - 3.211 \frac{\sqrt{I_i}}{1 + \sqrt{I_i}} \quad (10)$$

The organic phase from the coalescence zone ( $i = N+2$ ) is sent to an additional stage containing organic phase only ( $i = N+3$ ) which feeds the organic phase tank. Mass balances in this additional stage and in the tanks of aqueous and organic phases assume a first order delay to describe the dynamic response in these compartments. If long pipes between the tanks are used, the inclusion of a dead time in the circulation streams is required [6]. The model is a non-linear set of algebraic-differential equations, but substitution of Equations (8)-(9) into the mass balances Equations (3)-(7) results in an initial value problem with non-linear ordinary differential equations. Numerical solution has been obtained by the DASSL code [11]. Mass transfer and hydrodynamic parameters ( $\phi$ ,  $d_{32}$ ,  $k_A$ ,  $k_{CD}$ ,  $\alpha$  and  $\beta$ ) assumed to be stage and time independent have been estimated using the Hooke-Jeaves direct search optimisation method. In this work, the objective function is the total squared deviation between estimated and experimental concentrations of zinc and zinc-complex at the ends of the column at various times. The following start-up strategy has been adopted to initialise the numerical procedure: at  $t = 0^+$ , both phases circulate the entire plant but reaction is assumed to start only at  $t = 0^+$ . This physically unreal situation presumes an instantaneous hydrodynamic equilibrium and may not be valid for long columns.

## EXPERIMENTAL PROCEDURE

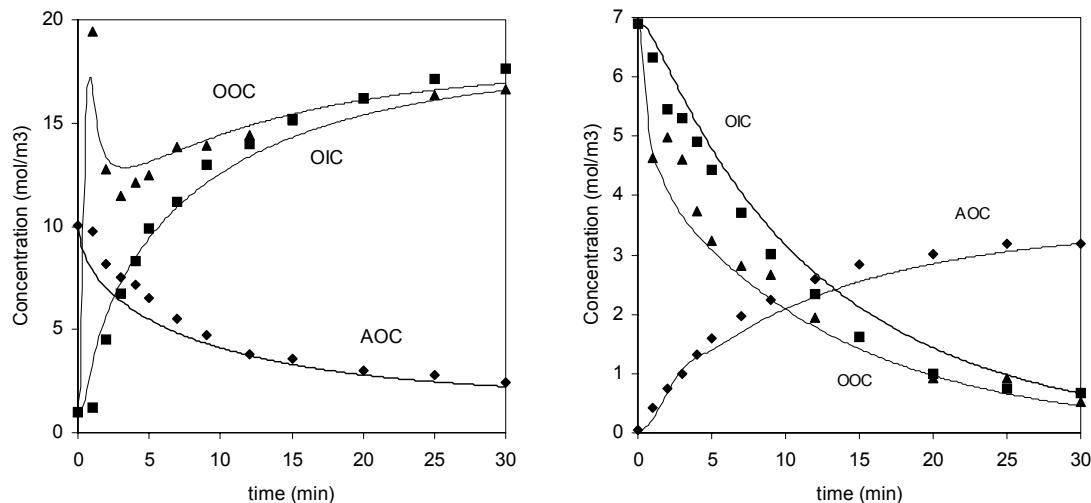

The experiments shown in Table 1 were carried out for 30 min with sampling at the ends of the column. Samples were analysed by atomic absorption. For extraction runs, the same liquor ( $10 \text{ mol/m}^3 \text{ Zn}^{2+} + 1 \text{ mol/m}^3 \text{ H}^+$ ) was contacted with  $75 \text{ mol/m}^3$  dimer-D2EHPA organic solution. For stripping runs, a fully loaded organic phase was contacted with sulphuric acid solutions at  $120 \text{ min}^{-1}$  and  $A/O = 2$ . Before each run, the column was circulated with continuous aqueous phase only, then dispersed organic phase was fed at  $t = 0$ . In all runs, the aqueous flow rate was kept constant at  $2 \text{ L/min}$ . The same total volumes of aqueous and organic phases were contacted (10 and 5 L, respectively).

*Table 1. Variable levels investigated to extraction and stripping runs.*

Run	Speed ( $\text{min}^{-1}$ )	A/O	Run	$C_{BD}^\circ (\text{mol/m}^3)$	$C_H^\circ (\text{mol/m}^3)$
E1	120	2	S1	75.0	100
E2	180	2	S2	75.0	1000
E3	120	4	S3	7.5	100
E4	180	4	S4	7.5	1000

## START-UP SIMULATIONS AND PARAMETER OPTIMISATION

Typical transient concentration outputs at the ends of the column are shown in Figure 1 (points are experimental data and lines are optimised concentration outputs). Labels AIC and OOC mean “Aqueous Input Column” and “Organic Output Column”, respectively. The zinc-complex concentration output at the end of the column for the extraction process exhibits a maximum at initial time due to the zinc-complex produced throughout the column that is accumulated and transported by the organic phase. A maximum at initial time is also observed for the stripping process, but the start-up strategy assumed to initialise the model is not realistic and led to failure in reproduce the OOC curve. Similar transient concentration outputs have been discussed in detail elsewhere [6].

*Figure 1. Dynamic extraction and stripping of zinc (runs E1 and S4, respectively).*

The hydrodynamic and mass transfer parameters shown in Table 2 have been estimated by fitting data from measured solute concentrations with the transient backflow model. The procedure yields data immediately useful for column design at minimal cost because operating parameters can be obtained from one experiment by model-fitting, but data should accurately measured [13].

Estimated average drop sizes are smaller than predicted by empirical correlations [12]. This result could be explained at least in part to the mass transfer effect which results in gradients of interfacial tension that affect coalescence/splitting rate of drops. It is generally ascertained in the literature that  $c \rightarrow d$  transfer tends to produce smaller drops, so larger drops should be expected in stripping runs. However, a reduction in drop size stabilising with time was observed visually, indicating that drop splitting prevails for the investigated stirring conditions. Estimated sizes in Table 2 are average values with time and stage. Therefore, as any change in drop size results in a change in the mean drop velocity, the estimated hold-ups in Table 2 are average figures. Hold-up values are reasonable but three drop size values seem unrealistic, possibly due to low data quality. Furthermore, the optimisation results have shown that drop size and hold-up are very sensitive parameters with some degree of correlation, possibly because only end of column data have been used. A distributor has been used to get acceptable drop sizes because the initial drop size distribution seems to influence results; a drop size distribution has not been employed in the model. The results indicate also that axial mixing effects are more likely associated with continuous phase flow rate because a null value of  $\beta$  has been estimated in most cases; no backward movement of drops was detected visually. On the other hand, estimated axial mixing coefficients for the continuous aqueous phase in extraction runs indicate strong mixing effects compared to predictions from correlations [12]. Sampling along the column is therefore necessary to identify real axial mixing effects.

*Table 2. Estimated mass transfer and hydrodynamic parameters.*

Run	$\phi \times 10^2$	$d_{32}$ m	$k_A (x10^4)$	$k_{CD}$	$\alpha$	$\beta$
E1	$8.19 \pm 0.02$	$(1.06 \pm 0.01) \times 10^{-3}$	$1.42 \pm 0.02$	$(3.41 \pm 1.10) \times 10^{-6}$	$\infty$	0
E2	$8.68 \pm 0.03$	$(5.68 \pm 0.01) \times 10^{-6}$	$\infty$	$(1.69 \pm 0.01) \times 10^{-9}$	$\infty$	0
E3	$3.19 \pm 0.02$	$(9.68 \pm 0.14) \times 10^{-4}$	$\infty$	$(4.81 \pm 0.05) \times 10^{-6}$	$\infty$	0
E4	$10.48 \pm 0.01$	$(9.14 \pm 0.70) \times 10^{-6}$	$\infty$	$(1.57 \pm 0.12) \times 10^{-9}$	$\infty$	0
S1	$4.96 \pm 0.03$	$(7.00 \pm 0.16) \times 10^{-5}$	$\infty$	$(2.24 \pm 0.05) \times 10^{-7}$	0	0
S2	$8.19 \pm 0.03$	$(2.63 \pm 0.01) \times 10^{-4}$	$\infty$	$(4.40 \pm 0.01) \times 10^{-5}$	$\infty$	0
S3	$9.39 \pm 0.12$	$(9.56 \pm 0.33) \times 10^{-4}$	$\infty$	$(1.80 \pm 0.21) \times 10^{-5}$	$0.20 \pm 0.36$	0
S4	$9.37 \pm 0.11$	$(6.13 \pm 0.15) \times 10^{-4}$	$\infty$	$(3.07 \pm 0.09) \times 10^{-6}$	0	0

The aqueous phase mass transfer resistance seems to be significant only for extraction experiments at low stirring speed (below  $120\text{ min}^{-1}$ ). Except at high stirring speed ( $180\text{ min}^{-1}$ ), the extraction rate is mainly controlled by the kinetics of the reaction, while the stripping rate is mixed-rate controlled (chemical reaction and organic phase mass transfer resistances) for the range of operational conditions investigated.

In general terms, it has been found the equilibrium model is suitable for reproducing extraction and stripping equilibrium data of the Zn-D2EHPA system for practical conditions. The backflow model is able to reproduce the start-up behaviour reasonably well.

## CONCLUSIONS

- (a) Design data generated from start-up experiments in short columns with circulation of both phases are significantly cheaper to obtain compared to steady-state experiments in long columns, but the reliability of the parameter estimates obtained from solute profiles depends on the accuracy and location of the measurements. Operating parameters can be obtained from one experiment by model-fitting.
- (b) Empirical correlations found in the literature have been developed to predict operating variables in columns at steady-state conditions, so these equations do not necessarily predict parameters well for transient situations.
- (c) A better mathematical description of hydrodynamics in columns is required to reproduce better the adopted start-up strategy. Models assuming transient hydrodynamic characteristics (in population balance models, for example) may improve data description and minimise any parameter correlation effects.

## ACKNOWLEDGEMENTS

The experimental work done at the University of Bradford was made possible by financial support received from the Coordenação de Aperfeiçoamento de Pessoal de Nível Superior (CAPES, Brazilian Government Agency, PICDT/UFMG and PDEE Doctorate Grant n° 0299/99-5), which is gratefully acknowledged. M.B. Mansur would also like to record his appreciation for financial support from Conselho Nacional de Desenvolvimento Científico e Tecnológico (CNPq), Brazil and Fundação de Amparo a Pesquisa do Estado de Minas Gerais (FAPEMIG), Brazil, to attend this Conference.

## NOMENCLATURE

$a$	interfacial area ( $\text{m}^2$ )
$C_j$	concentration of specie $j$ ( $\text{mol}/\text{m}^3$ )
$d_{32}$	average drop size (m)
$I$	ionic strength ( $\text{kmol}/\text{m}^3$ )
$k_i$	mass transfer coefficient of specie $i$ (m/s)
$k_F$	concentration-based forward reaction rate constant (m/s)
$K_C$	concentration-based equilibrium constant reaction ( $\text{mol}/\text{m}^3$ ) $^{1/2}$
$K_D$	concentration-based equilibrium constant reaction ( $\text{mol}/\text{m}^3$ ) $^{1/2}$
$Q$	volumetric flow rate ( $\text{m}^3/\text{s}$ )
$R$	overall molar flux of the heterogeneous reaction ( $\text{mol}/(\text{s} \cdot \text{m}^2)$ )
$RH$	molecule of monomer-D2EHPA
$S$	overall molar flux of the homogeneous reaction ( $\text{mol}/(\text{s} \cdot \text{m}^2)$ )
$t$	time (s)
$V$	volume ( $\text{m}^3$ )

### Subscripts

A	zinc ion
BD	dimer-D2EHPA
c	continuous phase
CD	dimer-D2EHPA complex
CM	monomer-D2EHPA complex
d	dispersed phase
H	hydrogen ion

### Greek

$\alpha$	backmixing coefficient continuous phase
$\beta$	backmixing coefficient dispersed phase
$\phi$	hold-up of dispersed phase

# THE IMPORTANCE OF HOLDUP IN PILOTING OF KINETICALLY CONTROLLED SX PROCESSES IN COLUMNS

Baruch Grinbaum

IMI(TAMI) Institute for Research and Development, Haifa, Israel

In chemical extraction, the residence time per theoretical stage must be at least equal to the time needed to complete the reaction. The holdup plays a crucial role in these processes, as the residence time of the dispersed phase increases linearly with the holdup. It is also important to run the pilot column at the minimum flux that yet allows high holdup. In many cases the residence time in the pilot may be too low to obtain the required recovery. In industrial columns this problem is less severe, as the HETS increases with the diameter of the column, and so for a similar residence time the flux may be higher. The experimental results should be analyzed, using the proposed scale-up procedures, to calculate the size of the industrial equipment.

## INTRODUCTION

Although a lot of work has been done on kinetic aspects of extraction, expressed usually through the rate coefficients [1], their impact on experimental procedures in columns is often neglected. The importance of the kinetics in SX process development is well known and the relevant models are widely documented in numerous papers and books, e.g., [1-3], to quote just a few. Yet, only few publications (e.g., [4]) mention the kinetic aspects in piloting of columns, and they are often left either disregarded or misinterpreted.

In chemical extraction, the time needed to complete the reaction, as a function of the temperature, must be known, from the literature, from previous experience or from simple batch kinitical experiments, prior to any piloting. The residence time per theoretical stage, of each phase, must be at least equal to this time.

### Residence Time

It is important to remember that the residence time of each phase in the column is different. For the dispersed phase, it is equal to:

$$\tau_d = Ah\phi e/F_d \quad (1)$$

and for the continuous phase:

$$\tau_c = Ah(1-\phi)e/F_c \quad (2)$$

where  $F_d$  and  $F_c$  are the flow rates of the dispersed and continuous phases,  $A$  is the cross-sectional area of the column,  $h$  is the total height of the column in which extraction takes place,  $\phi$  is the holdup, and  $e$  is the fractional free area in the column.

The residence time can also be expressed as a function of the flux J:

$$\tau_d = (1 + R)h\phi e/J \quad (3)$$

$$\tau_c = (1 + R)h(1-\phi)e/(RJ) \quad (4)$$

where R is the flow rate ratio,  $F_c/F_d$ , and is assumed constant through the column. The flux follows the standard definition:

$$J = F/A = 4F/\pi D^2 \quad (5)$$

where D is the diameter of the column.

To obtain the residence time per stage, h in Equations (1) to (4) should be substituted by the height equivalent to a theoretical stage (HETS). For most columns  $e \sim 1$ , and for the sake of simplicity it is omitted in the following discussion.

Figure 1 shows the residence times in the column, for each dispersion, at various fluxes and phase ratios, at constant holdup of 20%, and Figure 2 shows the influence of the holdup on the residence time.

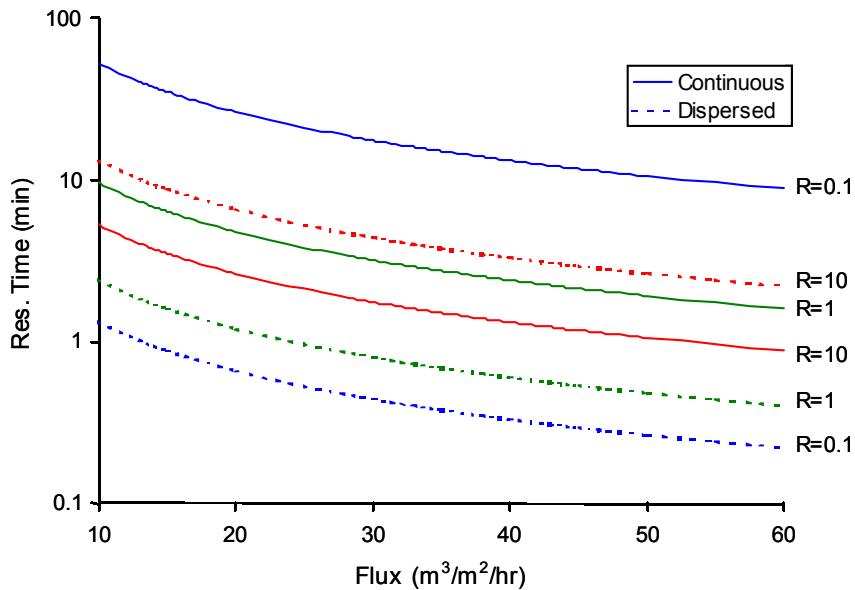

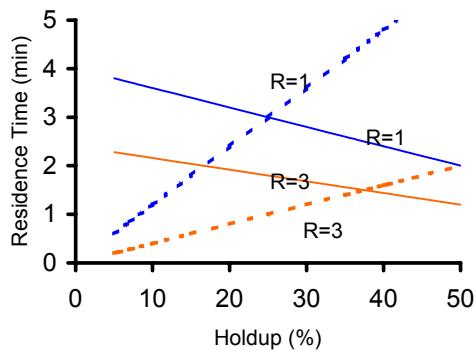

Figure 1. Residence time in a 1 m column vs. flux and phase ratio.

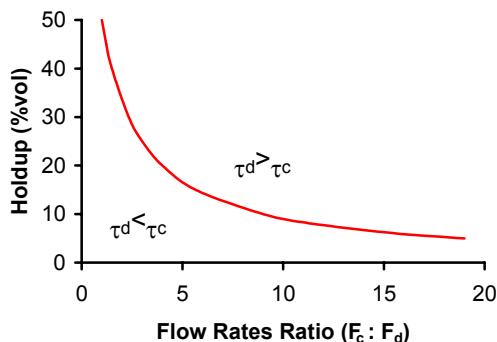

From Equations (3) and (4), the following equation is derived:

$$R = (1-\phi)/\phi \Leftrightarrow \tau_d = \tau_c \quad (6)$$

Equation (6) means that when the ratio of the flow rates R is equal to the relative volume of the phases in the column, both phases have the same residence time. As this condition ( $\tau_d = \tau_c$ ) assures the best kinetic performance of the column, for every R the best holdup  $\phi$  can be calculated. The graphical description of Equation (6) appears in Figure 3.

*Figure. 2. Influence of the holdup on the residence time (--- dispersed phase, - - - continuous phase).*

*Figure 3. Optimum holdup vs. the flow rates ratio.*

### **Which phase has a longer residence time?**

As one can see from both Figures 2 and 3, increasing the holdup, at constant phase ratio, eventually makes the dispersed phase the slow one, *i.e.*, with longer residence time. But this can happen only if the minor phase (*i.e.*, the phase with lower flow rate) is dispersed in the major one. As found by Arashmid and Jeffreys [5] and others, the holdup of the continuous phase is greater than (or at least similar to) the holdup of the dispersed one. When the major phase is dispersed, it always has the lower residence time, as its flow rate is higher and yet it occupies less than 50% of the active volume of the column.

### **When should the kinetics be considered?**

In pilot columns the HETS is usually below 100 cm, and in some agitated columns, *e.g.*, Karr or Scheibel, it may be even shorter than 20 cm. Substituting  $h = \text{HETS}$  in Equations (3) and (4), one finds directly the residence time per stage at given operating conditions, and may deduce whether kinetics should be considered.

For example, at phase ratio 1:1, holdup of 20% and a flux of 20-30 m<sup>3</sup>/m<sup>2</sup>/h, the residence time in a 20 cm length of a column is only 10-15 s, and in 100 cm – 50-80 s. At a flux of 50 m<sup>3</sup>/m<sup>2</sup>/hr or holdup of 10%, the residence time even in 100 cm drops below 30 s.

As a rule of thumb, kinetics should be considered for pulsed columns kinetics if the required residence time per stage exceeds 30 s, and in Karr or Scheibel columns, above 15 s.

### **Kinetic considerations in experimental procedure**

The standard procedure for SX process development, using columns (see [4]) is:

1. Determine the NTS and phase ratio, either from data given by the client or by simulation.
2. Determine the residence time for one equilibrium stage from batch experiments. This is the approximate residence time per stage needed for the quickest phase in the column.
3. Knowing the maximum height of your pilot column and the approximate HETS, calculate the maximum flux that provides the necessary residence time at both dispersions (O/W and W/O), using eqs. 3-4 and assuming holdup between 15-30%.

If this flux is within the normal range of the tested columns, no kinetic considerations are necessary. Otherwise, the special procedure for slow processes, which is given below, should be applied.

## PILOTING OF SLOW SX PROCESSES

### Hydrodynamic Tests

The piloting starts with the standard hydrodynamic tests, to find the flooding curve, *i.e.*, the flux as a function of the energy input. During these experiments the holdups are measured for every tested value of flux and energy.

Without kinetic constraints, the flooding curve is prepared for both dispersions, and the one that gives higher flux is chosen, unless there are special considerations to rule it out. For quick processes the holdup is of secondary importance, and any value above 5% is considered satisfactory.

For slow processes, there is a big incentive to keep the major phase continuous, in order to increase its residence time (the holdup of the continuous phase is always above 50% [5]). It is also very important to keep the holdup as near to the optimum calculated in Equation (6) as possible, to have similar residence time for both phases.

Sometimes, due to either process or hydrodynamic considerations, the major phase must be the dispersed one. From our experience, this is usually the rule at phase ratio above 1:10, as the mass transfer tends to be poor when the minor phase is dispersed. In this case it is important to achieve the highest possible holdup, above 30%. It should be kept in mind that holdup approaching 50% means that the maximum possible energy is applied, and further increase of the energy may cause flooding or phase inversion [5]. A holdup of 10% and below for such a process is often a no-go factor.

For a slow process, it is important to investigate the maximum holdup available at low fluxes. We noticed that the holdup tends always to drop at lower flow rates. The bottom line is that decreasing the flux may cause a lower residence time than at the higher flux. A comprehensive hydrodynamic test enables us to find the flux that yields maximum  $\tau$  of the quickest phase.

Knowing the holdups for a given flux, one can calculate the residence time of both phases,  $\tau_c$  and  $\tau_d$ , using Equations (3) and (4).

The available NTS of the experimental column, under the kinetic constraint, is:

$$\text{NTS} = \eta_s \cdot \min(\tau_c, \tau_d) / \tau_s \quad (7)$$

where  $\tau_s$  is the time needed to approach equilibrium, to the desired extend, on one theoretical stage, and  $\eta_s$  is the fraction of equilibrium achieved. It is important to remember that  $\tau_s$  does not have a unique value, and it depends on how near do we want to approach equilibrium. One may use an optimization technique over NTS in Equation (7), and find the residence time that yields the maximum overall number of transfer units. Often not enough data are available for such an optimization, and a reasonable guess is used instead. The author recommends residence time that enables ~90% of the equilibrium mass transfer.

The value of NTS from Equation (7) is always lower than one could expect, for similar column, without kinetic problems. It is often below the required NTS for the process.

### Mass Transfer Experiments

In a normal process, the mass transfer experiments enable the calculation of HETS and establish the recovery in the column. For a slow process, the feasibility of the process is proven in two stages:

1. The preferred dispersion and maximum flux are found in the hydrodynamic test.
2. The mass transfer experiments have to prove whether the NTS, calculated by Equation (7), and using the actual holdups, can be achieved. They should be carried out twice: once at the highest flux that enables working at the optimum holdup, and once under conditions that predict maximum recovery, *i.e.*, maximum NTS. If the experimental NTS is similar to the calculated one, in both cases, it means that there are no unexpected problems of mass transfer, and the extraction in the pilot is really kinetically controlled. Otherwise the kinetics is not the limiting constraint, and the diffusion should be addressed too, probably by using higher energy and lower flux.

### **Influence of temperature**

It is most important to carry out the experiments at the design temperature. In piloting normal process, a deviation of 5-10°C from the set temperature through the column may be tolerated, as its influence on the flux is within the accuracy of the experimental procedure. Kinetics are more sensitive to temperature than flux, as the reaction rate constant  $k$  is an exponential function of the temperature, through the Arrhenius law and an increase of 10°C may double the rate of the reaction [6]. It is very difficult to keep a constant temperature in a pilot scale column, with a diameter in the range of 25-100 mm. The problem is especially severe when the process temperature is above 50°C and a high phase ratio (>10:1) is applied. In this case, heating of the small flow is ineffective, and the heat losses from the column's surface cause a significant temperature drop over the column. As a rule, the large stream should be overheated, so that the temperature in the middle of the column is the desired one. From our experience, in long columns it is difficult, even if good insulation is used. The problem may be overcome by active insulation (*i.e.*, heating) of the column. If not feasible, the height of the column should be reduced, so that the temperature drop is as small as possible. The extrapolation of the results from a shorter column is more reliable than working with full-length column along wide range of temperature.

### **Next steps**

If the client believes in scale-up procedures based on extrapolation, then the experimental work is over, and the scale-up calculations, based on the experimental work, may be done – see next section.

Otherwise, experimental simulation of a longer column is needed. For extraction, the column is rerun with fresh solvent and the raffinate from the previous run is used as a feed. For purification/stripping, the purified/stripped solvent is rerun against fresh purification/strip solution. This procedure gives approximately the equivalent of a column with double length. It can be repeated again and again, so that with the existing column one can simulate a process that requires many stages. The rigorous procedure is described in [4]. The experiment becomes longer, but no extrapolation is needed.

Sometimes the piloting of columns is run in parallel to an existing plant with MS (mixer-settlers). This is usually done in order to test the feasibility of replacing MS with columns. In such a case, the experimental procedure is easier and more accurate. Assume that the tested battery has  $n$  MS stages: From Equations (3), (4) and (7) one can calculate  $j$  - the expected NTS of the pilot column. The column is first fed with the aqueous feed and a solvent from the  $j$ -th stage in the MSr battery. In the next experiment, the feed solvent and the aqueous phase from the  $(n-j)$  MS are used as feeds to the column. If the compositions of the outlet streams do not fit the results of the mixer-settler plant, our estimation of the NTS in the column must have been wrong, and the procedure is repeated for an updated value of  $j$ , until exact simulation with the column is obtained.

Is the second run really necessary? No, unless problematic mass transfer may be expected in the diluted end of the process, or if the client is reluctant to extrapolate and wishes to see the real thing coming out of the pilot plant.

One way or another, the pilot column enables the kinetic HETS in the pilot column to be calculated and the flux at which it was obtained  $J_k$ .

## SCALING UP

For an industrial column, in a kinetic-controlled process, the HETS must fulfill both the kinetic and the hydrodynamic constraints. The exact procedure of scaling up is done by the manufacturer of the equipment. But it is important for the researcher (and for his client) to make a rough estimation of the size of the industrial column - both diameter and height.

### **HETS – from Kinetic Considerations**

The recovery, at known flux and column length, is found from the piloting. A comparison to simulation or to known plant results yields the effective NTS, under the kinetic constraint. From here one can get the kinetic HETS or  $HETS_k$ , and the flux at which it was calculated  $J_k$ . These values determine the volume of the industrial column, as the residence time, *i.e.*, the speed of flow of both phases through the column, remains constant. Assuming that the holdup does not change in the scale up, it means that:

$$(HETS/J)_p = (HETS/J)_i \quad (8)$$

where the indexes  $i$  and  $p$  stand for industrial and pilot, respectively.

### **HETS - from Hydrodynamic Considerations**

In kinetically controlled process the true HETS in the pilot is not known. The safe guess is  $HETS = HETS_k$ , measured during the low flux mass transfer experiments.

In the industrial column the HETS is always larger than in the pilot one. For most columns it follows the empirical Equation (7):

$$HETS_i/HETS_p = K(D_i/D_p)^M \quad (9)$$

where  $K$  and  $M$  are efficiency scale factors.  $K$  is slightly greater than 1, and in some cases is omitted.  $M$  is in the range of 0.2-1.0, according to the type of the column, for example, for the Karr column  $M = 0.38$ .

Substitution of  $HETS_i$  from Equation (8) in Equation (9), using the value of  $J_i$  from Equation (5), yields:

$$D_i = \left( \frac{4F_i D_p^a}{\pi J_p} \right)^{\frac{1}{2+a}} \quad (10)$$

Knowing the diameter, it is possible to estimate the height of the industrial column and the flux in it, using Equations (8) and (9).  $J_i$ , obtained from these calculations, is always higher than  $J_p$ , the low flux at the pilot, that was used for the scale-up. But it must, of course, be smaller than the maximum value predicted by the hydrodynamic test.

Remark: The values obtained by these calculations are not necessarily the optimum, and they will be recalculated by the manufacturer. But they give an estimate about the size of the future plant, and a feeling whether columns are or are not feasible.

## CONCLUSIONS

The kinetic aspects in piloting of SX processes in columns are important, and sometimes overlooked. The holdup plays a crucial role in these processes, as the residence time of the dispersed phase increases linearly with the holdup. It is important to run the pilot at the minimum flux that yet allows high holdup. In many cases the residence time in the pilot may be too low to obtain the required recovery. In industrial columns the HETS increases with the diameter of the column, and so for similar residence time the flux may be much higher. Failure to get the required recovery in the pilot may lead to unjustified rejection of the column. The experimental results should be analyzed, using the recommended scale-up procedure, and only then the decision whether columns are yet an attractive option should be done.

## AXIAL MIXING IN A RECIPROCATING PLATE COLUMN

Alfredo I. C. Garnica, Márcia M. L. Duarte and Carlson P. de Souza

Departamento de Engenharia Química, Universidade Federal do Rio Grande do Norte,  
Natal, Brasil

The axial dispersion coefficient in the liquid phase has been measured by unsteady tracer response methods in a 5 cm internal diameter reciprocating plate column, using water as a continuous phase. The main variables studied were plate spacing (5-7, 5-10 cm), amplitude (2-4-6 cm) and frequency of reciprocation (0-1.85 Hz), superficial velocity (0.15-0.46 cm/s), and hole diameter (0.3-0.7 cm). Measured values of axial dispersion coefficient ranged from about 1 cm<sup>2</sup>/s to a maximum of 16 cm<sup>2</sup>/s. An empirical correlation for the axial dispersion coefficient is proposed by using the experimental results.

### INTRODUCTION

The efficiency of the reciprocating plate column is strongly affected by the axial dispersion, for this reason it is very important to determine the axial dispersion coefficient, which is the parameter that characterizes and quantifies the intensity with which this phenomena takes place.

The investigators have used two fundamental models for the determination of the axial dispersion coefficient. These models are: the dispersion model proposed by Levenspiel [1] and the backflow model proposed by Sleicher [2]. Other models were also proposed by Novotny [3] and Baird [4].

Using these models the investigators have proposed different correlations for the axial dispersion coefficient for counter current contactors mainly for extraction column [5]. Even though many correlations have been developed for predicting axial mixing there is a lack of agreement between these correlations regarding the form of the dependence of axial mixing upon the numerous parameters involved.

In this work the dispersion model was used according to the recent studies [6-9] carried out in this area where a tendency exists to use this model due to its reproducible results obtained by the other models. The purpose of this work, is to obtain a new correlation for the axial dispersion coefficients that provides a better knowledge on the dependence of some parameters of operation of the reciprocating plate column for this coefficient.

## COLUMN AND PLATE

The reciprocating plate column and ancillaries are schematically shown in Figure 1a. Water was fed to the base of the column by gravity. The column is made of a glass tube with 5 cm internal diameter. The reciprocating system is made of a motor with 370 W (0.5 Hp). The operating frequency can be varied up to 3 Hz and up to 6 cm amplitude. The measurements of the reciprocating plates (Figure 1b) used in this work are given in Table 1.

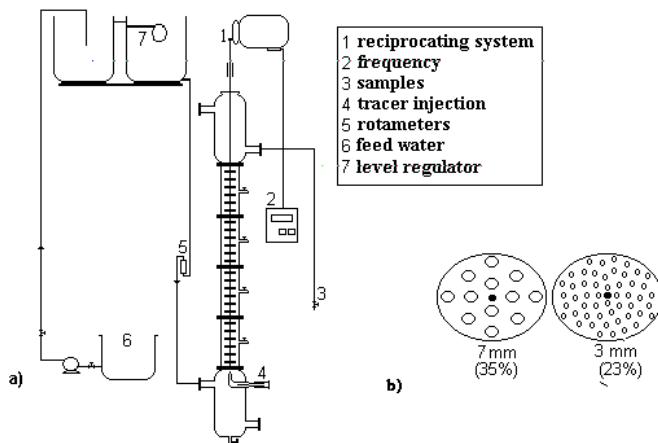

Figure 1. Reciprocating plate column and ancillaries.

Table 1. Column parameters, types of plates and ranges of operating conditions.

COLUMN	
Internal diameter (cm)	5
Active length (cm)	120

Thickness (cm)	0.12
% Fractional free area	23 and 35
OPERATING CONDITIONS	
Amplitude (cm)	0-4-6
Frequency (Hz)	0-1.85
Superficial water velocity (cm/s)	0.15-0.46
Plate spacing (cm)	5-7, 5-10
Number of plate (above spacings)	24-16-12

## AXIAL DISPERSION COEFFICIENT DETERMINATION

The dispersion coefficient ( $E$ ) was determined from a pulse tracer experiment. Here the tracer concentration of the column is measured as a function of time. The samples were collected each and every minute from the first plate on the top and then analyzed by spectrophotometry. Methylene blue was used as the tracer. From the tracer concentration data the mean residence time and variance were calculated and these values were then used to determine  $E$ . Using the equation of dispersion model in dimensionless form, we have

$$\frac{E}{UL} \frac{\partial^2 \Psi}{\partial \lambda^2} - \frac{\partial \Psi}{\partial \lambda} = \frac{\partial \Psi}{\partial \theta} \quad (1)$$

Using the boundary conditions for closed vessels, analytical solutions of equation (1) for the mean residence time,  $t_m$  and the variance are:

$$t_m = \tau \quad (2)$$

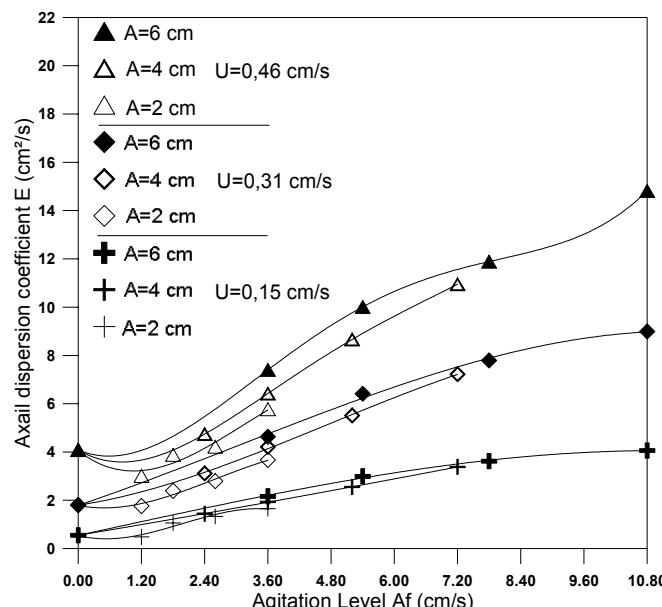

$$\frac{\sigma^2}{t_m^2} = \frac{2}{Pe} - \frac{2}{Pe^2} (1 - e^{-Pe}) \quad (3)$$

Using equations (2) and (3), the Peclet number ( $Pe$ ) can be calculated and hence the axial dispersion coefficient  $E$ .

## RESULTS AND DISCUSSION

The experimental values of the axial dispersion coefficient for a combination of three superficial velocities, three amplitudes and four frequency of reciprocation, three spacing plate, and two hole diameter, for a total of 216 data points, are separately presented in four figures. The diameter of the column was kept constant (Table 1).

The main variables affecting axial dispersion are the agitation level, which is determined by the product of the amplitude and frequency of reciprocation ( $Af$ ), and the superficial velocity ( $U$ ). In this work, when the axial dispersion coefficient has a significant value in the absence of agitation level, then it passes through a minimum as  $Af$  is increased. This tendency was also shown by Hafez [10], Karr [11] and Baird and Rama Rao [6]. This is due to the observed tendency of water flow to be poorly distributed across the column. The effect of the agitation level upon axial dispersion coefficient  $E$ , for three amplitudes is shown in Figure 2. It can also be seen that, when the values of the term  $Af$  increases, the value of  $E$  also increases. The same happens with the amplitude when the other parameters are kept constant.

*Figure 2. Effect of agitation level ( $Af$ ) and amplitude upon axial dispersion coefficient for plate spacing  $h = 10$  cm and hole diameter  $d = 0.3$  cm.*

The effect of superficial velocity is shown in Figure 3. In all the experiments the axial dispersion coefficient increases with superficial velocity mainly for a higher level of agitation. This is possible because this behavior is associated with the increase of the turbulence caused by the elevation of the superficial velocity providing better indexes of mixture.

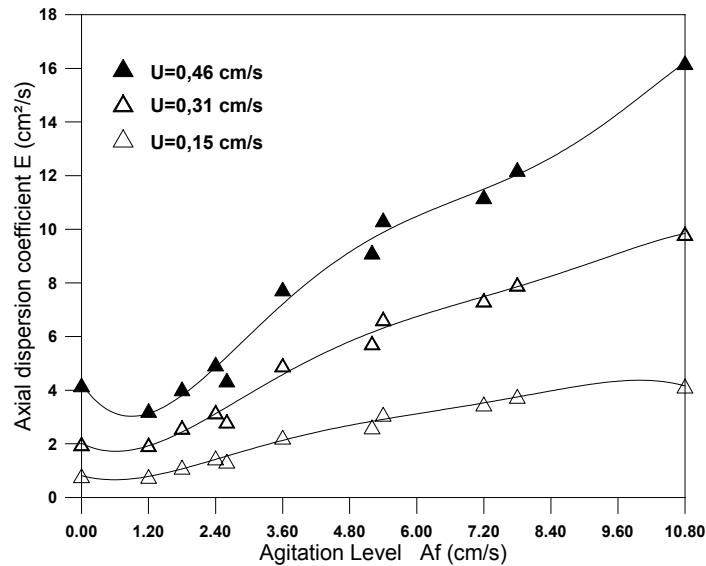

Figure 3. Effect of agitation level ( $A_f$ ) and superficial velocity ( $U$ ) for plate spacing  $h = 5 \text{ cm}$  and hole diameter  $d = 0.7 \text{ cm}$ .

The role of the plate spacing ( $h$ ) is examined in Figure 4. It was observed that the axial dispersion coefficient decreases when the spacing plate increases. This effect is more significant for higher values of the level agitation. This is possible because an increase in the numbers of plates produce a higher agitation and mixture hence the axial dispersion of the tracer in the continuous phase also increases. The effects of hole diameter ( $d$ ) are also shown in Figure 4. These results indicate that the axial dispersion coefficient increases when the diameter of the holes increases. This is due to the smaller eddy scale associated with the smaller holes.

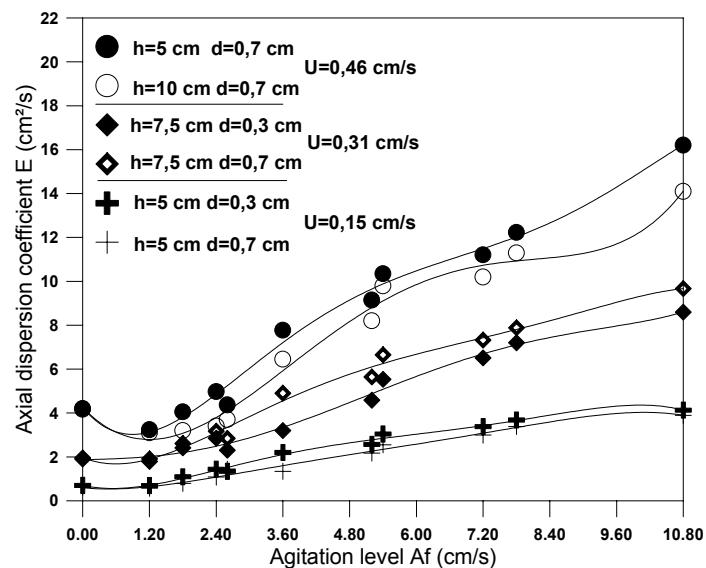

Figure 4. Effect of agitation level ( $A_f$ ), plate spacing ( $h$ ) and hole diameter ( $d$ ).

The experimental data were treated using non-linear estimation and an empirical correlation was proposed for the axial dispersion coefficient,  $E$  ( $\text{cm}^2/\text{s}$ ):

$$E = 5,6224 A^{0,867941} f^{0,650632} U^{1,109021} h^{-0,025506} d^{0,034861} \quad (4)$$

Comparison between observed and measured values of axial dispersion coefficient is shown in Figure 5.

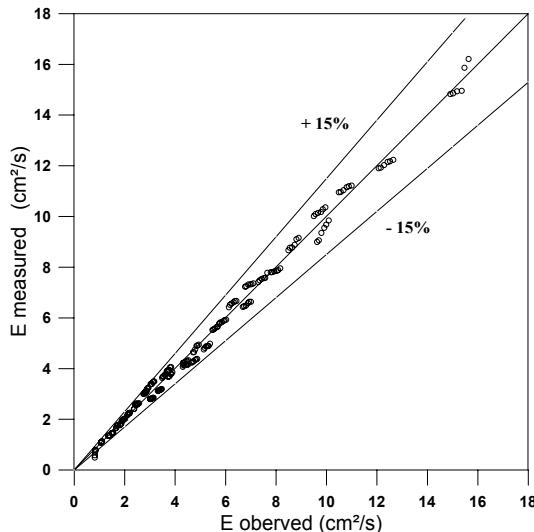

Figure 5. Comparison between observed and measured values of  $E$ .

## CONCLUSION

This paper discusses the determination of the axial dispersion coefficient in a reciprocating plate column. The values of  $E$  range from about  $1 \text{ cm}^2/\text{s}$  to a maximum of  $16 \text{ cm}^2/\text{s}$ . The amplitude, frequency of reciprocation and superficial velocity have an important impact on the axial dispersion coefficient. The axial dispersion coefficient has a significant value in the absence of agitation level ( $Af$ ) where it passes through a minimum as  $Af$  is increased. In general, the axial dispersion coefficient decreases when the plate spacing increases and hole diameter decreases. An empirical correlation is presented, giving  $E$  as a function of amplitude, frequency of reciprocation, superficial velocity of continuous phase, plate spacing and hole diameter.

## DESIGN OF PULSED EXTRACTION COLUMNS BASED ON LABORATORY-SCALE EXPERIMENTS

**Edwin Groß-Hardt, Martin Henschke, Sigrid Klinger and Andreas Pfennig**

Lehrstuhl für Thermische Verfahrenstechnik, RWTH Aachen, Germany

The design of pulsed extraction columns today still strongly relies on experimental investigations on pilot-plant scale with the specific system of interest. These experiments are time-consuming and expensive. We propose the ReDrop model (representative drops) for the simulation of extraction columns where about 2000 individual drops are followed as they move through the equipment. The effects considered acting on the drops are sedimentation, mass transfer, drop breakage and coalescence. The parameters of the models describing these effects are determined under very controlled conditions in laboratory-scale experiments with only some liters of liquid. The results of this prediction for pulsed sieve tray columns in the dispersion regime agree very well with experimental data for the coalescence inhibited system toluene + acetone + water.

### INTRODUCTION

In an extraction column many influencing factors are of roughly equal importance. Unfortunately these factors are strongly interrelated. Until now it has not been possible to identify any dominating influences and to describe them with sufficient accuracy. Thus for the safe design of extraction columns experiments on pilot-plant scale are still necessary. Such a design requires a large amount of substance and time and thus is expensive.

To improve the design procedure it is our goal to circumvent the expensive experiments on pilot-plant scale or at least to minimize them by substituting them with laboratory-scale experiments in standardized measuring cells with a small number of drops. These experiments are performed with a small amount of the original substances. Based on the results of laboratory-scale experiments the parameters determining the interplay between

- mass transfer to or from drops
- sedimentation of drops
- breakage of drops
- swarm behaviour

can then be determined. A method for the determination of coalescence parameters from these experiments is in progress. By suitably modelling this interplay additionally taking into account axial dispersion all basic effects acting on the droplets in a pulsed extraction column can be accounted for. Fortunately a variety of models is available for correlating the individual effects acting on the drops since the idea of describing extraction-column performance from single-drop behaviour is followed by several groups worldwide. The model we then use for the description of the entire extraction column is the ReDrop model [1, 2] which considers the individual behaviour of a sufficiently large number of drops in the column. The column behaviour is thus predicted from the single-drop behaviour characterized in the measuring cells.

## MASS-TRANSFER CELL

The laboratory-scale cell for the determination of mass transfer of single drops which was developed in collaboration with Bayer AG, Leverkusen, is shown in Figure 1 [3, 4]. A drop of the dispersed phase is generated with a computer controlled syringe. This drop then rises until it reaches a stable position in the thermostated conical part of the cell because of the counterflow of the continuous phase. If then the flow rate of the continuous phase is turned off for a short period of time, the drop rises further and reaches the withdrawal funnel which is also connected to a computer controlled syringe. Thus it is possible to generate a drop with a defined volume and contact it with the continuous phase for an arbitrary time span while it is virtually freely rising. For the generation of different drop volumes different syringes and nozzles have to be used.

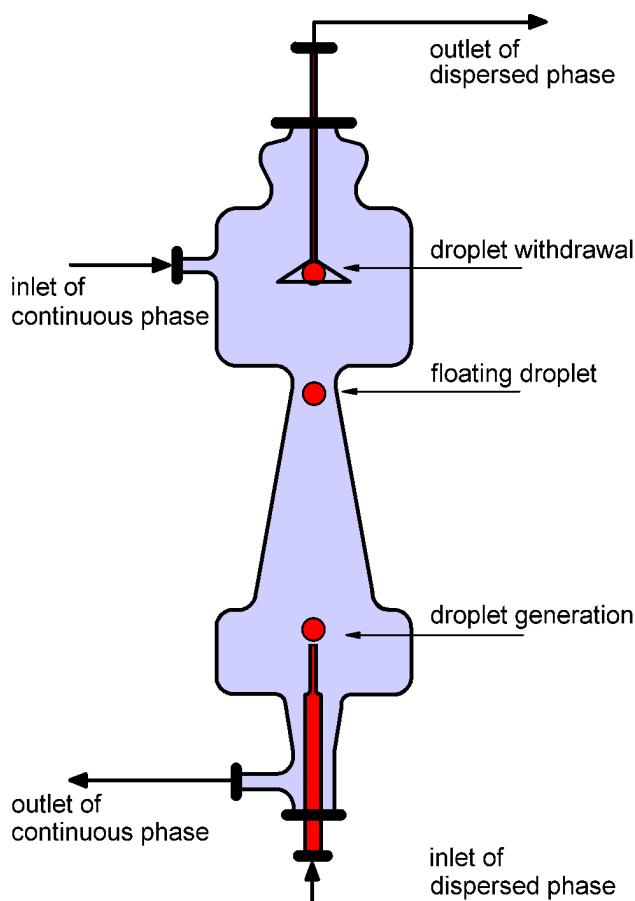

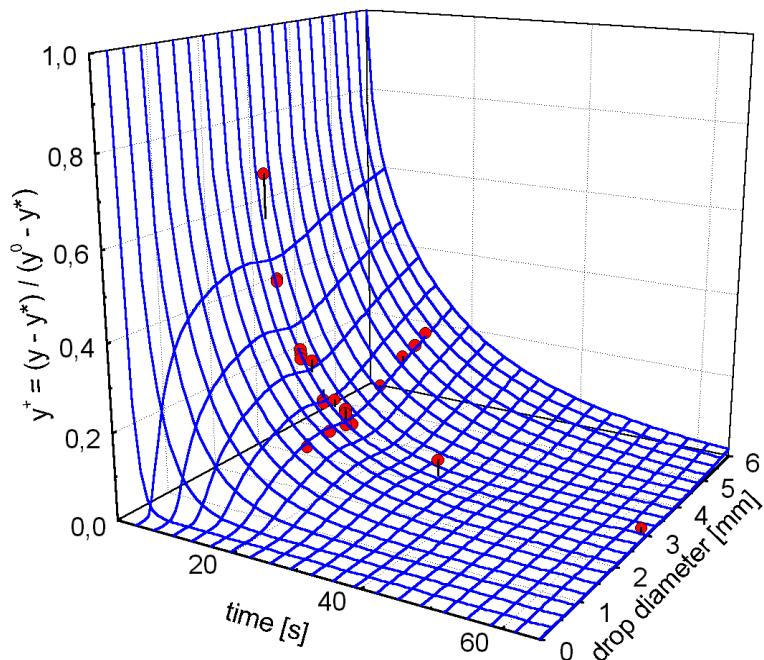

Figure 1. Schematic drawing of the laboratory-scale measuring cell for mass transfer.

Results obtained with this cell are presented in Figure 2. The dimensionless driving concentration difference which decays from unity at the start of the experiment to zero in equilibrium is plotted versus contact time and drop diameter. The specific slope of the surface obtained is a result of the various flow conditions of the drop as its diameter increases. While small drops behave like hard spheres a circulation is induced for larger drops. For even larger drops the shape begins to oscillate. This of course has direct influence on the mass-transfer rate. The model developed for the description of this behaviour takes these effects into account and additionally includes the enhancement of mass transfer by interfacial turbulence [4]. It can be seen that this correlation is able to describe the mass-transfer data with good accuracy. In further experiments the sieve-tray influence on mass transfer has been investigated in the same apparatus [5]. This correlation obtained for a single drop is later used directly for the simulation of an arbitrary large number of drops in an extraction column.

*Figure 2. Mass transfer of single drops in the system:  
n-butyl acetate (d) + acetone (t) + water (c), mass-transfer direction: c to d.*

Laboratory-scale cells of comparable size are used for the determination of sedimentation velocity also under the influence of mass transfer and the breakage [6] and coalescence probabilities. The sedimentation velocity is e.g. obtained from an evaluation of a video recording of drops sedimenting over 500 mm in a glass tube filled with continuous phase. Especially in the range of interest around 2.5 mm drop diameter it turns out that the sedimentation velocity is strongly affected by mass transfer, which compares well with literature [7].

### THE REDROP MODEL

The individual models obtained for a specific system with these laboratory-scale measuring cells are then joined together in the ReDrop model (representative drops). Additionally the axial dispersion of the continuous phase has to be taken into account. The idea of the ReDrop model is to follow a representative number of individual drops through the entire column with all the effects acting on them as quantitatively determined from the single-drop measurements. Typically 2000 drops are considered to obtain reliable results. The advantage of this approach is that all interactions between the different effects can be accounted for without problem.

A screenshot of the ReDrop model for a pulsed sieve-tray column is presented in Figure 3. On the left the column is shown with a representative number of individual drops and the sieve trays. As the simulation proceeds these drops are rising and it is then also indicated whether drops break or are coalescing in every time step. To the right of the column the drop size distribution is shown at all positions where it has been measured. In this case it has been measured only at the top of the column. Next the concentration and hold-up profiles (lines) are shown again in comparison with the experimental data (dots, for overall hold-up the straight line). It can be seen that the agreement of the concentration profiles is excellent while the hold-up shows slight deviation which is still in the range of experimental uncertainty. In the rightmost column some numerical data are shown which represent results as well as several control variables.

The ReDrop model for sieve-tray columns has then been tested against column data in our data base. This data base for pilot-plant scale columns has been collected with the support of several companies and universities and can be obtained from the authors.

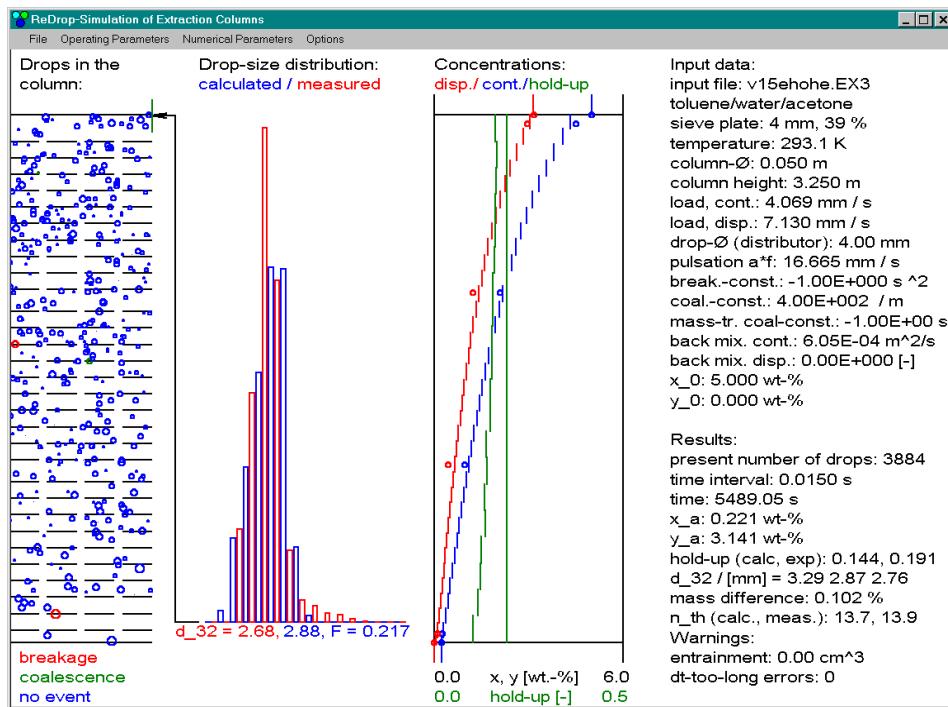

Figure 3. Screenshot of the ReDrop model.

## RESULTS

While coalescence is in principle taken into account already in the ReDrop simulation the coalescence parameters can not be determined until now. Thus only coalescence inhibited systems like toluene (d) + acetone (c → d) + water (c) can be simulated today. Another restriction is that only the dispersion regime is considered in the model equations. Furthermore only dual-flow sieve trays are investigated and the calculations are restricted to a single transfer component. Since these restrictions are no principle limitations progress is directed at extending the applicability of the ReDrop model beyond these limitations.

Some results obtained with the ReDrop model as it is available today are shown in Figure 4. Here the measured number of theoretical stages is compared with the predictions of the ReDrop simulation. This simulation is indeed a true prediction since only single drop data and available correlations for swarm behaviour [8], which are extended for liquid drops, are used and no column data have been applied in fitting the model parameters. The agreement between experiment and simulation is roughly 10% which is fully sufficient for a first design of an extraction column.

The simulations with ReDrop also describe the dynamic behaviour of the extraction column. Thus we investigated whether ReDrop is able to predict the dynamic limits of the extraction process, namely flooding. The corresponding results are shown in Figure 5 in comparison with experimental data [9]. It is obvious that ReDrop is in principle able to determine the limits of operation with high confidence.

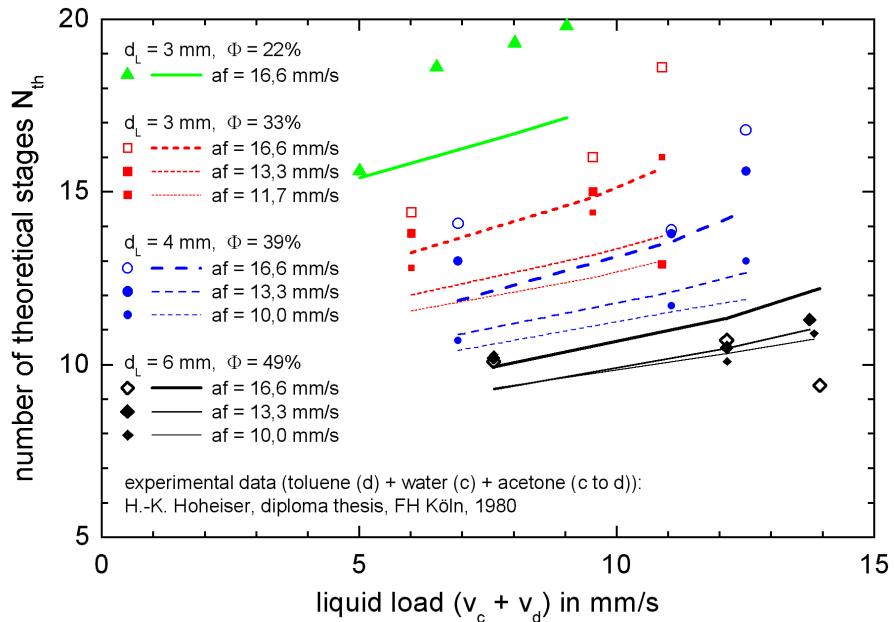

Figure 4. Comparison of experiment and ReDrop on the basis of column efficiency.

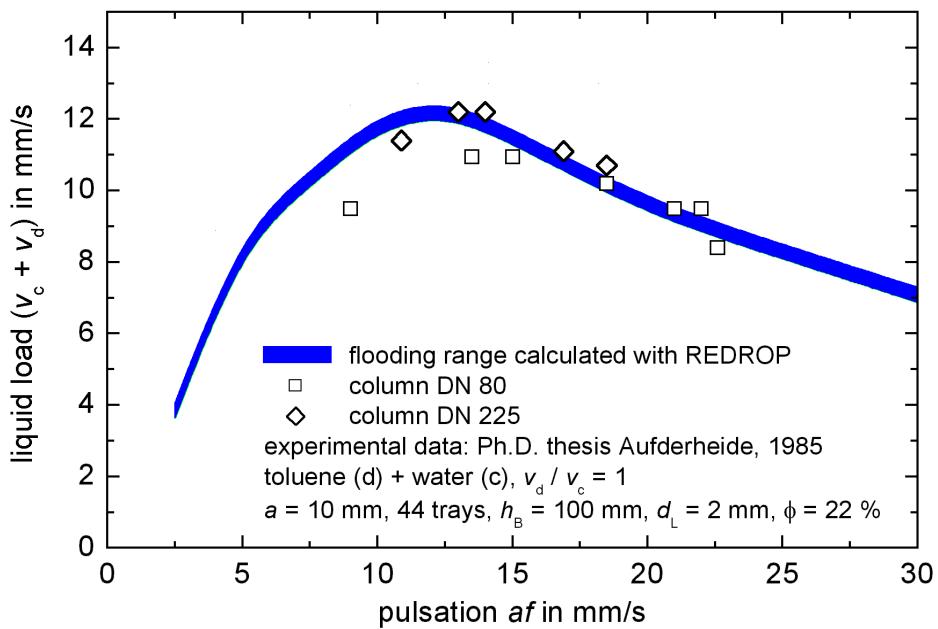

Figure 5. Flooding as predicted with the ReDrop model in comparison with experiment.

## CONCLUSIONS

It has been shown that based solely on the results of single-drop experiments it is possible to predict the behaviour of pulsed sieve-tray columns on pilot-plant scale. Even the dynamic limits of the operation of the column can be predicted with high confidence in the example shown. Future work will now be directed at extending the applicability of ReDrop to coalescing systems and to pulsed columns with packings. In a joint project with the groups of Professor Bart, Kaiserslautern, and Professor Stichlmair, Munich, all commonly used column types including those with rotating internals will be modelled based on laboratory-scale experiments. From these standardized experiments it is then possible to perform simulations for all column types and decide on the optimum design of the column in a knowledge based fashion.

## A DISTRIBUTOR FOR LIQUID-LIQUID EXTRACTION COLUMNS

Alfons Vogelpohl and Jörg Koch\*

Technical University of Clausthal, Clausthal-Zellerfeld, Germany

\* RTM 2000 AG, Langelsheim, Germany

Extraction columns equipped with ordered packing allow for a large operating range between 10 and 90 % of the load at flooding. In order to take full advantage of this flexibility, a new distributor design and operating mode has been developed, which produces a very uniform drop-size distribution and allows control of the average drop size at changing throughputs.

The main feature of the new design is the use of a pressure pulse produced by a mechanically excited PTFE membrane attached to the distributor and operated at a frequency of up to 50 Hz. The pressure pulse serves to control the disengagement of the drops formed at the holes of the distributor independent of the velocity of the liquid exiting the holes of the distributor and thus of the liquid throughput.

### INTRODUCTION

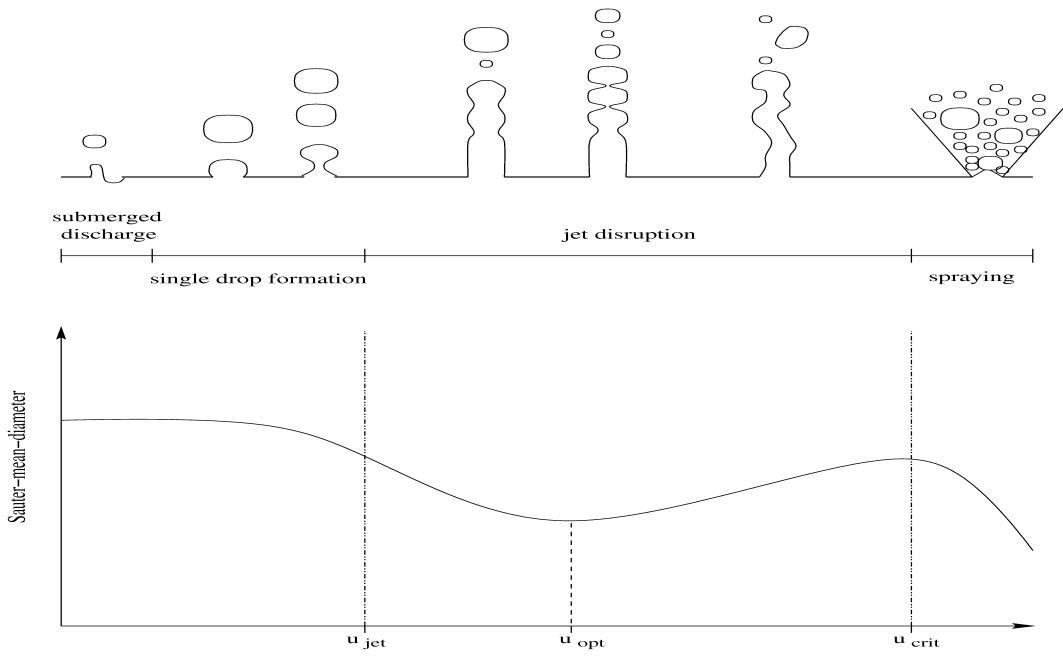

In liquid-liquid extraction one liquid is dispersed in a second immiscible liquid. The interfacial area required for mass transfer depends largely on the drop-size distribution generated by the primary distributor. Most conventional distributors generate the drops by the flow of the liquid through defined orifices and jet disruption. The drop size changes, however, with the liquid velocity in the orifices and, therefore, with the flowrate of the dispersed phase.

Figure 1 shows the different mechanisms of drop formation and the main dependency of the drop size on the velocity in the holes of the distributor. At very low velocities the drops are formed similar to a dripping water tap. This range is of no interest for technical use because of the low flowrate and the formation of very large drops. An increasing velocity leads to a periodic formation of single drops of equal size. In the medium range a jet is formed. The drops are generated by disruption at the top of the jet. With increasing velocity the jet length increases up to a maximum length and then decreases. At even higher velocities many small drops are formed by spraying.

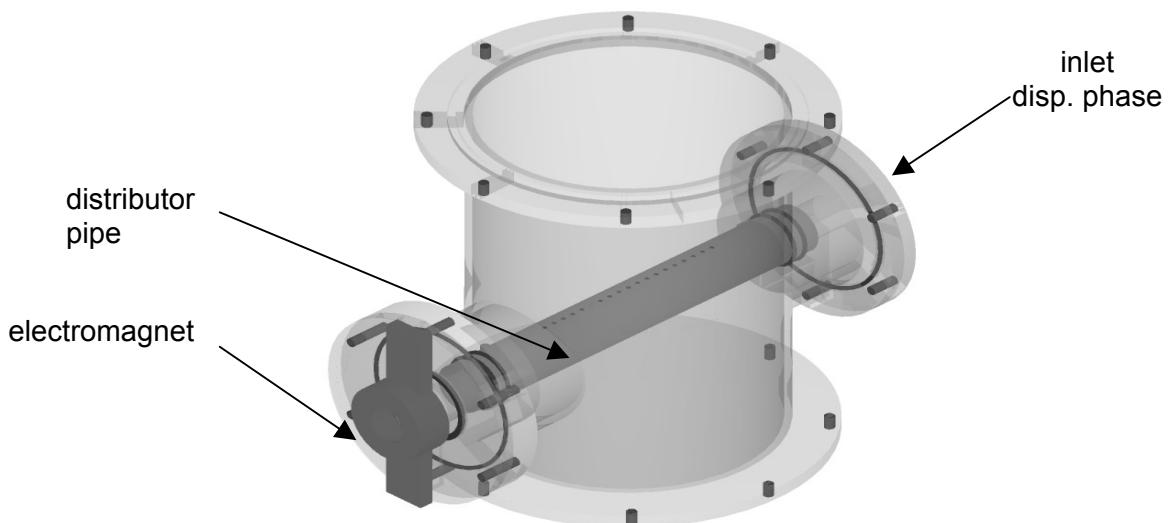

For an economic operation of an extraction column and for modeling the mass transfer a narrow and constant drop-size distribution at all flowrates is desired. This requires an additional possibility of adjusting the drop size independent of the flow velocity through the orifice. This adjustment can be affected in several ways: by a multi-stage distributor [1], by the flow of continuous phase around a capillary in a two-phase nozzle [2], by pulsation of the total column content [3] or by pulsation of the dispersed phase [4, 5].

## EXPERIMENTAL PROCEDURE

In these experiments the pulsation of the dispersed phase inside the distributor was chosen for controlling the drop size. The experiments were carried out with a normal tubular distributor with 21 orifices of  $d_O = 2$  mm diameter. The dispersed phase was fed to one end of the distributor by a centrifugal pump. The opposite end of the distributor pipe was closed by a PTFE membrane. With a conventional electromagnet a periodic mechanical impulse was generated on the film and transferred to the liquid inside the distributor. The pulsation frequency was adjusted with a frequency generator [6]. The pulsed distributor was attached to the bottom of a laboratory scale extraction column with a diameter of 190 mm as shown in Figure 2.

*Figure 1. Mechanism of drop formation and drop-size for different velocities.*

*Figure 2. Column section with the load independent distributor.*

Demineralized water was used as the continuous phase, the dispersed phase was ShellSol D70 ( $\rho_d = 798 \text{ kg m}^{-3}$ ,  $\eta_d = 1.7 \cdot 10^{-3} \text{ Pa s}$ ,  $\gamma = 34.3 \cdot 10^{-3} \text{ N m}^{-1}$ ). In all experiments the continuous phase was at rest. 350 mm above the distributor, the drop-size distribution was measured with the capillary suction method and the mean drop diameter was calculated. By changing the flowrate, the mean liquid velocity in the orifices was varied between 0.2 and  $1.15 \text{ m s}^{-1}$  in steps of  $0.1 \text{ m s}^{-1}$ . The pulsation frequency was changed between 0 and 45 Hz in steps of 5 Hz. At lower flowrates not every orifice was operating and at higher flowrates spraying started. A pulsation frequency higher than 45 Hz had no effect as the amplitude is too small due to the inertia of the oscillator.

## RESULTS AND DISCUSSION

Figure 3 shows the Sauter mean diameter for all combinations of liquid velocity and pulsation frequency in form of a fitted hyper surface. Without pulsation, corresponding to  $f_p = 0 \text{ Hz}$ , the well known dependency of the drop size on the velocity was observed with a distinct minimum at a velocity of  $0.4 \text{ m s}^{-1}$  and an increasing drop size at lower and higher velocities.

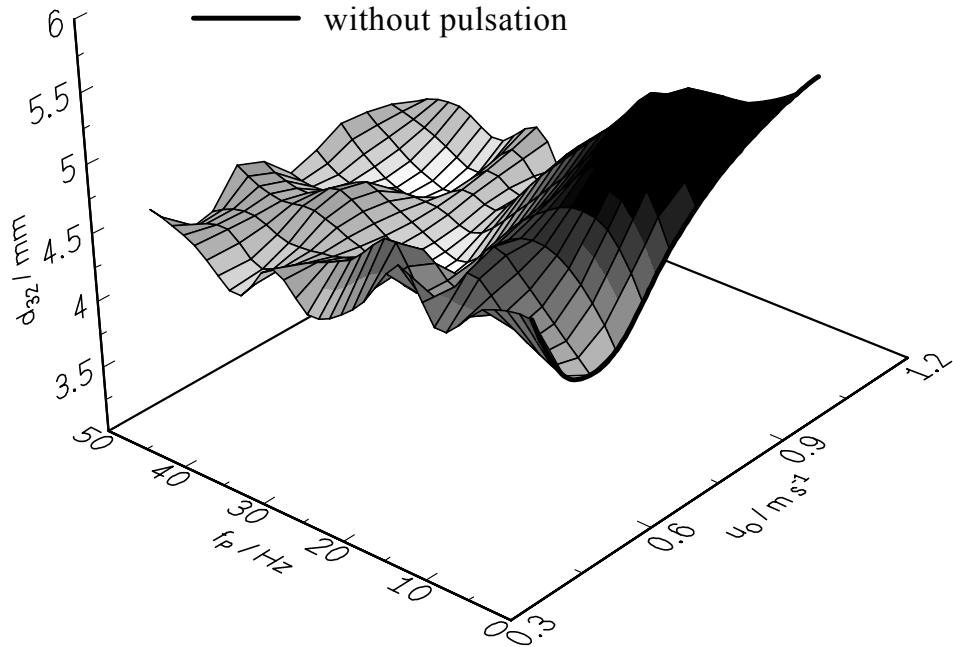

Figure 3. Sauter mean diameter vs. velocity and pulsation frequency.

The pulsation allowed the control of drop size. The diameter remained at the low level of the minimum in unpulsed operation and was independent of the liquid velocity and, therefore, of the flowrate of the dispersed phase. The operating range for a desired drop size of the distributor was widened substantially. If the distributor is designed for a velocity of  $0.4 \text{ m s}^{-1}$  without pulsation, with pulsation it can be operated between  $0.3$  and  $1.2 \text{ m s}^{-1}$  which corresponds to a load ratio of 1:4.

Besides the mean diameter the width of the drop-size distribution is an important criterion. Figure 4 shows the measured drop-size distribution for two different operating conditions. The upper part of the figure shows the drop-size distribution at unpulsed conditions, the lower part for a

pulsation frequency of  $f_P = 35$  Hz. In both experiments the mean liquid velocity was  $u_O = 0.53 \text{ m s}^{-1}$  which corresponds to a Weber number of  $We = 13$ . Without pulsation a bimodal distribution typical for drop formation by jet disruption was observed. A pulsation of  $f_P = 35$  Hz forced 80 % of all drops to be formed in a class of 0.2 mm width, i.e., the drop-size distribution was nearly monodisperse.

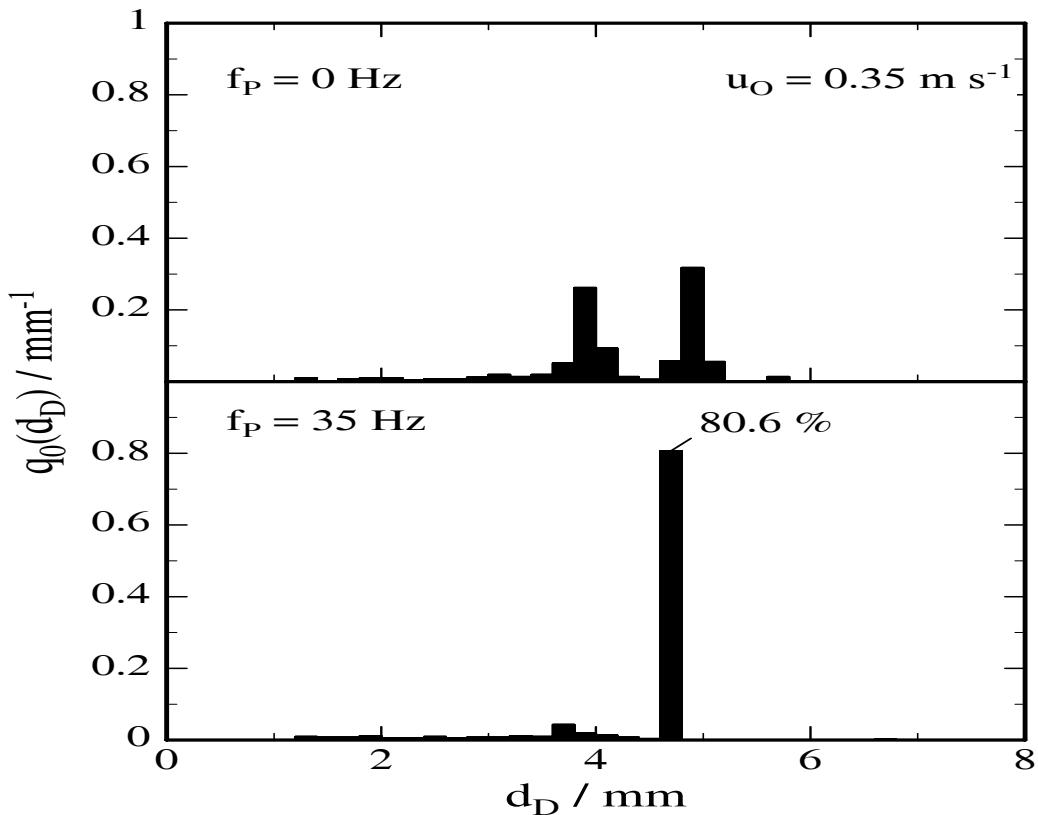

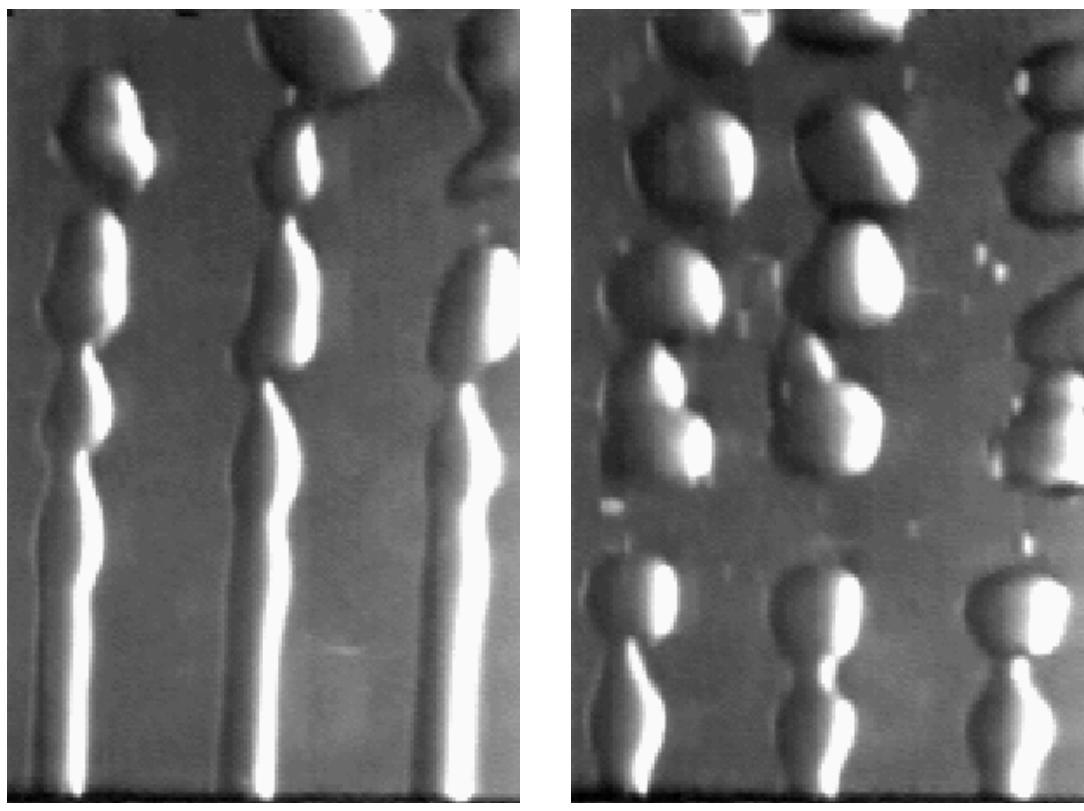

Figure 4. Drop-size distribution at pulsed and unpulsed conditions and a liquid velocity of  $u_O = 0.53 \text{ m s}^{-1}$ .

The pulsation triggers the detachment of drops from the jet at the pulsation frequency so that equally sized drops are formed. Figure 5 shows digitized still frames of a high-speed video sequence of both experiments. The drop formation under unpulsed conditions is shown in Figure 5a. Instabilities were forming waves on the surface of the jet. (The dark line at the bottom is the top surface of the distributor pipe.) If the length of the jet exceeded one wavelength of the disturbance, a drop was formed by disruption. If the jet length is not an integer multiple of the wavelength, Meister and Scheele [7,8] observed an alternation of the drop size and jet length between two stable states. This phenomenon was observed at the central jet in the picture. The two drops above the jet were of different size. The complete video sequence has clearly shown the alternation of the jet length. The bimodal drop-size distribution in Figure 5a proves this fact.

Figure 5b shows the drop formation at the same liquid velocity under pulsed conditions. The liquid jets were shorter than without pulsation, all drops formed being nearly the same size. The drop formation under pulsed conditions occurred by jet disruption, too, but the disturbance was generated by the pulsation and not by instability of the flow. Without pulsation such short liquid jets can be observed only at the transition from single drop formation to jet disruption at a lower liquid velocity. The pressure impact of the mechanical impulse from the electromagnet creates a much stronger disturbance as the natural disturbance generated by surface forces at the interface between the continuous phase and the jet.

a) without pulsation

b) at a pulsation of  $f_P = 35 \text{ Hz.}$

*Figure 5. High speed still frames of drop formation at a liquid velocity of  $u_O = 0.53 \text{ m s}^{-1}$ .*

## CONCLUSIONS

Mechanical pulsation of the liquid in a distributor allows control of the drop size independent of the flowrate in a wide load range. Very narrow, nearly monodisperse drop-size distributions are produced, which is not possible with conventional distributors. The operating range is much enlarged compared to unpulsed conditions.

For liquid-liquid extraction columns with structured packing this behavior is of particular advantage with respect to mass transfer as these columns may be operated in a wide load range. The narrow drop-size distribution also reduces the forward mixing of the dispersed phase because drops of the same size have the same rising velocity in the column. Since all the required additional equipment is installed outside the column, the free cross section in the distributor area of the column is not affected.

## APPLICATION OF DRIFT FLUX THEORY TO PACKED EXTRACTION COLUMNS

Lintong S. Hutahaean, Vincent Van Brunt and Jeffrey S. Kanel\*

Department of Chemical Engineering, University of South Carolina, Columbia, USA  
\*Dow Chemical Company, South Charleston, USA

Wallis drift flux theory was used to develop flooding correlation for continuous-phase-wetted packed liquid-liquid extraction columns. The average absolute error associated with the new correlation is 21.7% for 295 data points, almost a factor of 2 less than previously developed correlations. The Wallis drift flux expression was modified to  $j_{dc} = V_\infty \alpha (1-\alpha) \exp(m\alpha)$ . Here,  $V_\infty$  is a characteristic velocity,  $m$  measures the deviation of slope of the square root superficial velocity plot from the theoretical value of -1, and  $\alpha$  is the dispersed phase holdup. The new correlation method predicts  $V_\infty$  and the maximum drift flux at flooding ( $j_{dc,max}$ ), through which the parameter  $m$  is then determined.

### INTRODUCTION

Wallis [1] developed a one-dimensional drift flux model to describe two-phase flow in a column. Equation 1 is the definition of drift flux ( $j_{dc}$ ) where  $\alpha$  is dispersed phase holdup while  $j_d$  and  $j_c$  are flux or superficial velocities of the dispersed and continuous phases respectively.

$$j_{dc} = (1-\alpha) j_d + \alpha j_c \quad (1)$$

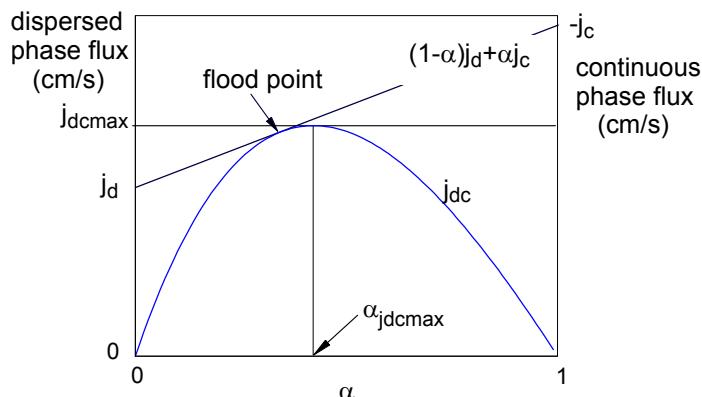

Figure 1. Relation between  $j_{dc}$ ,  $j_c$ ,  $j_d$ , and  $\alpha$ .

The right hand side of equation 1 represents a straight line connecting points  $(0, j_d)$  and  $(1, j_c)$  on plot of holdup versus flux that is tangent to  $j_{dc}$  curve as shown in Figure 1. Wallis [1] suggested equation 2 to approximate the relationship between  $j_{dc}$  and  $\alpha$ .

$$j_{dc} = V_\infty \alpha (1-\alpha)^n \quad (2)$$

Our previous investigation [2] revealed that a modification of equation 2 to the form shown by equation 3 was needed to improve the approximation.

$$j_{dc} = V_\infty \alpha (1 - \alpha) \exp(m \alpha) \quad (3)$$

Superficial velocities of both phases can be correlated in terms of  $V_\infty$ ,  $m$  and  $\alpha$  as follows. Equating equation 1 and equation 3, and inspecting the tangent results in

$$j_d = V_\infty \alpha e^{m\alpha} - \alpha / (1 - \alpha) j_c \quad (4)$$

$$j_c - j_d = dj_{dc}/d\alpha = V_\infty e^m [1 + (m-2) \alpha - m \alpha^2] \quad (5)$$

Combining equations 4 and 5 leads to the following explicit equations for  $j_d$  and  $j_c$ .

$$j_c = V_\infty e^{m\alpha} (1 - \alpha) [1 + (m-1) \alpha - m \alpha^2], \quad j_d = -V_\infty e^{m\alpha} \alpha [(m-1) \alpha - m \alpha^2] \quad (6), (7)$$

Thus, to determine  $j_d$  for a given  $j_c$ , one has to first solve for  $\alpha$  from equation 6 then calculate  $j_d$  using equation 7.

### Extracting $V_\infty$ and $m$ from Flooding Data

Most flooding data do not provide holdup values; thus it should be extracted from the data. For flooding data that form a straight line on  $j_c^{1/2}$  vs.  $j_d^{1/2}$  with slope  $k_2$ , the following relation can be derived and used to estimate holdup from flooding data.

$$\alpha = j_d^{1/2} / (j_d^{1/2} - k_2 j_c^{1/2}) \quad (8)$$

Thus a representative holdup for each data point and its corresponding drift flux (equation 1) can be calculated provided that a representative value of slope exists. Hence, the constants  $V_\infty$  and  $m$  can be extracted from each flooding data series by fitting the resulting  $j_{dc}$  and  $\alpha$  values to equation 3. Figure 2 shows representative flooding data and their respective holdups that were obtained using the above procedure.

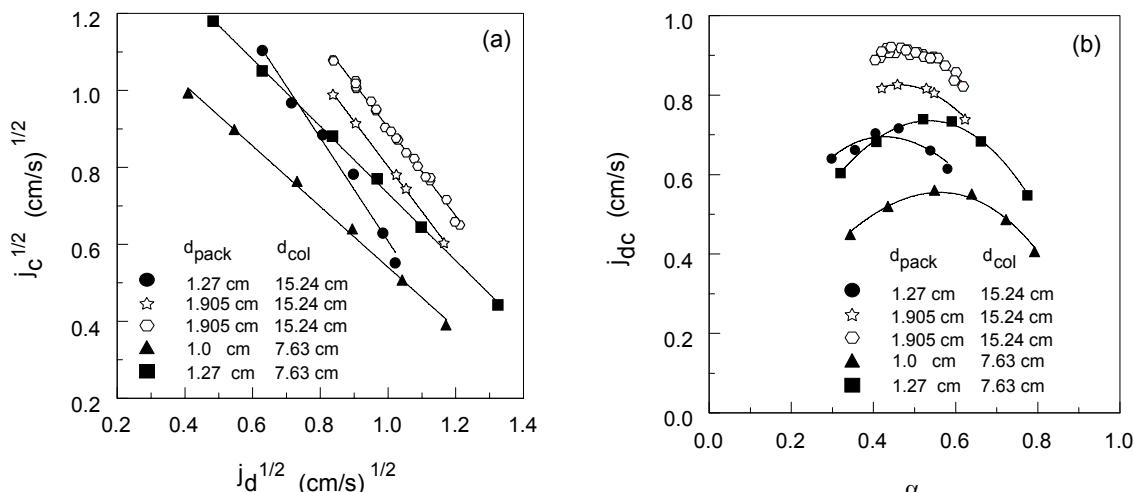

Figure 2. (a) Flooding data of methyl isobutyl ketone (*d*)-water systems with Raschig rings [7] and (b) their corresponding holdup and drift flux;  $d_{pack}$  and  $d_{col}$  are packing and column diameters, respectively.

## CORRELATION DEVELOPMENT

There are two constants,  $V_\infty$  and  $m$ , that need to be correlated in terms of physical and packing properties: densities ( $\rho_d$ ,  $\rho_c$ ), density difference ( $\Delta\rho$ ), viscosities ( $\mu_d$ ,  $\mu_c$ ), interfacial tension ( $\sigma$ ), packing void fraction ( $\varepsilon$ ), specific surface area ( $a_p$ ), and packing size ( $d_p$ ). Observation on the resulting  $V_\infty$  and  $m$  values and the values of the maximum drift flux ( $j_{dc,max}$ ), which corresponds to a condition where  $j_d = j_c$ , suggests that correlation be developed to predict  $V_\infty$  and  $j_{dc,max}$ . Once  $j_{dc,max}$  and  $V_\infty$  are predicted, the value of  $j_{dc,max}/V_\infty = f_\alpha = \alpha_{jdcmax}(1-\alpha_{jdcmax}) \exp(m\alpha_{jdcmax})$  can be calculated. Furthermore, since  $\alpha_{jdcmax}$  is also a function of  $m$ , that is (by solving  $d_{dc}/d_\alpha = 0$  for  $\alpha$ )

$$\alpha_{jdcmax} = \left( m - 2 + \sqrt{m^2 + 4} \right) / (2m) , \quad (9)$$

$m$  can be determined from  $f_\alpha$ . For convenience, the following explicit functions were developed and can be used as alternatives.

$$\text{For } f_\alpha \geq 0.25: m = 1.6648 [\ln(4 f_\alpha)]^{0.8695}. \quad (10)$$

$$\text{For } f_\alpha < 0.25: m = \ln(0.1211 - 4.5331 f_\alpha + 47.488 f_\alpha^2 - 61.3402 f_\alpha^3). \quad (11)$$

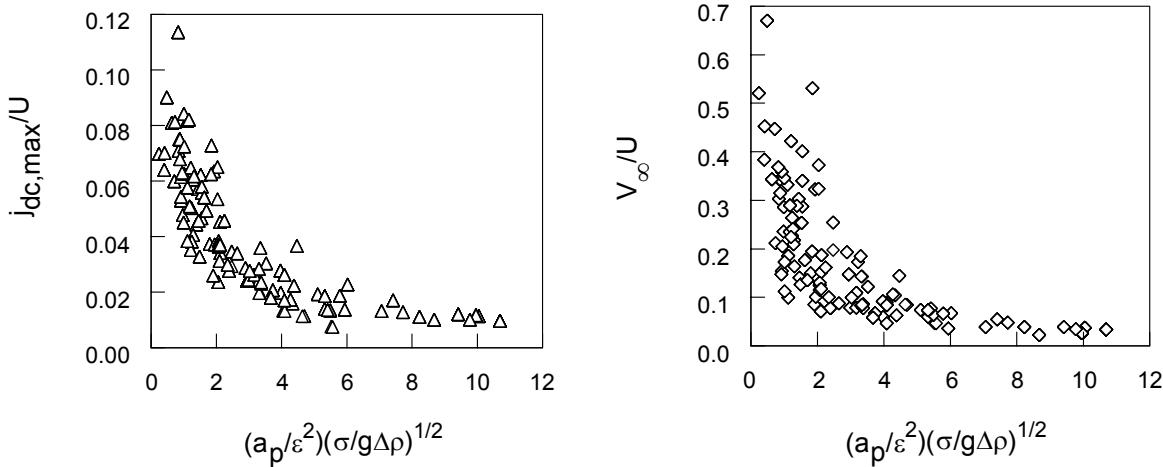

Figure 3. Maximum drift flux and characteristic velocity plotted against  $N_1$ . Both were made dimensionless by dividing them with terminal velocity calculated with equation 12.

For correlation development purposes,  $j_{dc,max}$  and  $V_\infty$  were made dimensionless by dividing them with the terminal rise velocity of a single drop in an infinite continuous phase,  $U$ , calculated using the recently published prediction of Jamialahmadi et al. [3] as shown by equation 12 below. By taking the drop characteristic length as  $(\sigma/(g\Delta\rho))^{1/2}$ ,  $U^{sp}$  is a modified Hadamard-Rybczynski [4,5] terminal velocity of a small sphere subject to internal circulation and  $U^w$  is a modified drop rise velocity from wave analogy for large drops.  $U^{sp}$  and  $U^w$  are given by equations 13 and 14, respectively. With this choice it is expected that the ratio of  $V_\infty$  to  $U$  will asymptotically approach unity as  $N_1 = (a_p/\varepsilon^2)(\sigma/(g\Delta\rho))^{1/2}$ , which measures the ratio of drop-size to the packing size, approaches zero; thus, it represents a measure of flow resistance due to the packing.

$$U = \frac{U^{sp} U^w}{\sqrt{(U^{sp})^2 + (U^w)^2}}, \quad U^{sp} = \frac{1}{18} \frac{\sigma}{\mu_c} \left[ \frac{3\mu_c + 3\mu_d}{2\mu_c + 3\mu_d} \right] \quad (12), (13)$$

$$U^w = \sqrt{\frac{2(g\sigma\Delta\rho)^{1/2}}{(\rho_c + \rho_d)} + \left(\frac{g\sigma}{4\Delta\rho}\right)^{1/2}} \quad (14)$$

Dimensionless forms of maximum drift flux ( $j_{dc,max}/U$ ) and characteristic velocity ( $V_\infty/U$ ) are plotted against  $N_1$  in Figure 3 for 130 data series representing 798 data points. Both figures show that the effects of various factors decrease as  $N_1$  increases. Although all previously correlated dimensionless groups used for development of flooding correlations by other researchers [6,7,8] were tried, only the following groups were found to significantly affect the correlation.

$$\begin{aligned} N_1 &= a_p/\varepsilon^2(\sigma/(\Delta\rho g))^{1/2} & N_2 &= a_p d_p & N_3 &= \rho_d/\Delta\rho & N_4 &= (\Delta\rho^2 g/\mu_c^2)^{1/3}/a_p \\ N_5 &= \Delta\rho/\rho_c & N_6 &= \mu_d/\mu_c & N_7 &= (\rho_d+\rho_c)/\Delta\rho \end{aligned}$$

### Flooding Correlation for Systems that meet Criteria

In practice, most commercial packed columns are designed to meet both of the packing size criteria; packing diameter should be larger than  $2.42[\sigma/(g\Delta\rho)]^{1/2}$  and the ratio of packing diameter to column diameter should be less than 1/8. Therefore, it is important that the correlation be developed only using data that meet both these criteria. Various combinations of equations involving the above dimensionless groups were tried; dependencies on influencing groups were evaluated graphically by examining the residuals and goodness of fit parameters. The following correlations were obtained using only data that meet both criteria whose physical property ranges are listed in Table 1. The average absolute relative error for predicting  $V_\infty$  and  $j_{dc,max}$  are 16% and 8%, respectively.

$$\ln\left(\frac{V_\infty}{U}\right) = \left(C_1 \varepsilon^{4.2} + C_2/N_2 + C_3/N_4 + C_4 N_5^{0.29}\right) N_1 + C_5 N_3 N_4^{-0.337} + \left(C_6 \varepsilon^{5.3}/N_2 + C_7 N_3^{0.55} + C_8\right) \ln(N_1 + 1) \quad (15)$$

$$\begin{aligned} C_1 &= -1.495 \pm 0.190 & C_2 &= -2.08 \pm 0.17 & C_3 &= 1.318 \pm 0.168 & C_4 &= 0.448 \pm 0.029 \\ C_5 &= -0.744 \pm 0.047 & C_6 &= 10.85 \pm 1.66 & C_7 &= 0.912 \pm 0.069 & C_8 &= -2.239 \pm 0.093 \end{aligned}$$

$$\ln\left(\frac{j_{dc,max}}{U}\right) = \left(P_1(1-\varepsilon)/\varepsilon + P_2 N_3^{-0.47}\right) N_1 + P_3 N_3 N_6^{0.1} + P_4 + \left(P_5/N_2 + P_6 N_7^{-8.4} + P_7/N_4 + P_8 N_5\right) \ln(N_1 + 1) \quad (16)$$

$$\begin{aligned} P_1 &= 0.146 \pm 0.014 & P_2 &= -0.319 \pm 0.034 & P_3 &= -0.110 \pm 0.004 & P_4 &= -1.618 \pm 0.025 \\ P_5 &= -2.725 \pm 0.137 & P_6 &= 26.02 \pm 2.20 & P_7 &= -1.093 \pm 0.150 & P_8 &= -0.574 \pm 0.053 \end{aligned}$$

The dimensionless number  $N_2$  in the correlations accounts for the differences in random packing shape; different types of random packings with the same nominal size have different specific surface areas. For structured packings the nominal diameter is approximated as  $5.5\varepsilon/a_p$  thus  $N_2=5.5\varepsilon$ .

Although no adjustable specific constants for each type and size of packing are used in the correlation, the prediction is significantly better than that of existing correlation. In Figure 4, all the prediction points have been moved, in  $j_d$  vs.  $j_c$  space, so they collapsed into a single curve of  $j_d^* = 1 + j_c^* - 2j_c^{*1/2}$  or  $j_d^{*1/2} + j_c^{*1/2} = 1$ . The average error for the predicted dispersed phase velocity is only 21.7% for 295 data that meet the criteria. This is compared to the approximate 35% error of the direct correlations of Kumar and Hartland [8], Dell and Pratt [7], and Hutahean, Van Brunt and Kanel [6]. When tested with all data that meet the packing to column diameter ratio criterion regardless of packing size (482 data), the correlation has a 24.3% prediction error. Comparison to other correlations is also presented in Table 2 where the error associated with each type of packing is presented.

*Figure 4. Predicted and observed of flooding in terms of square root of superficial velocities for data that meet both criteria. The lines are relations based on corresponding percentage of predicted flooding. The prediction was calculated using equations 15, 16, 6, and 7.*

## CONCLUSIONS

New flooding correlations were developed, and they are the first ones for liquid-liquid systems derived using drift flux theory and without incorporating specific constants that depend on type or size of packing. The correlations, equations 15 and 16, have an average absolute relative error of 21.7% for 295 data points in predicting the dispersed phase velocity, very far below the errors possible with previously developed correlations using the same data set. They can easily be used with new packings since  $\varepsilon$ ,  $a_p$  and  $d_p$  are used in correlations. Most data fell within a band from 75% to 125% of predicted flooding. Using these correlations, design based on 50% of predicted flooding can be considered conservative.

## A BACKFLOW MODEL TO DETERMINE BACKMIXING IN A VIBRATING PLATE EXTRACTION COLUMN FOR A DISSOCIATION EXTRACTION

Bridget Hutton, Ales Heyberger\*, Peter Myburgh\*\* and Ilse Godwin

CSIR Bio/Chemtek Speciality and Fine Chemicals Programme, Modderfontein, South Africa

Prague, Czech Republic

\*\*Private Consultant, Johannesburg, South Africa

An industrial process was developed whereby a phenolic derivative and a semi-oxidised form of a phenolic derivative were separated using dissociation extraction. The large difference in the component de-protonation constants, and the fact that the ionic forms of both components are not soluble in the solvent, was exploited. The system characteristics were quantified by performing shake tests and then piloted using a mixer-settler and a vibrating plate extraction column. In order to quantify the axial mixing characteristics of the column, a specific backflow model was developed which accounted for the properties of the system.

### INTRODUCTION

A phenolic derivative (referred to as component B) was produced by preferential oxidation of a mixture of various constituents. The post oxidation mixture was subjected to various unit operations prior to the dissociation extraction, which was used to separate the product B from a residual phenolic reagent (component A). The components were separated by exploiting the large difference in the de-protonation,  $pK_a$  constants (9.8 and 7.7 respectively) and the fact that the ionic forms of neither A nor B were soluble in the solvent. The pH was adjusted to the required level by adding a stoichiometric deficiency of a mineral acid, thereby allowing selective protonation of component A and not component B. The re-protonated species of A was then extracted using an organic solvent, while the sodium salt of component B remained in the residual raffinate for subsequent processing. Downstream processing required significant removal of component A from the raffinate, while project economics constrained the allowable loss of component B in the extract. The extraction was piloted using a conventional mixer-settler and a vibrating plate extraction (VPE) column. Since the piloting was performed for the purposes of generating scale-up data for design of the commercial process, it was important to determine axial mixing in the extraction column. The use of a backflow model, as opposed to a diffusion model for quantifying axial mixing in VPE columns is well established.

## EXPERIMENTAL WORK

Shake tests were performed, whereby aqueous feed and solvent were mixed, the pH adjusted to the required value by addition of a mineral acid to allow selective protonation and extraction of component A, while component B remained in the residual raffinate. Extensive bench and pilot-scale testwork was performed on the system. The equipment used consisted of a single stage mixer-settler and a VPE column, set up in a counter-current manner, as depicted in Figure 1. Raffinate from the mixer settler was used as feed for the VPE and extract from the VPE as solvent for the mixer settler. The mixer-settler extract was subject to distillation to recover component A and the solvent, which was recycled back to the VPE.

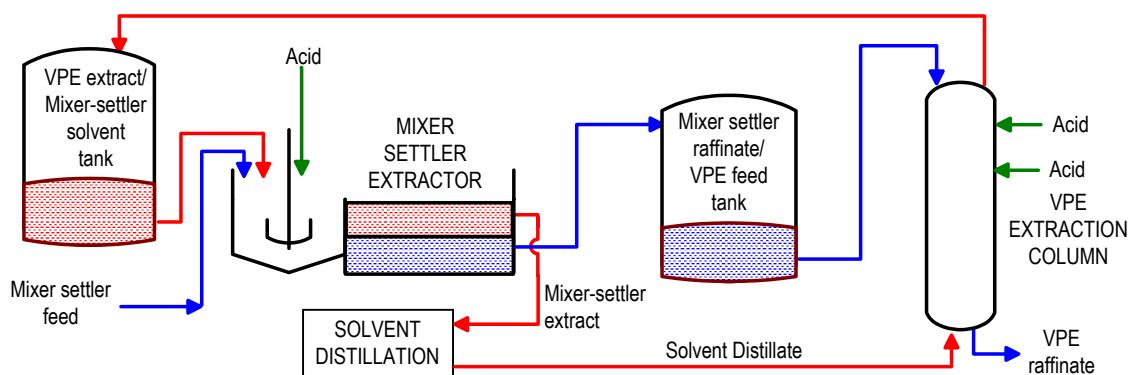

Figure 1. Set-up of the mixer-settler and VPE.

The VPE column is a type of reciprocating plate extractor, similar to the Karr column, but differing in plate design and mode of operation. The pilot-scale column of 50 mm diameter, was operated with 6 m of active height and stainless steel plates. The plates used had two types of holes; 3 mm holes for passage of the dispersed phase and 10 mm holes for the continuous phase. Acid requirements for each extraction test were pre-determined by performing acid titrations. The acid was added to the VPE at two positions; two thirds of the total acid required was added after 600 mm and the remaining third, 1 790 mm from the top of the VPE, respectively (to account for the decreasing concentration of component A in the aqueous phase). It was found that component A acted as a co-solvent for the extraction of component B - the higher the concentration of protonated component A in the solvent, the greater the loss of protonated component B. To minimise losses of component B, it was necessary keep the concentration of protonated B low in the mixer settler by maintaining a high pH of 10, while in the VPE, a low pH of 9 was required for sufficient removal of component A from the raffinate. In the VPE, any component B that was extracted in the region below the acid addition points was back extracted in the region above the first acid addition point, where the pH was high.

## THEORY

The de-protonation of any particular acid will have an equilibrium constant,  $K_A$  which is a measure of the extent of de-protonation in an aqueous solution:

By incorporating the definitions of the extent of de-protonation,  $pH$  and  $pK_A$ , it is possible to derive the following equation [1], which allows determination of the extent of de-protonation:

$$Dep = \frac{1}{10^{pK_a - pH} + 1} \quad (2)$$

Consider two components A and B, which exhibit an appreciable difference in their strengths as acids. Knowing the respective  $pK_a$  values and applying Equation (2), the theoretical extent of de-protonation versus  $pH$  can be plotted, as depicted below in Figure 2.

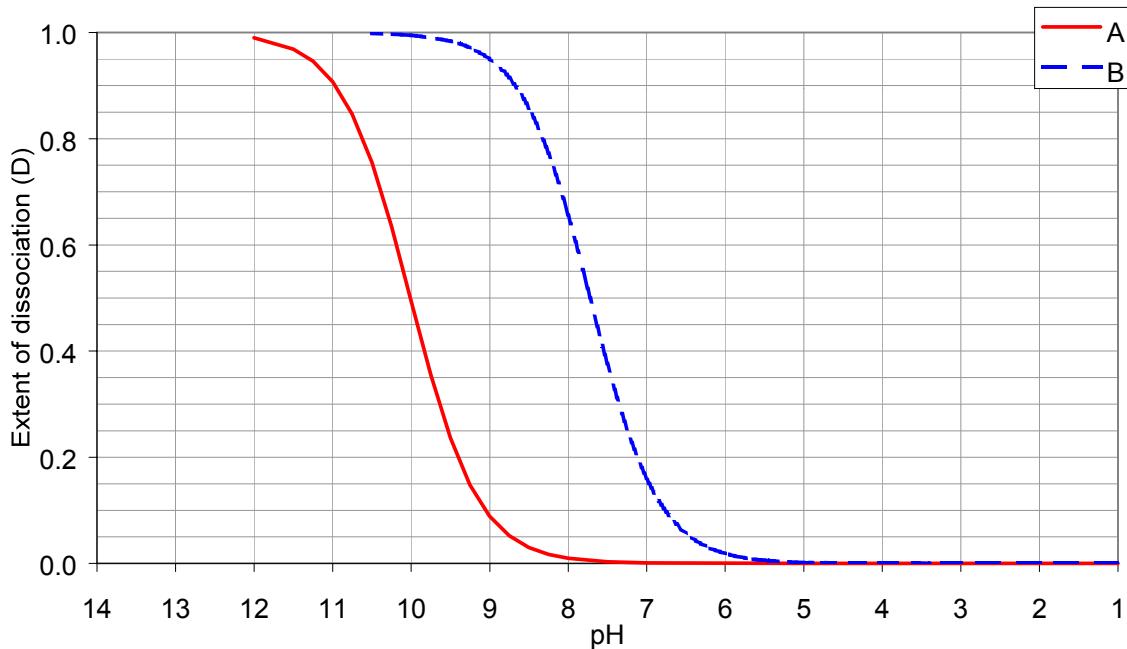

Figure 2. Extent of de-protonation versus  $pH$ .

The analytical method employed for determining the concentrations of components A and B does not differentiate between the protonated and de-protonated forms. Conventionally in solvent extraction, a distribution ratio is determined for one particular species and consequently when considering the distribution of component A, only the protonated species in each phase is considered. Not differentiating between the two species results in an average distribution ratio, which is strongly pH dependent (an overall distribution ratio), and which can be defined as follows (solubility of the de-protonated species of component A in a non-polar organic can be expected to be very low, and as such considered negligible, i.e.,  $C_{A,E} = 0$ ):

$$D_A = \frac{C_{A,E} + C_{A^-,E}}{C_{A,R} + C_{A^-,R}} \quad (3)$$

When calculating the true distribution ratio ( $D_A$ ) of component A between the aqueous and organic phases only the protonated species in each phase is considered, which results in a partition coefficient that is independent of pH. Using Equation 2 and the total concentration of component A (determined analytically), it is possible to distinguish between protonated and de-protonated forms of component A in the aqueous phase and calculate the distribution ratio:

$$m_A = \frac{C_{A,E}}{C_{A,R}} \quad (4)$$

## THE MODEL

The behaviour of the VPE is such that a layer of the dispersed phase forms above or below the reciprocating plates (depending on which phase is dispersed), the droplets coalesce and are then re-dispersed by the action of the plates. This partially stagewise mode of operation determines the applicability of a backflow model to determine axial mixing in the VPE. For the industrial process under consideration, it was necessary to modify the conventional models.

The characteristics of the process, which had to be taken into account by the model, included:

- only the protonated species of component A was extracted by the solvent, while the ionic species remained in the raffinate.
- acid was added at two points along the length of the column, resulting in re-protonation of component A,
- the equilibrium relationship of component A was non linear.

In order to account for the fact that only the protonated species was extracted, the model could be structured using one of two approaches:

- either using the pH profile through the length of the column to calculate the concentration of protonated component A,
- or, considering the addition of acid as addition of protonated component A to the column.

The second method was selected since it allowed a more simplified approach. Some acid was consumed by organic impurities in the system and it was necessary to estimate the proportion of the acid that was used to re-protonate component A. By considering the ratio of the moles of re-protonated component A to acid protons added it was found that approximately 53% of the acid was used to re-protonate component A.

The specific form of the backflow model applied to the system was the conventional "Mass Transfer Coefficient model" [2] where both forward and backmixing were taken into account. The backmixing coefficients of the continuous and dispersed phases were assumed constant through the length of the column. This assumption was adopted since it substantially simplified the mathematical description of the process. The model was set up in an Excel spreadsheet. Experimental steady state concentration profiles of component A in both the dispersed and continuous phases were measured. Using the theory described above and the sample pH measurements, it was possible to determine the concentration of protonated component A in the aqueous phase. The results were then interpreted by "force fitting" the model to the experimentally determined concentration profiles using the excel solver function. This allowed determination of the coefficients of backmixing and the overall mass transfer coefficient.

## RESULTS

The equilibrium data (total concentrations of component A) are plotted in Figure 3. The pH represents the pH of the raffinate after reaching equilibrium. Since only the protonated species is extracted into the organic solvent, the overall distribution ratio of component A (ionic and protonated) is dependent on pH (effectively is a measure of the extent of de-protonation). Using the total concentration of A and the measured pH, the concentration of de-protonated species in the aqueous phase was calculated (Equation 2), which allowed determination of the concentration of the protonated species in the aqueous phase. The equilibrium data of the protonated species is depicted in Figure 4. The distribution ratio of protonated species A is independent of pH, however it is not constant, but dependent on the concentration of protonated species A in the organic phase, probably as a result of the association of simple molecules into complex molecules in the organic phase.

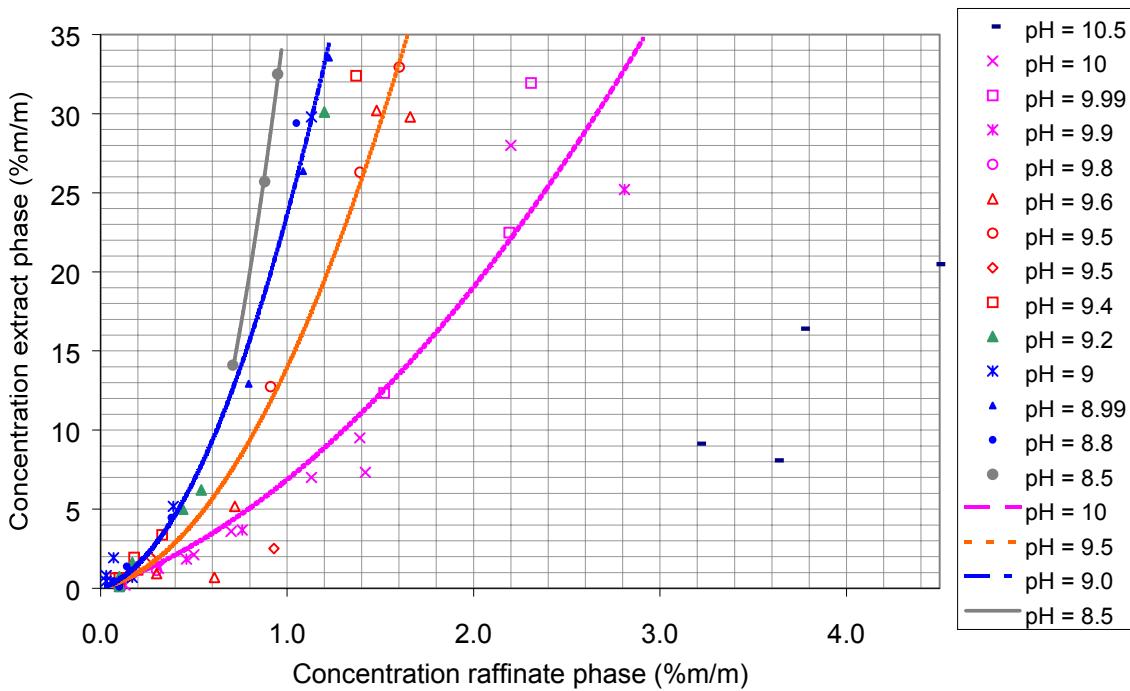

Figure 3. Analytical equilibrium data.

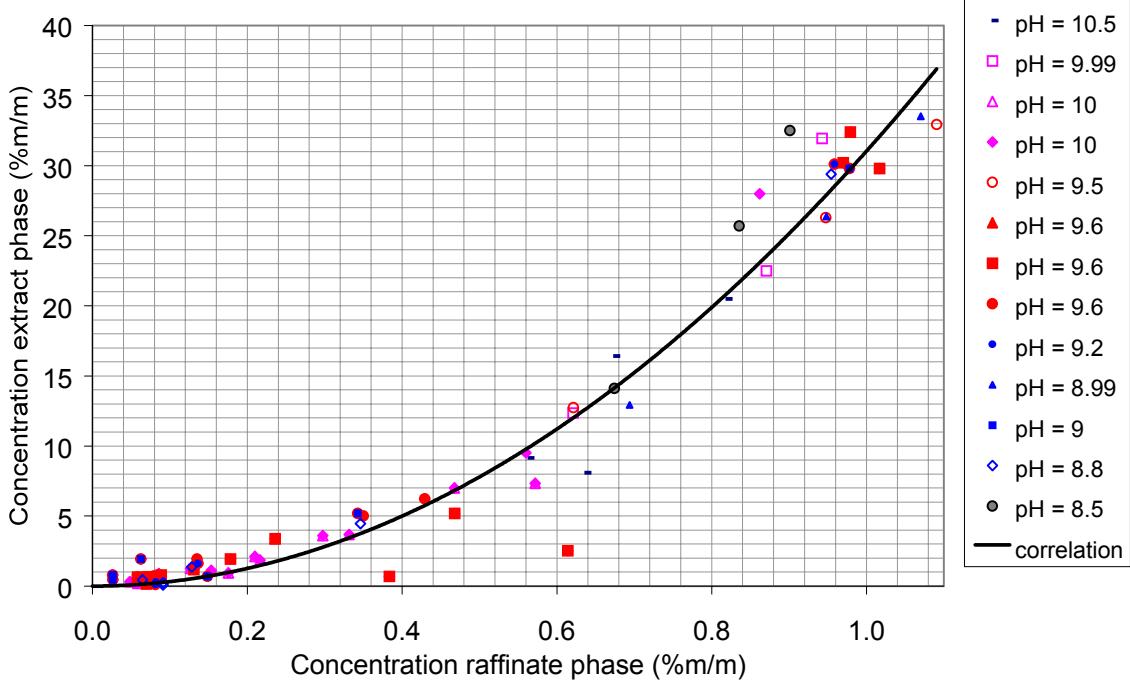

Figure 4. Protonated species equilibrium data.

During piloting the mixer-settler extracted 75% of component A, while the VPE extracted 92% of the residual component A. The entire extraction operation reduced the feed concentration of component A from 8.5% m/m to less than 0.2% m/m in the VPE raffinate, while losing only 2% of component B in the mixer-settler extract. The column concentrations profiles of protonated component A were “force fitted” with the model to evaluate the model parameters (backmixing ratios and the overall mass transfer coefficient). A typical operating line, as predicted by the model is depicted in Figure 5. The operating line discontinuities represented the points at which acid was added to the column, since the acid releases protonated component A, thereby

changing the protonated component A mass balance (essentially three operating lines exist). It was found that backmixing of the dispersed and continuous phases in the VPE was low, a property typical of the VPE.

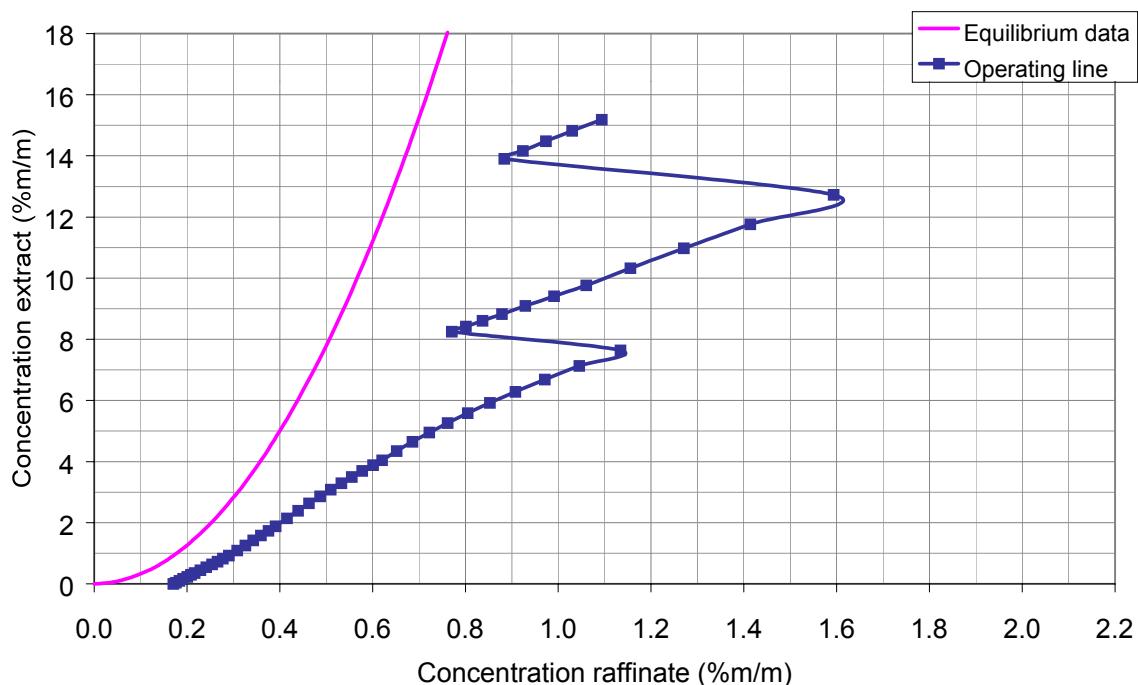

Figure 5. Typical equilibrium line and operating line predicted by the model.

## CONCLUSIONS

The novel use of a VPE to perform a dissociation extraction was proven. The theoretical methods of predicting the extent of protonation of component A allowed quantification of the equilibrium data. The general form of the Backflow model was modified to allow prediction of a dissociation extraction and axial mixing in the VPE was found to be low.

## LIQUID-LIQUID MINIPLANT EXTRACTOR – A NOVEL TOOL FOR PROCESS DESIGN

Peter Kolb and Hans-Jörg Bart

Institute of Thermal Process Engineering, University of Kaiserslautern,  
Kaiserslautern, Germany

Experimental studies using a 32 mm diameter miniplant extractor are presented including a description of the auxiliary equipment and measuring techniques for hydrodynamic data acquisition. In single backmixing experiments linear relationships were found between the dispersion coefficient and stirrer agitation speed and the dispersion coefficient and the flow rate. Dispersion coefficients calculated using CFD agreed well with experimentally measured values. It was shown that CFD contributes to a better understanding of the basic mechanisms governing the hydrodynamics of liquid-liquid extraction.

### INTRODUCTION

For the development of new industrial processes in the chemical industry the use of lab-scale continuous plants (miniplants) without piloting, in combination with simulation tools, finds increasing application. The reasons are the reduction of costly and time consuming experiments in pilot plants, which leads to a cheaper and faster realisation of the industrial process.

Liquid-liquid-extraction is superior to distillation for special separation processes like the reconditioning of very dilute solutions or temperature sensitive products. Flow rates around 10-L/h can be used in laboratories without special permits. Such flow rates are in the range of 30 mm miniplant extractors [1,2]. Information on hydrodynamic parameters such as the axial dispersion, hold-up and throughput is important for the scale-up and design of extraction columns. This work reports on the hydrodynamic behaviour of such a miniplant extractor. The parameters studied include throughput (flooding), axial dispersion, hold-up and velocity profiles. The results are discussed and compared with computational fluid dynamics (CFD) simulations.

### EXPERIMENTAL SETUP

The Kühni miniplant extractor used is a glass unit with an internal diameter of 32 mm, equipped with four 6-bladed stirrers mounted on an axial shaft. The stirrers rotate inside 34 mixing compartments separated by stator rings which are electrically isolated. Four of those compartments are composed of stainless steel and can be used as sampling or injection ports. The general arrangement of the column and auxiliary equipment such as storage tanks, pumps etc. is shown in Figure 1.

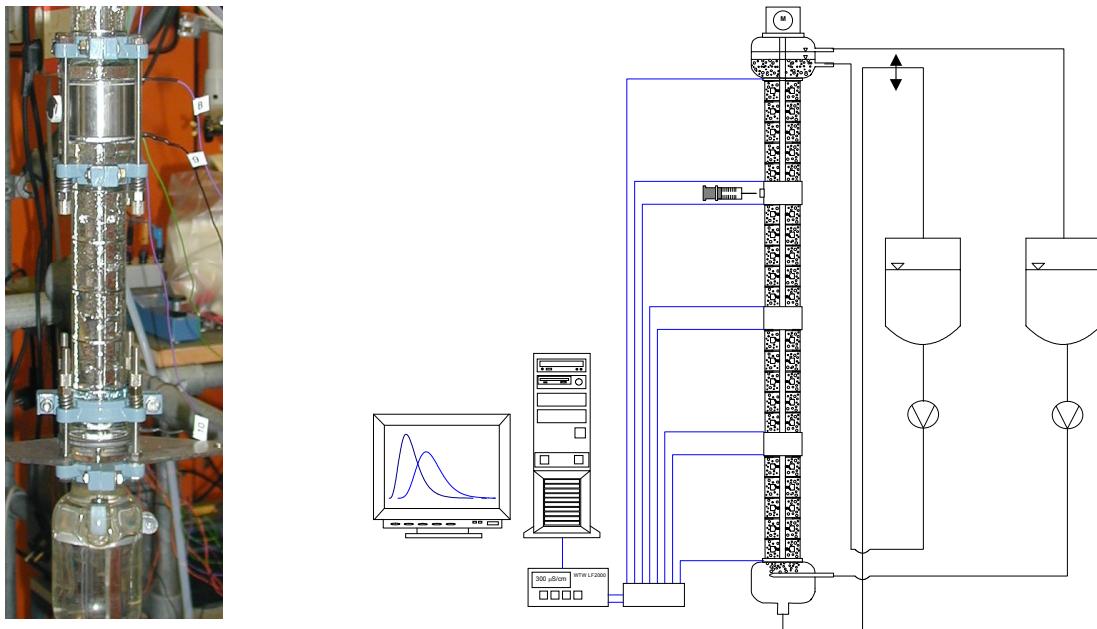

Some of the physical design parameters of the miniplant unit are given in Table 1.

*Table 1. Miniplant specifications (mm).*

Column inside diameter $d_c$	32
Column total height	1545
Compartment height $H_c$	37
Stirrer diameter	20
Stator ring inside diameter	18.5

Axial mixing for single-phase flow was quantified by injecting 0.5 mL of aqueous 0.02 N KCl pulses through an inlet port in the upper part of the column, and measuring the electrical conductivity at two locations in the lower part of the column. In principle, only one measuring point is necessary if the tracer injection is in the form of a perfect delta pulse. However because of the difficulty in obtaining a perfect pulse and other experimental shortcomings it is usual to monitor the attenuated pulse at two sample points. The generated data plots were fitted to the analytic solution of the well-known dispersion model of Levenspiel [2] (open-open condition) using the "convolution" method:

$$C_2(t) = \frac{1}{2\sqrt{\pi\tau(D_{ax}/v_c L)}} \int_0^t \exp\left[-\frac{(D_{ax}/v_c L)[\tau - (t-\theta)]^2}{4\tau(t-\theta)}\right] d\theta \quad (1)$$

*Figure 1. Schematic experimental setup of the miniplant (left: lower part of the column with adapted stainless steel compartment).*

## CFD-MODELLING

One objective of this work was to examine the capabilities of CFD in the field of liquid-liquid extraction. This multidimensional approach can give deeper insight into the details of the flow structure [4], while it can also supply information required in the "classical" one-dimensional methods of column design. For the CFD-simulation the commercial software FLUENT, which is based on the finite volume method, was used. Due to the identical geometry of the compartments a periodically repeating flow pattern can be expected. Furthermore, the

symmetry of the geometry can be exploited to reduce the number of computational cells. Consequently, just two adjacent compartments of the column were modelled and a slice between two stirrer blades was assumed to be sufficient. The computational mesh, a structured-hexahedron mesh, consisting of approximately 200,000 cells, is shown in Figure 2. As boundary conditions the column wall and the stators were considered to be fixed walls and the shaft and the stirrers as moving walls (moving reference frame). In the axial and circumferential directions periodic boundary conditions were used. The turbulence was taken into account using the standard k- $\varepsilon$ -model.

## TWO-FLUID-MODEL: EULER-LAGRANGE

For the determination of the backmixing of the continuous phase the Euler-Lagrange model has been used [5]. In this model, the continuous phase is described by fields of velocity and pressure (Euler approach), whereas the 'dispersed' phase is represented as an ensemble of particles whose trajectories have to be computed (Lagrangian approach) by integration of equation (2) which results from a simple force balance at a particle.

$$\frac{du_i^P}{dt} = \frac{3\eta C_D Re_P}{4\rho_P d_P^2} (u_i - u_i^P) + f_i^P \quad (2)$$

Figure 2. Computational mesh.

Axial periodic boundary conditions normally do not allow the flow to be traced with Lagrangian particles. Therefore in a first step the stationary flow for a certain throughput and agitation speed has been calculated. In a second step the calculated velocity profile at the inlet has been taken for a change of the boundary condition from periodic to a standard velocity inlet. Afterwards, approximately 10,000 particles of 10  $\mu\text{m}$  in diameter and equal density to the continuous phase have been calculated to receive a residence time distribution curve (RTD) which is independent of the amount of particles. For single droplet behaviour, in particular 'inert' particles, the coupling between the particle and the continuous fluid flow field does not need to be considered [6]. To obtain a hydrodynamic parameter that is comparable to the 'classical' method of column design, these curves have also been fitted to the analytic solution (2) of Levenspiel. Because in the CFD-simulation the ideal Dirac delta function can be obtained, a direct fitting without the use of the convolution integral is possible.

## RESULTS AND DISCUSSION

The values of dispersion coefficient obtained for the miniplant column are illustrated in Figure 3. There is a linear relationship between the coefficient and the impeller speed. By increasing the number of stirrer blades the dependency becomes stronger. As usual the dispersion coefficient increases with increasing flow rate. Also for the continuous phase throughput and the dispersion coefficient a linear relationship can be observed (Figure 5). Similar results which take into account this linear relationship (3) have been published for Kühni columns [8]. The values determined in this study are in accordance with this correlation, which is now valid for a wide range of column diameters ( $d_c = 32$  to  $600$  mm).

$$D_{ax} = 0.046 \cdot n \cdot d_c \cdot h_c \cdot \varepsilon + 0.14 \cdot h_c \cdot v_c \quad (3)$$

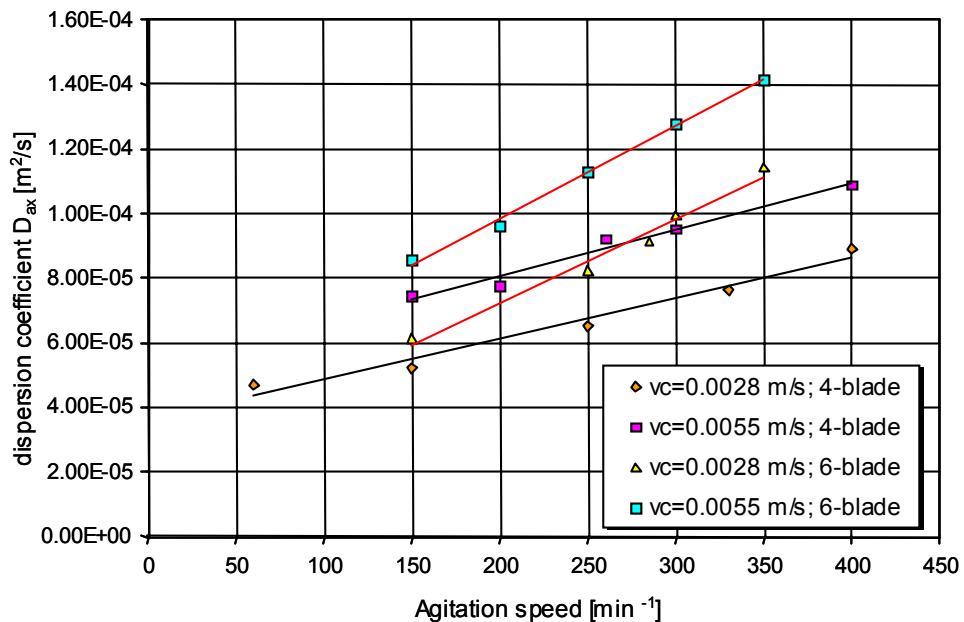

Figure 3. Relationship between dispersion coefficient and agitation speed.

Figure 4 illustrates the residence time distribution (RTD) for an ideal pulse of inert particles at the inlet of one compartment. The shapes of all C1-response curves (response after the first compartment) obtained in our CFD studies are well described by the dispersion model. For the C2-curves another result was obtained. Curve fitting of the data mostly gave poor results which were unable to describe the shape of the simulated curves. The only difference between the 'measuring' ports used to obtain the response curves is that for the C2 data, the tracers really leave the computation region and so multiple passing for them is not possible. In Figure 5 simulated dispersion coefficients were plotted against measured ones. If the assumptions of the CFD model, e.g., to neglect the baffles inside the column, are taken into account, good agreement is obtained.

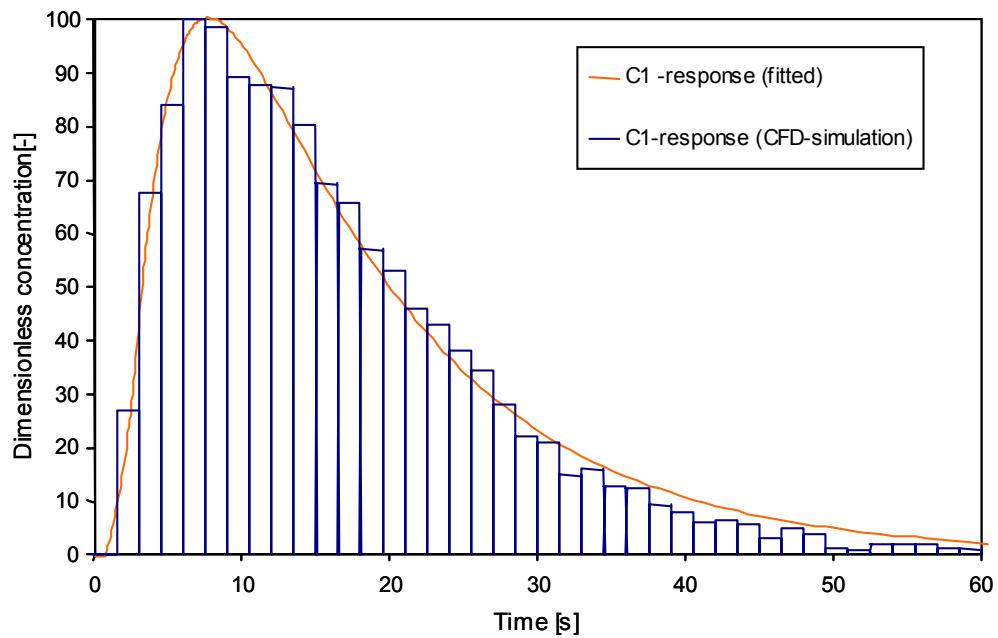

Figure 4. Response curve for an ideal pulse (agitation speed  $300\text{ min}^{-1}$ ,  $V_P=13.2\text{ L/h}$ ).

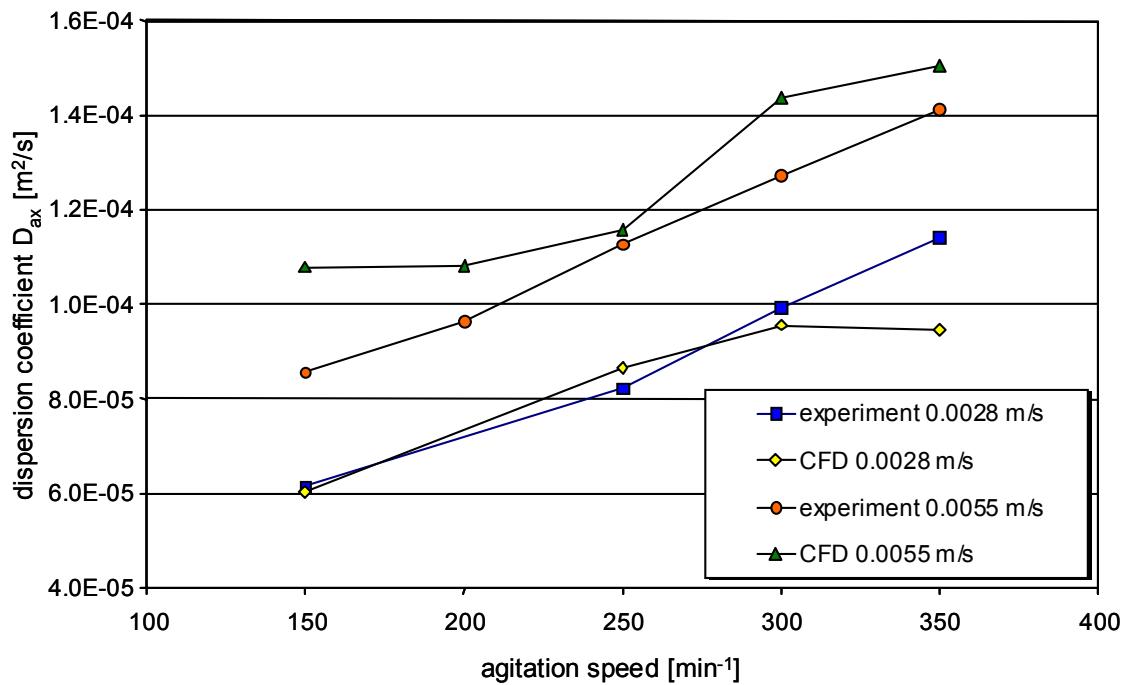

Figure 5. Comparison of measured and simulated dispersion coefficients.

## CONCLUSIONS

In single-phase backmixing experiments a linear relationship between the dispersion coefficient and the stirrer agitation speed was obtained. The relation between the dispersion coefficient and the throughput was also linear. In a theoretical analysis of the data, it has been shown, that it is possible to predict dispersion coefficients using CFD. Furthermore CFD can contribute to better understanding of the basic principles governing the hydrodynamics of a 3-D two phase flow (backmixing, channeling, etc.). Multidimensional computational approaches open the possibility of cross-checking against the conventional 1-D methods (which rely on empirical coefficients) and of improving the semi-empirical correlations making possible a more sound design of columns various geometries. Also the effect of different liquids could be easily investigated. However, the challenge remains to link disperse phase and mass transfer with this hydraulic design.

## ACKNOWLEDGEMENTS

The support of this research by the 'Kommission für Technologie und Innovation (KTI)', Bern and the companies Kühni, Novartis, Roche and Lonza (Switzerland) is gratefully acknowledged.

## ADVANCED METHODS FOR DESIGNING TODAY'S OPTIMUM SOLVENT EXTRACTION MIXER SETTLER UNIT

Bernd Gigas and Michael A. Giralico

LIGHTNIN, Rochester, USA

Optimization of impeller designs, mixing and settler tank configurations, and the understanding of the mixing and separation process requirements, has resulted in optimized solvent extraction mixer settler designs.

The size and expense of the equipment and flow rates hamper experimental settler optimisation efforts. Computational Fluid Dynamics offers the opportunity of quick and relatively inexpensive settler design. The model consists of a steady state solution using a segregated solver in unstructured grids. Phase separation is analysed using multiple species for the aqueous and organic phase. Experimental validation shows good agreement between the computational and experimental solutions in both flow field and phase separation on small scale.

The model is used to show performance differences between various choices of settler geometry and flow rates, allowing the development of optimised settler designs. This paper focuses on major design components of the settler and how future technological advances of said components can lead to further improvements.

### INTRODUCTION

Solvent extraction processes in copper mining involve the use of kerosene based solvents and sulphuric acid to increase the copper concentration and purity of the copper rich electrolyte pumped to the electro-winning house. The complete solvent extraction chain typically involves two extraction steps (E1 & E2) where copper is extracted from the pregnant leach stream (PLS) into the organic stream, one or two stripping steps (S1 & S2) where copper is stripped from the organic phase into unladen sulphuric acid from the electro-winning house and finally a wash step (W1) where further impurities are removed from the PLS prior to being pumped to the electro-winning house.

While each of the process steps in the solvent extraction process sheet performs a unique function the design of the equipment is based on the same operational principles. The discussion of mixer-settler designs can thus be done in generic terms, independent of its application as an extraction, stripping or wash step. The focus of this paper is on the performance and optimisation of the settler portion of the process only.

The operational concept of the settler requires phase separation of the immiscible liquid-liquid dispersion of the organic (kerosene) and aqueous (sulphuric acid) components. Common configurations feed the dispersion through a launder at the centre of the settler, followed by an angled picket fence to evenly distribute the inlet stream and followed by a second picket fence located at approximately one third of the total settler length to assure even flow distribution

further downstream. The exit section of the settler consists of an overflow weir for the lighter organic phase and an underflow-overflow weir for the heavier aqueous phase. Typical volume ratios of organic to aqueous in the settler are 1:2 to 1:1. Conventional design methodology for rectangular settlers is based on hydraulic theory and empirical results from pilot plants and full scale installations. Generally speaking, the basic settler dimensions are derived from open channel flow theory to develop linear velocity targets, specific flow rate (total flowrate per settler footprint area) and picket fence design. Empirical results have refined the linear velocity, specific flowrate, and total settler depth guidelines derived from theory.

The commercial use of solvent extraction technology in copper mining application supports the claim that the simple rectangular arrangement commonly in use is successful both technically and economically. Nonetheless several issues remain that offer the opportunity for improvement in settler performance. Organic entrainment in the aqueous phase is a cost consideration. Organic lost into the aqueous phase during stripping and wash is sent to the tank house and lost during electro-winning. While there are several ancillary technologies available to recover the entrained organic after the settler, any improvement in the settler itself would be beneficial.

A second concern is the generation of crud or scum. This is a three phase semi-stable emulsion consisting of solid particulate, organic liquid and entrained air. Depending on the continuous phase of the dispersion this emulsion may collect at the organic weir between the organic and aqueous phases and block transport between the two layers [1]. It can thus lead to a shortened effective length of the settler, it also provides a source of organic material that erodes from the crud layer into the aqueous phase. As the degree of crud generation varies between mine sites there are multiple approaches to dealing with this problem ranging from doing nothing to regular removal using specialised suction devices.

A third and less obvious issue is the flow pattern in the settler itself. The flow in a settler is not completely laminar and channelling occurs. Specifically, the flow velocity in the centre of the settler can be different than at the edges and reverse flow can often be observed, particularly behind the second picket fence. It is difficult to assess the entrainment impact of this behaviour without major modifications to either the shape of the settler or its internals. At minimum however, reverse flow negates the assumption of plug flow used in coalescence review and indicates that for a given total design flow rate existing rectangular settlers exceed the minimum foot print requirement for process.

A number of authors have published papers covering design features to improve the operational efficiency of the solvent extraction settler [1, 2, 4, 5]. These cover the design requirements for the settler in terms of hydraulics, coalescence speed, phase inversion, etc. The approach in these developments is typically based on empirical correlations from literature followed by experimental validation in either pilot plant or full scale. This approach is valid for many of the design features such as overall dimensions, overflow weir sizing, basic picket fence designs etc. The drawback of purely experimental validation is however that most analysis is based on global values such as average linear velocity and average specific settler flowrate. Local values or phenomenon are not usually considered since observation of all but surface effects is very difficult due to the opaque nature of the lighter organic phase.

This paper reports on current efforts to incorporate computational fluid dynamic (CFD) analysis into the design process of solvent extraction settlers. CFD offers the opportunity of evaluating the conditions at local points of interest in the settler. This can be used to develop improved designs of the inlet launder, picket fences, coalescence rails and overflow weir structure. Overall settler models can be used to evaluate the impact of settler shape and flowrate variation. We will also report on early results of phase separation modelling and the associated complications with this type of model.

## SMALL SCALE MODEL

Giralico and Gigas [3] reported on CFD validation of a small scale settler using mineral oil and water as the organic and aqueous phase, respectively. The model consisted of a 32" wide by 34" long by 4.5 deep trapezoidal acrylic settler using a total flow rate of 2 gpm. To facilitate experimental validation of CFD results no picket fences were installed.

Computational model details were 43,000 cells in a structured mesh, operating through a coupled viscous solver, single phase, multiple species. A steady state laminar flow field is assumed since the Reynolds number is below 2000. The numerical approach was to model the organic and aqueous phase as different species with a diffusivity of 1E-08 m<sup>2</sup>/s in order to show phase separation of the inlet stream. A more rigorous approach is to model a two phase system using an Eulerian-Eulerian model such as Volume-of-Fluid. In consideration of the computational effort required to run this multiple phase, non-steady model the simpler approach was tried. The justification for this approach was that phase separation from gravitational effects are assumed to be controlling the overall performance, not primary or secondary coalescence.

The results of this study were encouraging. Overall flow predicted from CFD matched actual flow well in terms of the flow field in the model settler. The phase boundary location was also found to be in good agreement between the experimental and computational model. Phase separation in terms of predicted entrainment was however high and this particular model exhibited limitations that were difficult to quantify within the parameters of this study.

Figure 1 shows the results of the small scale computational work. The red/light grey areas represent pure organic flow, the dark blue/black represent pure aqueous flow. Notable in the results are the accurate prediction of the organic plume directed toward the left side of the settler in the direction of the weir outlet and the interfacial boundary location. The velocity field is not shown here but also correlated well. Validation of a full scale single phase, multiple species model was attempted using this approach.

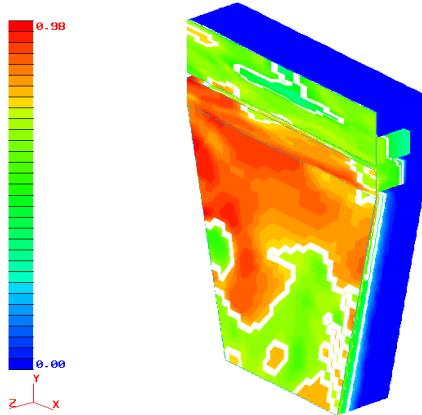

Figure 1. Small scale computational results.

## FULL SCALE MODEL

The next step in the development of CFD as a tool for overall solvent extraction settler design was to model a full scale operating settler and validate the results of the computational model with experimental data. The requirements from the model are to accurately predict the overall flow features of the settler and to locate the interfacial boundary between the aqueous and organic phases. At this time little emphasis was to be placed on accurately predicting the entrainment values. The operational settler has external dimensions of 28'-5" wide by 55'-3" overall inside length. It is equipped with two standard picket fences located near the entry zone and 9'-0" into the settler.

Computational details are similar to the small scale settler with the exception of the grid size which is now approximately 130,000 cells. Results of this overall settler analysis are not presented here as the current model shows severe convergence problems. This problem is rooted in the numerical sweep direction and is particularly notable in the picket fence region resulting in incomplete species separation. While the model continues to show promise for future overall settler analysis the current state of the technology does not readily permit the use of CFD for the expedient and practical optimisation of the overall solvent extraction settler design required for industrial application.

## INDIVIDUAL FEATURE DESIGN

The current inability to model the entire flow and process features of a settler requires a reassessment of the usefulness of CFD for application in this process. A number of observations in both small scale experimental modelling and full scale settler analysis indicate that CFD may offer the opportunity to optimise individual features of a settler. Observation of the flow pattern in the inlet region of the settler shows strong channelling toward the centre and inlet launder and first picket fence modelling from a fluid dynamic perspective appears useful. Recirculation in the flow field in the section after the second picket fence puts the overall settler shape and second picket fence design into question. Observation of the flow in front of the organic weir points to potential entrainment sources stemming from the weir shape. Finally, CFD allows relatively quick analysis of the flow pattern changes that can be expected from changes in operating flow rate.

### Inlet Launder

Figure 2 models a 9.3 m wide by 0.9 m deep settler from the 2 m wide inlet launder to the front end of first picket fence located 6.9 m into the settler. Inlet flow velocity is 1 m/s corresponding to common full scale application. The model is run 3-D, laminar steady state. Note that only a single phase is modelled. This represents a relatively accurate picture of the flow before the first and second fence as phase separation often has not occurred until after the second fence. Since the inlet launder is assumed to be located in the centre of the settler only one half is modelled, the mirror image half is inferred along the centreline symmetry axis.

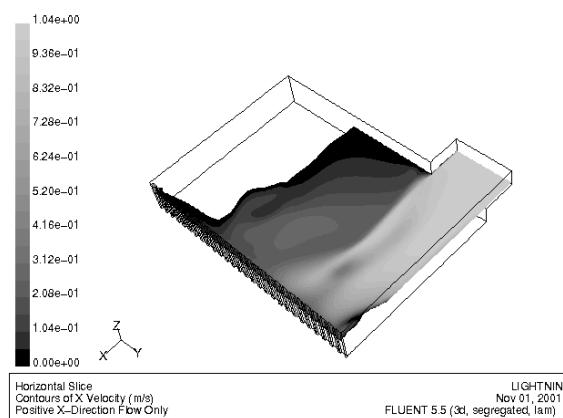

Figure 2. Horizontal slice, velocity magnitude – positive X.

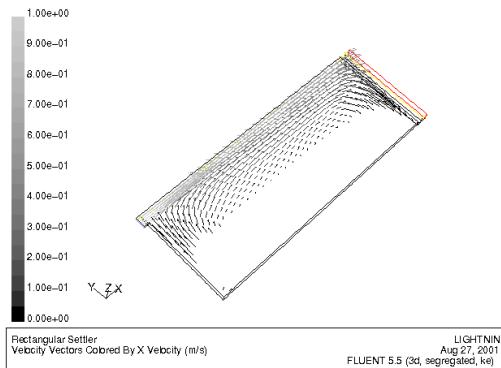

The positive x-direction velocity field distribution of this arrangement is shown in Figure 2. Note that clear areas indicate reverse flow in the settler. Here, a plane located 0.35 m off bottom is highlighted showing strong recirculation of the flow within the front section of the settler not only in the horizontal plane but also vertically (plot not shown for brevity).

Clearly the assumption of plug flow does not hold in the front end of the settler and the degree of flow circulation further questions the validity of the laminar flow assumption. The axial distribution of the velocity field can be avoided either through the use of an inlet launder spanning the entire height of the settler (as shown in later sections) or by angling the launder from the inlet to the settler floor. The recirculation in the horizontal plane can be avoided through the use of inlet launder directional vanes or through modified picket fence design, or a combination of both.

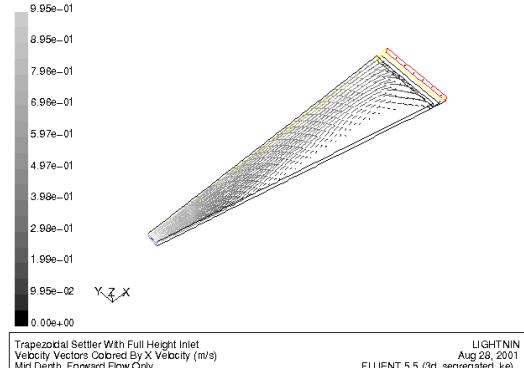

### Overall Settler Shape

Figures 3 and 4 show two settler designs with identical overall settler length, launder width, weir width and liquid depth. The sole difference lies in the trapezoidal shape of the settler in Figure 4 where a significant portion of the foot print has been removed. The inlet velocity is set at 1 m/s, overall dimensions of the rectangular settler are appropriate for operating settler design.

Figures 3 and 4 show x-direction velocity field distribution in the horizontal plane located 0.35 m off bottom. Note that clear areas reflect flow in the negative x-direction, or flow reversal. Both designs show recirculation in the outside portion of settler thus necessitating picket fences for flow distribution. The trapezoidal settler shows a lesser degree of recirculation coupled with smaller foot print. While the average residence time of the trapezoidal settler will be shorter due to the reduced volume the distribution will be closer to plug flow than the rectangular settler of equal weir width. In order to fully qualify the concept of a reduced foot print settler experimental validation using tracer studies are required to evaluate residence time distribution in comparison to primary and secondary coalescence time.

*Figure 3. Positive x-direction flow field in rectangular settler.*

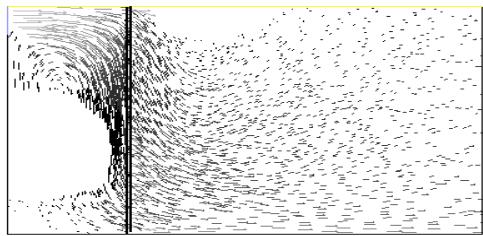

*Figure 4. Positive x-direction flow field in trapezoidal settler.*

### Fence Spacing & Design

In order to facilitate the evaluation of picket fence designs in a settler this section of the work is done in 2D. Due to the relatively small size of the pickets and inter-picket spacing in relation to the overall settler dimensions a 3-D analysis is computationally not reasonable for the scope of this paper.

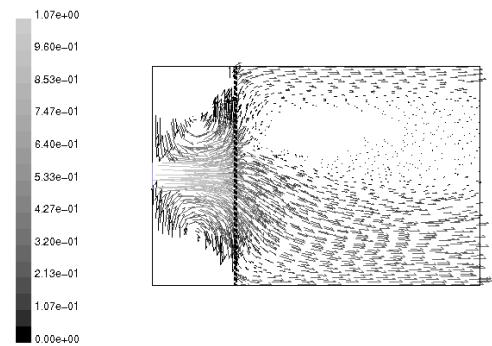

A 2-dimensional plot of a rectangular settler without picket fence is equivalent to Figure 3. Figure 5 adds a single picket fence located roughly 1/3 into the settler. The model pickets are 0.1 m wide with 0.025 m spacing. Overall settler dimensions are 25 m wide by 20 m long, inlet velocity is set at 1 m/s. The resultant flow pattern shows the distribution across the width of the settler. This particular picket arrangement is not optimised as the flow preferentially channels to the outside of the settler.

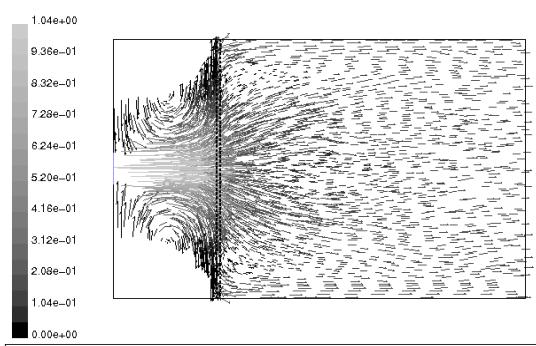

*Figure 5. Rectangular settler – single picket fence.*

Figure 6 refines the picket fence arrangement through the use a double picket fence to produce a more even flow field. Note that the x-direction flow field shown is not completely symmetric as the fence arrangement is slightly offset from centre. This represents a common arrangement of fence pickets since the design is typically started on one side of the settler and terminates with pickets cut to size on the opposite end. The resultant flow asymmetry is significant in that a large part of the settler flow behind the picket fence is reversed, i.e., toward the settler inlet.

Figure 7 represents the flow field generated in a settler with symmetric double picket fence. All parameters of the settler shown in Figure 7 are identical to that shown in Figure 6 with the exception of the picket locations. For Figure 7 all pickets are centred and completely symmetric. The resultant flow field is uniform and raises the question if single picket fence arrangements are feasible full scale installations.

*Figure 6. Rectangular settler double picket fence.*

*Figure 7: Rectangular settler double symmetric picket fence.*

### Weir Design

As we progress through the settler the final major feature in the design is the weir section. While the basic concept of an overflow weir is simple care must be taken to avoid cross phase entrainment as well as air entrainment. The modelling of air entrainment in the overflow section of the weir requires multiphase modelling that is not addressed here but other features of the weir can be evaluated using single phase modelling. Figure 8 shows a plain rectangular organic weir cross section. By nature of the design the organic-aqueous interface lies on the vertical wall thus forming a stagnation point some distance upstream of the weir itself. Transport of fluid from front to back in the settler locates any accumulated crud in the interfacial region right at this stagnation point.

Note the downward flow velocity of the liquid from the interfacial region toward the organic weir underflow. This phenomenon has been validated experimentally and can lead to crud layer erosion and entrainment losses of organic in aqueous. Specific design modifications to alleviate this problem are not addressed here but their evaluation via CFD is a logical starting place.

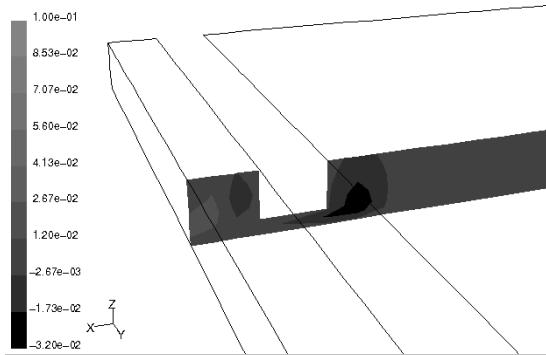

Figure 8. Organic weir cross section.

### Flow Rate Sensitivity

Once modelling has lead to an optimised settler configuration CFD offers the opportunity of evaluating various operating parameter changes. The most common is inlet flow rate change. The most effective way to model the impact of velocity step changes can be reviewed using an unsteady model. Figure 9 shows plots of velocity changes in the vertical plane six seconds after a step change of inlet velocity from 1 m/s to 3 m/s.

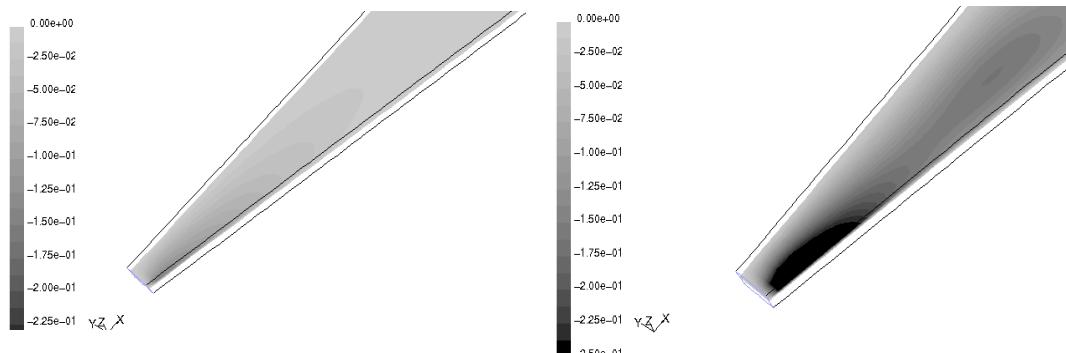

Figure 9. Vertical velocity field change after inlet velocity step change.

Note the steep increase in vertical velocity in the inlet region noted by the darker areas. Similar behaviour should be expected behind picket fences and helps to explain the entrainment surges often associated with inlet flowrate changes.

As has been pointed out by Miller [6] the full scale operating solvent extraction settler is not operating at a true steady state. Inlet surges of either liquid phase lead to transient behaviour in the settler and are at least partially responsible for entrainment losses in the settler. Unsteady CFD models allow a first glance at the impact of these transient flows and future two phase CFD work should lead to a better understanding of these transient flows and their impact on settler performance.

## CONCLUSIONS

To date attempts to develop a single comprehensive computational design tool for solvent extraction settlers have met with very limited success. A single phase, multiple species model has shown good agreement with experimental results in small scale open models. This concept has yet to be successfully validated on full scale copper mining solvent extraction processes due to numerical convergence difficulties.

Nonetheless, CFD can be used to develop optimised solutions for individual settler components such as inlet launders, picket fence design and location, overall settler shape and overflow weir design.

Generalised results are that a trapezoidal shape of the settler offers a reduction in overall foot print coupled with improved plug flow performance and reduced organic inventory. Pilot plant experiments are under way to validate small scale and computational results with respect to the flow field as well as to characterise the entrainment impact of CFD derived design modifications to the inlet launder, picket fences and overflow weirs.

## TESTING NOVEL FEATURES IN MIXER-SETTLER PROTOTYPES

Alberto Gauna, Claudio Andaur and Fernando Granatelli

Comisión Nacional de Energía Atómica, Buenos Aires, Argentina

A mixer-settler with novel qualities has been developed as part of an advanced non-proliferating PUREX process program to collect experimental data.

Some of its operating features are:

- Air pulsed mixing with two different height nozzles in each mixer. The nozzles and a special baffle in the mixing channel give a better mixing distribution and allow high viscosity mixture or crud to flow smoothly from the mixer to the settler.
- An independent aqueous-phase flow for each of the mixer-settler stages achieved by pumping of small air-lifts to get a very low overall pressure drop.

Some of its manufacturing features are:

- The mixing and settler cells and the air-lift channels were carved and drilled in the central plastic block.
- Materials such as high-density polythene and tempered glass were used to obtain a suitable watertightness and are a good option for hot cell operation.

These features could be applied to any kind of mixer-settler configuration.

### INTRODUCTION

A small high-performance mixer-settler specially suitable for use in high uranium concentration processes was developed as part of an advanced and non-proliferating PUREX process development program conducted in the Centro Atómico Ezeiza (C.A.E.) of the Comisión Nacional de Energía Atómica de la República Argentina. This experimental work is currently being carried out with natural uranium, but experimental works using tracers at an early stage and small quantities of spent nuclear fuel subsequently, are scheduled to begin at a new hot cell laboratory called LFR very soon. For this reason, our Department work team has decided to develop a small, simple and reliable mixer-settler prototype that could also be highly resistant to corrosion and opacity generation and also provides suitable watertightness.

### FEATURES OF THE MIXER SETTLER

#### Selection of Materials and Manufacturing Features

The results obtained from a thorough analysis of durability and visibility limitations in the equipment helped to solve some operating problems.

As is widely known today, materials such as polycarbonate, acrylic and other polymers typically used to manufacture prototypes for process development are not corrosion free and tend to get corroded under the action of nitric acid and tributyl phosphate, or are likely to show opacity as a result of cracking.

After their mechanical endurance and chemical resistance have been verified by means of calculations and tests, high density polythene charged with titanium dioxide and tempered glass were selected to manufacture the central block and the cover plate respectively.

Bibliographical and experimental data about the behaviour of high density polythene and tempered glass confirmed that such materials were the proper choice. Some experimental data about their endurance to radiation were collected in the C.A.E.'s hot cells, where <sup>99</sup>Mo is produced. The first one of these materials was found to be highly resistant and long lasting in a radiation field of 36 Sv/h during 8 hours a week and a permanent field of 0.054 Sv/h. Although the second material presented some fragility and opacity problems, this was only developed after several months of being exposed to the same conditions.

Experimental decontamination works with small quantities of spent nuclear fuel of irradiated material are under schedule in the C.A.E. They will be performed in the L.F.R. Laboratory hot cells, where the radiation field is much lighter than in the <sup>99</sup>Mo hot cells mentioned above.

The widely known configuration with oblique settlers was selected in this event, but other arrangements could be made under the same characteristics of this device.

The three most important pieces of the device are:

- A central block made of polythene where mixers, settlers, channels and holes were carved.
- Two tempered glass plates. One of them has the holes where special connections for the stream outlets pass through.
- A pair of stainless steel frames and screws to press the central block and the plates together in order to get enough watertightness (See Figure 1). The applied pressure is compatible with the compression resistance of polythene.

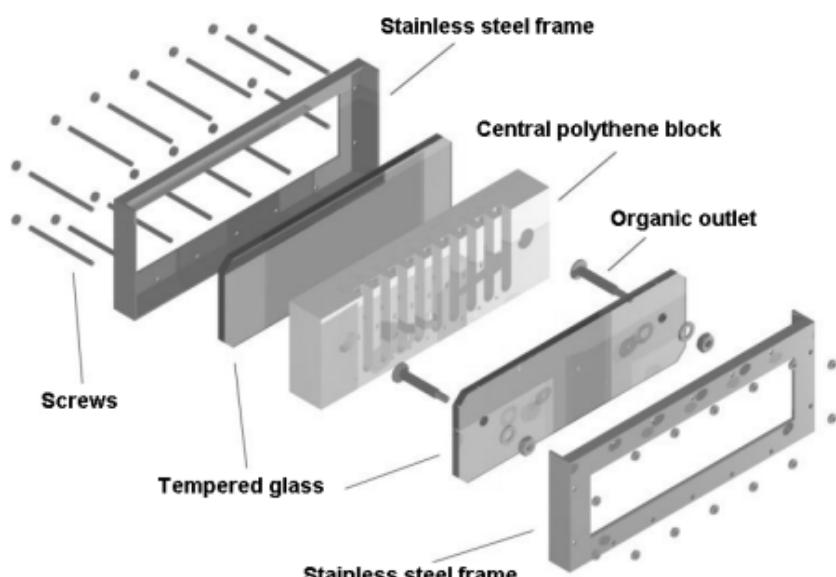

Figure 1. Mixer-settler prototype assembly.

## **Standard Operating Features**

This design includes standard and novel operating features. The standard operating features are:

- The input streams (organic phase, scrub solution, and uranium feed) could be directly fed in the correct mixers by any kind of dosage system. In this particular case, externally controlled diaphragm pumps were used.
- The organic phase flows by gravity from one settler to its corresponding mixer through a channel drilled in between every mixer and settler.
- The mixers are agitated by air pulses. The pulses are generated by diaphragm pumps and transmitted by means of typical liquid seals.

## **Novel Features**

Advanced and non-proliferating processes can involve high uranium concentration gradients with sharp density variations.

Three novel features were incorporated after a testing period in a small single-stage mixer-settler where the best geometrical and operating conditions were found:

- Different height and position of the two nozzle ends (one is at the top and the other at the bottom of the mixer), in order to gain a better mixing distribution. Classical air pulsed mixing systems have equal height and are placed at the top of the mixer [1].
- The upper ended nozzle makes the mixed phase flow smoothly from mixer to settler through the mixed-phase channel, because the stream pulsed by this nozzle is directed to a specially orientated baffle placed in the mixing channel. Each pulse of mixing phase crashes into the baffle and goes into the settler. As a result, it is possible to break off the high viscosity mixture or crud, which are formed under certain conditions, and to let the mixed phase flow easily from mixer to settler. The best angle for the baffle was determined in the single-stage mixer-settler.
- The aqueous phase flows from a settler to the corresponding mixer through a combination of holes made in each stage. A small tube is inserted for each stage into one of these holes. This tube is supplied with compressed air so that a small air-lift is generated to pump the aqueous phase to the corresponding mixer. (See Figure 2). This pumping eliminates the accumulation of pressure drop along the device and eases the aqueous phase circulation if a density step is formed at the bottom of the settler. The achieved effect is similar to pump-mixer-settler behaviour.

The flow rate of the small air-lifts was adjusted in the single mixer-settler. It must be five to ten times the aqueous phase flow fed to the mixer-settler.

The organic phase flows by gravity conventionally from one settler to its corresponding mixer through a channel drilled in between every mixer and settler.

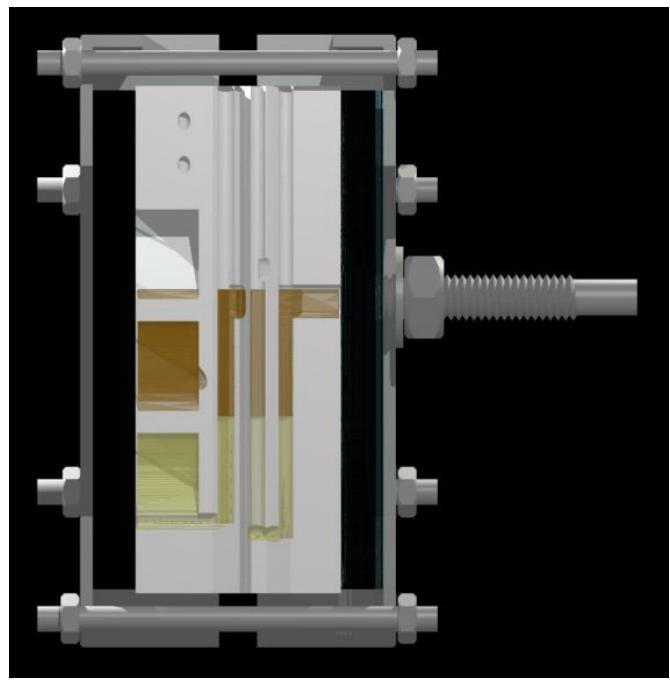

Figure 2. Computer generated mixer-settler section. Air-lifts holes are visible in the central area. Modelized organic and aqueous phases were coloured in brown and yellow respectively. The organic outlet is also visible.

## EXPERIMENTAL WORK

The device was tested in an extraction-scrubbing and stripping cycle consisting of seven-stage and nine-stage mixer-settlers respectively, under two different process conditions.

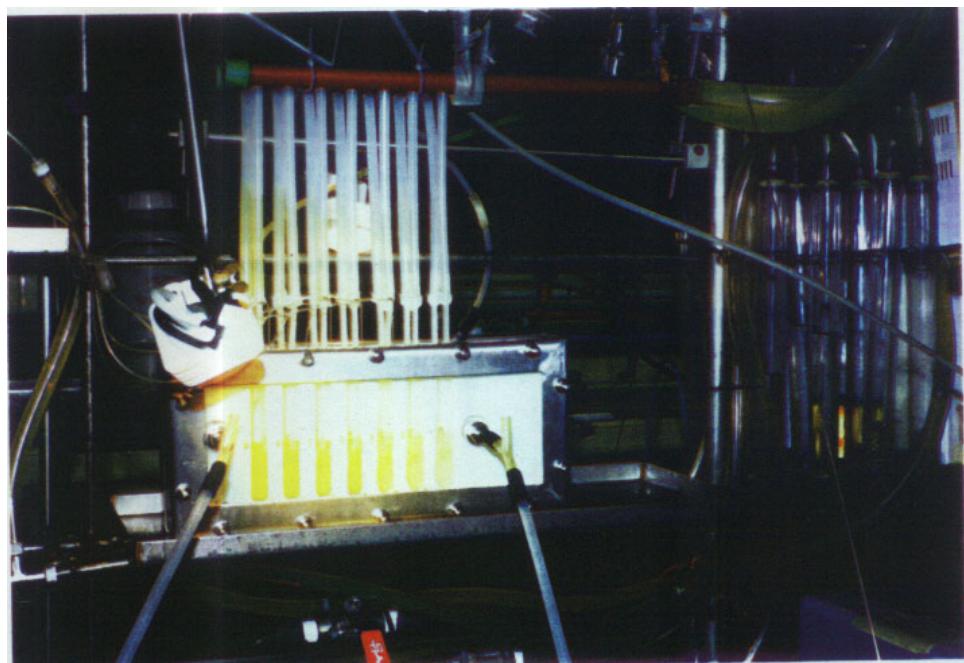

Figure 3. Mixer-settler prototype during extraction tests in laboratory.

At first, PUREX process conditions were tested during several continuous periods of 14 hours. Considering the flow rate and the uranium concentration of the fed solution into the corresponding mixer and its volume, values as 3.52 g U/h.cm<sup>3</sup> and 0.50 g U/h.cm<sup>3</sup> for the extraction feeding mixer and for the 7 stages mixers of the device respectively were obtained, as a measurement of production capacity. An average stage efficiency of 81 % and an overall efficiency of 73 % were obtained. A typical concentration profile obtained in one of these experiments can be seen in Table 1.

*Table 1. Typical uranium concentration profile for PUREX process conditions.*

Stage	Organic U concentration [g/L]	Aqueous U concentration [g/L]
1	32.8	104.2
2	38.5	105.1
3	45.5	105.6
4	10.4	43.5
5	4.5	13.5
6	2.5	1.17
7	0.156	0.47
8	0.01	0.065

Then, a high concentration uranium process like IMPUREX [2] was tested during several continuous periods of 14 hours too. The cycle was automatically controlled by means of a loop integrated by an optical measurement of uranium concentration, a PC software specially designed and externally operated pumps. A typical concentration profile [3] obtained in one of these experiments can be seen in Table 2.

*Table 2. Typical uranium concentration profile for IMPUREX process conditions.*

Stage	Organic U concentration [g/L]	Aqueous U concentration [g/L]
1	0	0
2	0	0.36
3	13.2	4.4
4	35.3	15.62
5	103.6	63.2
6	121.9	60.9
7	122.1	61.3

Watertightness, stability, perfect mixing, correct circulation of phases and high mass transfer rate were observed.

## CONCLUSIONS

Materials such as high density polythene and tempered glass have been demonstrated to be highly resistant to corrosion and radiation, they have a long lasting visibility, and when pressed together, they perform within suitable watertightness values. They can be used in hot cells, so they are a good option for use as experimental mixer-settlers.

The different height of the two air-mixing nozzles produces an optimum mixing.

The upper ended nozzle directed to a special baffle placed in the mixing channel allows any high viscosity mixture or crud to flow easily from the mixer to the settler. Back mixing was not observed.

A small air-lift placed in every stage eliminates the overall pressure drop and breaks aqueous phase density steps, as a result of sufficient pumping of aqueous phase from settler to mixer.

The data collected from the test series have demonstrated the following advantages: high stage and overall efficiency and high mass transfer per unit of time and mixer volume, to become this device in a good option for hot cell operation.

## THE INFLUENCE OF EXPERIMENTAL DROP SIZE ERRORS ON LIQUID-LIQUID EXTRACTION MODELLING EVALUATION

M.L.A.C.N. Gomes, M.M.L. Guimarães, J.M.M. Cardia Lopes, C.M.N. Madureira\*,

Improved performance of modern computers has added pertinence to the possibility of testing the predictions of complex theoretical models of liquid-liquid extraction processes against experimental data. However, a search of the available literature has shown that comprehensive studies of the errors in the measurement of drop size distributions have never been performed. Analysis is performed in this work of the random errors of experimental data from a pilot-scale Kühni-type column at the Technical University of Munich.

Also, although several hydrodynamic simulation models have been developed in the past, their authors seem never to have felt the need to take experimental error into consideration when evaluating their proposed models. As gauged by our random error estimates, simulation results for the Coulaloglou-Tavlarides' interaction model exhibit excellent agreement with our drop size distribution experimental data and fair conformity with those concerning dispersed phase hold-ups.

### INTRODUCTION

Mass transfer of solute between two liquid phases (one being dispersed into the other in a contactor) is known to be highly dependent on the hydrodynamics of the drop interaction occurring within the dispersed phase. This interaction consists of break-up and coalescence of individual drops, which take place as a consequence of the chaotic movements of the fluids, which are known to greatly affect the hydrodynamic and mass transfer / reaction performance of liquid-liquid contactors/reactors, through their influence on the drop size distribution and the redistribution of solutes/reactants among the dispersed phase drops.

In the last decades, mechanically agitated devices for liquid-liquid contact in extraction equipment have acquired great importance, due to their capacity to create and maintain large interfacial areas, which accelerate mass transfer. The efficient behaviour of these columns has been shown to be due, not only to these large interfacial areas, but also to the mixing effects caused by drop interactions (breakage and coalescence). Thus, it is obviously necessary to describe both physically and mathematically those interaction processes, in addition to the actual mass transfer fluxes, in order to simulate the behaviour of such systems and predict the effect of the process variables on the extraction efficiency.

In recent years, many authors have spent great effort in modelling such contactors and attempting experimental validation of their models. Models such as those of Cruz-Pinto [1], Casamatta and Vogelpohl [2], Laso *et al.* [3], Tsouris *et al.* [4] and, more recently, Gerstlauer *et al.* [5], have been reported as able to describe with reasonable accuracy the results of their authors' experiments, even though most of them adopted drastic simplifications in order to ensure time-effective computation.

Recently, a simplified version of an algorithm previously developed by Ribeiro [6], and further streamlined by Regueiras *et al.* [7], has been proved able to accurately describe the transient behaviour of a continuous ideally agitated vessel, requiring only modest computer resources and very low computation times. This algorithm, further adapted to model an agitated column by solving the population balance equations in dynamic conditions, was designed to obtain the drop size distribution, solute concentrations and local dispersed phase hold-up profiles along the column height. However, the evaluation of such models so far has never benefited from a detailed assessment and quantification of the experimental errors with which local drop size distribution and dispersed phase hold-up experimental data are obtained. To our knowledge, only one previous study [1] attempted to consider the similar, but much simpler, problem of the consequences of the experimental variability in measured overall (average) dispersed phase hold-ups and Sauter-mean drop diameters on both the experimental and model-predicted column (RDC – Rotating Disc) mass transfer efficiencies.

## EXPERIMENTAL WORK

The experimental work was carried out by Gomes [8] at the TUM in a Kühni pilot-plant column (150 mm inside diameter, active height 2520 mm, divided into 36 stirred compartments with free passage area of 25%). The equilibrated (no mass transfer) standard high interfacial tension toluene (dispersed phase) – water (continuous phase) system was used in these studies.

The extraction column was equipped with measurement devices that allow the investigation of the hydrodynamic conditions along the column. A photoelectric technique initially developed by Pilhofer (Genenger *et al.* [9]) was used to measure the axial profile of drop size distributions at steady state. This was installed in five compartments (2<sup>nd</sup>, 5<sup>th</sup>, 11<sup>th</sup>, 21<sup>st</sup> and 35<sup>th</sup>) of the column. It should be noticed that the experimental set-up does not provide for the acquisition of the feed drop size distribution or even of the drop size distribution at the first column stage. Samples of 1000 drops were collected for each measurement of the local drop size distribution. Local hold-ups were dynamically monitored (at four compartments: 4<sup>th</sup>, 10<sup>th</sup>, 16<sup>th</sup> and 22<sup>nd</sup>) using a non-invasive ultrasonic technique described by Yi and Tavlarides [10]. Simultaneously, the global hold-up was measured using the pressure difference between the top and bottom of the active part of the column. All these data as well as intensity of agitation and flow rates of the dispersed and continuous phases were recorded on-line on a personal computer.

Under normal industrial or pilot-plant experimental conditions, the drop size distribution may be influenced by fluid contamination, which in turn induces variations in the interfacial tension, a key variable affecting the drop interaction dynamics. It is almost impossible and highly uneconomical to stop an industrial installation in order to perform fluid cleaning operations, although periodical removal of impurities accumulated at the top and bottom interfaces may be adopted as routine procedure. Further, interfacial tension is highly dependent upon temperature, an environmental variable that is uneconomical to try to stabilise.

Several experiments were planned and performed, under both steady and transient states. Since, in the experimental set-up, environment conditions were not either controlled or measured, repeated runs, were planned in order to study the reproducibility of the hydrodynamic performance, as well as the measurement and sampling errors. These, including those directly resulting from slightly varying (drifting) interfacial tension, were later used to assess the quality of the model's predictions.

The standard operating conditions (labelled B16-standard in Gomes [8]) used in this paper were ( $F_d = 160 \text{ L.h}^{-1}$ ;  $F_c = 125 \text{ L.h}^{-1}$ ; rpm = 140). For these conditions, six measurements of drop size distributions and thirty measurements of global and local hold-ups were obtained, in two different work periods. The reason for the selection of these specific measurements was the critical importance of the corresponding variables / operating conditions on the contactor's performance [1, 8].

## ERROR ANALYSIS

In any experimental work two kinds of errors, systematic and random, are to be expected. Ideally, systematic errors should be identified and then corrected. During the experiments carried out with the extraction column, we have detected some evidence of systematic errors affecting the drop size measurements at the fifth column stage. Unfortunately, we were not able to identify and correct their source(s).

Random errors, however, cannot be totally avoided, so that a statistical treatment must be performed in order to assess their magnitude. The meaning of results quality is, of course, quite subjective: what may be thought of as good quality in one instance may be quite unacceptable in another one. In order to have some assessment of measurement quality we used the 98% probable width of the random error interval of the experimental results. In order to do this, we must estimate not only the average,  $\mu$ , but also the mean square deviation,  $\sigma$ . Under favourable circumstances, normal (gaussian) sampling theory will be adequate for this purpose. We, however, came across time and expense limitations, which limited the maximum size of the drop sample to be taken. In this case, small-sample theory must be invoked, the uncertainty introduced by the poor estimation ( $\bar{x}, s$ ) of the population parameters ( $\mu, \sigma$ ) must be accounted for, and the confidence interval must be calculated as

$$\bar{x} \pm \frac{t.s}{\sqrt{n}} \quad (1)$$

where

$n$  = Number of available samples

$t$  = Student's statistic  $t$  for the appropriate significance level (98% in our case) and number of degrees of freedom ( $n - 2$ , because two of them have been spent in the estimation of the average and the mean square deviation). The values for Student's  $t$  may be found in any standard statistical hand- or textbook.

## CONFIDENCE CHANNELS

The absolute instrumental error implicit in the size class-by-class drop counts impinges upon the relative error, because drops may be assigned to one class when they should be assigned to a neighbouring one. Figure 1 (left) shows the relative error as computed from the Student's  $t$ -distribution for six runs performed under the operating conditions designated B16-standard. The graph is typically *U*-shaped, both small and large size-classes exhibiting anomalous high relative errors.

In the case of small sizes, this may be ascribed to small-diameter drops not being stretched enough by the capillary, and thus not presenting enough length to be individually counted. The fact of the error being minimal for drop diameters just above the capillary diameter (0.8 mm) seems to confirm this interpretation. According to this analysis, the anomalous high errors in the smaller size classes must be thought of as systematic, or instrument-related, and cannot be removed or decreased by statistical means.

In the case of large sizes, which are characteristically infrequent, the sampling error is expected to be correspondingly higher since even one misplaced drop translates into a large relative error. This interpretation seems to be confirmed by the error increasing upwards along the column, the direction along which, under the present conditions, the number size distribution becomes narrower and narrower, as Figure 1 (right) shows.

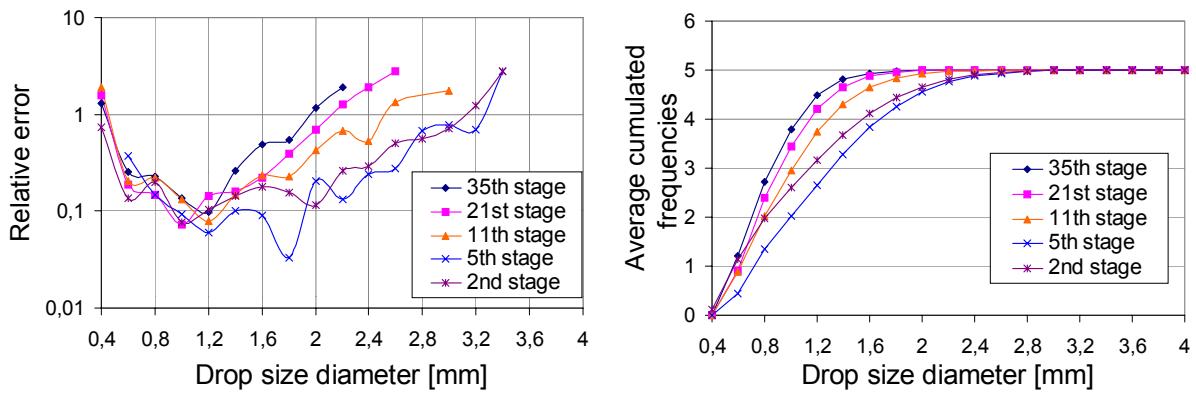

Figure 1. Left: Relative error calculated from number drop size distributions for the different stages of the column, under B16-standard operating conditions.

Right: Average cumulated frequencies for the number drop size distributions for the different stages of the column, under B16-standard operating conditions.

For the assessment of model performance, we used the error in cumulative size distributions, in order to minimise the relative error for the larger size classes. In fact, by taking cumulated frequencies, *i.e.*, counting in each class all drops smaller than the upper limiting size of the class, instead of the individual frequencies, the error curves become significantly different because the larger size classes now contain a considerably larger number of drops, as Figure 2 (left) shows.

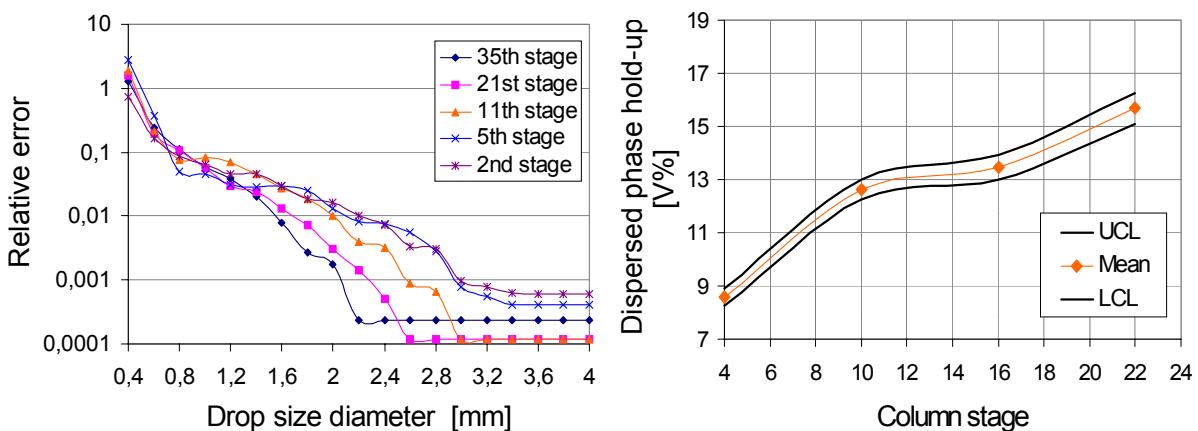

Figure 2. Left: Relative error for the cumulative number drop size distributions at different stages of the column, under B16-standard operating conditions.

Right: Confidence channel for the dispersed phase hold-up measured profile (UCL = Upper (98%) confidence limit; Mean = Average; LCL = Lower (98%) confidence limit).

The relative (random) error for the local hold-up measurements under B16-standard conditions was consistently about 4% of the average value, as shown in Figure 2 (right). This is remarkable, since mean drop sizes, temperature and illumination are bound to vary significantly along column height.

The relative (random) error for the global hold-up of the column has been estimated as 2.30% for the B16-standard operating conditions.

## CONFIDENCE INTERVALS AND MODEL PARAMETER ESTIMATION

The parameter optimisation algorithm selected was Levenberg-Marquardt's, for its recognised capability of handling highly multidimensional spaces (up to nine parameters were to be considered) and its frugality on function calls (the execution time of each call, involving the dynamic simulation of the process until it reaches steady-state, in a 300 MHz Pentium III, with 64 Mbytes of core memory, may, in certain cases, result in up to 2 hours of processor time). The objective function was defined as a weighed sum of the square deviations between calculated and experimental values of the overall and local dispersed phase hold-ups and of the local cumulative number-based drop size distributions. The C<sup>++</sup> code used was written by Regueiras [11] and based on Nash [12], using double precision in all critical number representations and special care in the estimate of derivatives.

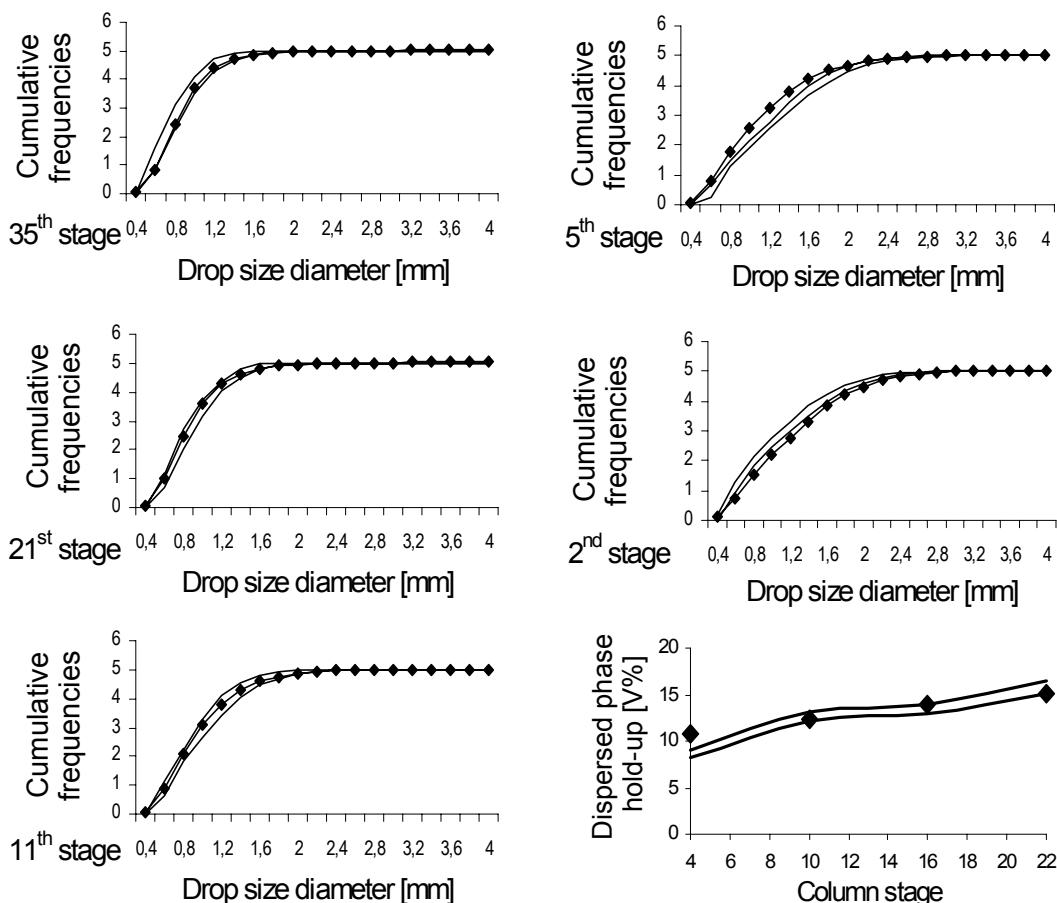

In the absence of direct experimental measurements for the dispersed phase feed size distribution, this was assumed to be lognormal. In fact, preliminary runs have shown that, among several common distribution types, this was the most adequate to describe our data. The average and standard deviation of the feed drop size distribution have been adjusted together with the model parameters.

As seen in Figure 3, the simulated cumulative drop size distributions and local hold-up profiles globally fall within the experimental confidence limits of the data. The most important exceptions occurred in stages 2 (subject to influence of the unknown dispersed phase feed distribution) and 5 (where systematic errors, due to deficiencies in the column instrumentation, were suspected). Thus, evidence has been obtained that the minimized predicted to experimental data residuals are consistent with the experimental errors.

The present work extends the previous study by one of the authors [1], in which experimental overall dispersed phase dispersed phase hold-ups and local drop size distributions, and experimental and predicted extraction efficiencies (forward mixing model with no drop breakage/coalescence and rigid or oscillating mass transfer model, for the dispersed phase, and plug flow with axial mixing, for the continuous phase [1, 13]) were obtained for four sets of duplicate experimental runs, in an RDC column. This study highlighted the importance of the variability of experimental hydrodynamic data even for weakly interacting dispersions, and, when interaction rates are high, one can only expect much stronger effects, in view of the strong dependence of the drop breakage and coalescence frequencies on the local dispersed phase hold-ups and drop size distributions.

## CONCLUSIONS

An estimation of the (random) relative error of experimental data, as computed from Student's *t* for replicate data was shown to be important for checking the goodness-of-fit between simulated and experimental values. Model parameter values fitted by the Levenberg-Marquardt algorithm with the sum of squares of deviations as an objective function exhibited excellent agreement with experimental data concerning drop size distributions and fair conformity with those concerning hold-ups.

*Figure 3. Simulated values, together with confidence limits. Left: drop size distributions to 35<sup>th</sup>, 21<sup>st</sup> and 11<sup>th</sup> stages; Right: drop size distributions to 5<sup>th</sup> and 2<sup>nd</sup> stages and local dispersed-phase hold-up profile.*

## VERIFICATION OF A PROCESS IN A DEMONSTRATION PLANT: HOW LONG DOES IT TAKE TO FIND ALL THE PROBLEMS?

**Baruch Grinbaum, Leni Kogan**

IMI(TAMI) Institute for Research and Development, Haifa, Israel

A demonstration plant is erected to fully simulate the future plant. Its configuration and type of equipment is similar to the full-scale plant, and it should be run in the designated site, using the real raw materials. Its main purpose is the verification of the process, which was developed on the bench-scale or pilot plant scale, regarding production rate, recovery, product quality and analysis of accumulation phenomena.

Quick accumulation phenomena can be detected and solved during the running-in of the bench or pilot plant. Slow phenomena, which are detected after a few weeks or months, are the more problematic ones. They are caused by solvent decomposition, oxidation, precipitation or extraction of traces of harmful elements. A crucial problem is to decide how long should the running-in be.

An example of a full follow-up of a process in a demonstration plant is given.

### INTRODUCTION

The most difficult problem in scaling up SX processes is to predict and solve various accumulation phenomena. All other scaling-up parameters can be successfully determined in an adequate process and/or equipment pilot plant, during relatively short running-in, typically a few weeks of experimental work. The accumulation phenomena, on the other hand, take a long time to be detected – typically a few months and more. One of their worst properties is that often they are quite unpredictable, and only after being discovered can one start thinking about a possible solution. Quick accumulation phenomena can be detected and solved during the running-in of the bench or pilot plant, if the pilot is run with the real raw material of the future plant. Slow phenomena, which are only detected after a few weeks or months, are the more problematic ones. They may be detected in a demonstration plant only. A demonstration plant is erected to fully simulate the future plant. Its configuration and type of equipment is similar to the full-scale plant, and it should be run in the designated site, using the real raw materials. Its main purpose is the verification of the process, which was developed on the bench-scale or pilot plant scale, regarding production rate, recovery, product quality and analysis of accumulation phenomena.

### What causes Accumulation Phenomena?

Accumulation phenomena are caused by solvent decomposition, oxidation, precipitation or extraction of traces of harmful elements. The common phenomena are: poisoning (by irreversible reaction with the solvent), precipitation of scale, decomposition of the solvent, foaming or deteriorating phase separation (due to creation of surface active compounds or very fine solid particles in the solvent).

The detection of the accumulation phenomena is slow. Every detected problem has to be solved and the running-in should be continued, until the next one is spotted and solved, and so on. In many cases, once an accumulation problem was detected and its cause understood, the solution is rather quick. Sometimes the solution is difficult, or even impossible. Often the symptoms of one problem mask the others, and only after solving the first problem, the other ones (sometimes more problematic) are detected and treated.

To find all of them requires a long verification run.

But how long should it be? Usually, the running-in of the demonstration plant goes on until one of the following conditions is satisfied:

***Full proof:***

The running-in was long enough to ensure a profitable process, even if the plant needs to be shut down for periodic cleaning or the solvent has to be totally exchanged in the future. In other words: the expected profit on the product is high enough to cover the cost of a periodical cleanup or total exchange of the solvent. Sometimes the deterioration of the solvent goes on slowly, despite all the direct or side-stream treatments, but the solvent remains good enough to enable profitable production.

***Time criterion:***

A period, set before the running-in started, passed without any new problem being discovered. A typical period of 2-6 month is recommended.

***The budget or time limit expired:***

There is no satisfactory proof that the solvent works “forever”, but on the other hand it did not fail during the time allocated to the experiment. The management has to use its best judgement and decide what to do.

## THE STORY OF THE LONGEST RUNNING-IN OF A DEMONSTRATION PLANT

The running-in of the demonstration plant for extraction of CaBr<sub>2</sub> from Dead Sea Brines demonstrates the methodology and problematics of the running-in.

**The Process**

The process for extraction of CaBr<sub>2</sub>, that was developed by IMI(TAMI) for Dead Sea Bromine (DSB), was a classic case for erection of a demonstration plant. The final product of the process is a clear solution of 52% CaBr<sub>2</sub>, with less than 0.5% Cl<sup>-</sup>.

The idea of the process is to extract the CaBr<sub>2</sub> directly from the brine, using a solvent that has high selectivity for both Br<sup>-</sup> over Cl<sup>-</sup> and Ca<sup>2+</sup> over Mg<sup>2+</sup>. The extraction process consists on 3 steps, each carried out in a separate battery. First, the Br<sup>-</sup>, together with Ca<sup>2+</sup> and some Cl<sup>-</sup> and Mg<sup>2+</sup> are extracted in the extraction battery. The extract, which contains relatively high concentration of Cl<sup>-</sup> and Mg<sup>2+</sup>, is purified in the purification battery by part of the product. Finally, the pure CaBr<sub>2</sub> is re-extracted from the purified extract by distilled water. The resulting solution is concentrated to 52 %, to make the final product.

The proprietary composite solvent was a mixture of amine and fatty acid in a diluent. The approximate composition of the Dead Sea end brine is: 0.75-0.95 % Br, 22-27 % Cl<sup>-</sup>, 2-5 % Ca<sup>2+</sup> and 5-7 % Mg<sup>2+</sup>. The concentrations are higher in the summer, and decrease in the winter. The distribution coefficients for all ions rise sharply with increasing ionic strength of the brine and drop with increasing temperature. The flux through the plant increases significantly with the temperature, as the viscosity decreases and the coalescence is quicker.

The overall performance of the plant was expected to be much better in the summer, and the production rate in summer was expected to be double relative to that in the winter.

The process was designed carefully, including good process simulation, and the only question marks, that convinced DSB to erect the demonstration plant, were the unknown accumulation phenomena.

### **The Demonstration Plant**

The most important strategic decision was to make a huge demonstration plant, with production rate about 10 % of the industrial plant, *i.e.*, flow rates above 100 m<sup>3</sup>/hr. Such a big plant makes the design of the industrial plant in the future much safer, as the total scale-up is just by factor of 10. Moreover, the product made by such a big plant can pay the variable costs of the operation, enabling a longer running-in without excessive budget limitations.

The plant consisted of mixer-settlers, arranged in three batteries: extraction, purification and washing.

### **The Running-in Design and Startup**

One of the most problematic features of the process is that it *practically never reaches steady state*. The composition of the brine changes between summer and winter, and so does of course the temperature. The influence of the ionic strength of the brine and of the temperature was known from the simulation to be very strong. The practical meaning for the running-in was that *variations in the flux and bromide recovery could be attributed to seasonal changes as well as to deterioration in the solvent performance*. The plant was started in the summer, when both the flux and the production rate are at maximum. So, any deterioration in the plant performance in autumn and winter could have been attributed to the seasonal changes just as well as to real deterioration due to accumulation problems. The direct conclusion was, that the running-in must take more than one year, to overcome this point and to get data about the expected performance in every season.

The running-in program was simple: operate the plant at maximum possible flux, while fine tuning the operational parameters that were calculated by the simulator, *e.g.*, phase ratio in the extraction, degree of washing, concentration and flow rate of the reflux stream etc. The product was to be sold, and, in addition to checking the market, had to cover most of the current costs of the operation. No *a priori* dead time for the running in was set, yet nobody expected that it would take six years.

The start-up was promising: after 3 weeks, the production rate of the plant was well above the design values. By then, the operating time of the demonstration plant was equal to the total period of the running of the bench scale, equipment and process pilot plant. However there remained the unavoidable question; what will strike first and when?

Over all, many accumulation phenomena were encountered and solved. The most interesting ones are listed below.

#### **Accumulation of ions**

The first, and quite unexpected problem, was the uneven loading of the solvent. After a few weeks significant deterioration in the washing of the solvent was observed. A crash research program revealed that under real process conditions either Br<sup>-</sup> or Ca<sup>++</sup> (depending on the pH of the brine) may accumulate on the solvent without a counter-ion, creating a stable amine bromide or calcium acid salt. As these ions cannot be washed out with water, they decrease the net loading of the solvent. Once detected and understood the problem was solved readily: an analytical method to determine the concentration of the bound ions was developed, and they were stripped by continuous addition of HBr or NaOH to the wash water.

### **Deposition of scale**

This was also an unexpected problem. After a month of successful running, some blockages of the pipes were observed. They were identified as  $\text{CaCO}_3$  and  $\text{CaF}_2$ . The precipitation of the carbonate could have been expected, as its presence in the brine, although in low concentration, was known, and the affinity of the amine to carbonate was common knowledge too. The presence of  $\text{F}^-$  was a surprise, as according to the solubility product its maximum concentration should not have exceeded 1 ppm. Yet, a concentration of 10 ppm  $\text{F}^-$  in the brine was detected, most of it being preferentially extracted by the solvent, and washed in the washing battery.

There was no way to prevent the extraction and creation of scale. The preventive treatment was to wash periodically the instrumentation, valves and narrow pipes with HCl.

The  $\text{CaF}_2$  was also the main culprit in the creation of crud – see below.

### **Solvent deterioration**

Early stability tests in the laboratory confirmed that the fatty acid and the diluent are stable, while the amine may undergo slow decomposition in the presence of oxygen. To avoid it, the plant was constructed with a nitrogen blanket. According to both the literature and laboratory tests this should have been more than enough (it was well known that, in many hydrometallurgical plants, amines are used without nitrogen blanketing and no deterioration was reported over years). Yet, after about 3 months a slow but steady deterioration in the performance of the plant was observed. It included lower yield on one hand and slower phase separation, which led to decreased flow rated on the other. As it was already autumn, the deterioration could have been attributed to the seasonal changes just as well as to problems with the solvent. The only reliable way was to compare the output of the plant with the results as predicted by the simulator. And this was really the way the problems with the solvent were detected. Once the problem was identified, the chemical decomposition of the amine was verified analytically. It was found, that at the summer temperature of the Dead Sea brines (close to 50 °C) even the small amount of oxygen, fed with the inlets or entering the vessels in spite of the nitrogen, was enough to oxidize the solvent. The solvent was used for another 6 month, with slow but irreversible deterioration. Meanwhile an efficient chemical additive, which could stop the oxidation, was developed and tested. Once the stability tests were positive, the entire batch of solvent (near to 100 m<sup>3</sup>) was removed, the plant was cleaned up and a new batch of solvent was introduced. In parallel, a device to strip the oxygen from both the feed brine and the wash water, using nitrogen, was installed in the plant. A year after the initial start-up the plant was restarted. The additive proved to be efficient, and practically zero oxidation was detected in the following years.

### **Crud**

Crud started accumulating at the interface after a few days, but a few months passed before it started affecting the plant performance. It caused increased thickness of the dispersion zone in the settler, and increased entrainment of both O/W and W/O, eventually decreasing the possible flow rates.

Initially the crud was attributed to the decomposition of the amine, which by then was already known. Only about three months *after* the new solvent was introduced, the crud was positively identified as a harmful accumulation phenomenon, and another six months passed until it was fully understood. Its main component was silica silt, which was readily identified. It was hardly a surprise, but the good news was that it caused no trouble and after a few months its accumulation stopped, i.e. the amount of silica in the feed and in the raffinate was equal. The real harm was done by  $\text{CaF}_2$  that precipitated in the washing battery as very fine crystals (<1μ in diameter), adsorbed molecules of the solvent, and created a colloidal gel that

traveled through the entire plant (its concentration was equal in all the batteries). To overcome it, two alternative side stream treatments were developed and tested.

The first one was chemical: it was found in the laboratory, that at pH<1 the colloid was broken, the captured solvent released and the CaF<sub>2</sub> precipitated on the bottom. HCl was the most convenient acid to use. But to get to this pH all of the amine had to react with the acid, to yield amine chloride. To complete the process, all the amine chloride had to be neutralized with NaOH. In the demonstration plant this operation was done batchwise, in a side-stream mixing vessel with a conical bottom, through which the fine solids were removed. This solution had harmless wastes (NaCl solution), but the cost of the reagents was relatively high.

When the chemical treatment was finally developed, the solvent was in a really bad condition, with a very low production rate. To speed up the cure, the entire batch of solvent – about 100 m<sup>3</sup> – was treated in a quite complex logistic operation. After two weeks the plant was restarted – and the solvent worked almost as new.

The other treatment was physical, and consisted of passing the solvent through a decanter centrifuge, in which the gel was separated. It was developed in order to save the cost of chemical reagents needed for the chemical treatment. This procedure was efficient but not really cheaper, mainly due to the solvent losses: the separated gel contained above 50 % amine and fatty acid. There was no economical way to recover them, and they were discarded, adding the cost of waste treatment to the solvent losses and direct cost of the decantation.

Both methods were tested, each for more than one year. Both were efficient in keeping the CaF<sub>2</sub> at a level, which caused no significant harm, and enabled continuous running of the plant.

#### ***Entrainment of aqueous phase***

As the O:W phase ratio in the purification and washing batteries exceeded 20, the aqueous entrainment in these batteries had to be very low. The plant was designed to meet this constraint, and all the settlers were “furnished” with partitions, to decrease entrainment. In the first few month the entrainment was well below the allowed 0.5 %. Yet, during the second winter (about six months after the plant was restarted with the new solvent) the entrainment rose sharply. The highest entrainment was in the last (i.e. the most diluted) stage of the washing battery – up to 4 %, which was unacceptable. It took a few months to realize that it was a combined problem of the lower temperature, which increased the viscosity, and the influence of the colloidal gel, which increased the width of the dispersion band. The immediate (and trivial) solution was to decrease the flow rates and to wait for the summer. During the summer, although the entrainment significantly decreased, it remained well above the design values. In the next winter the side-stream treatment was already operating, yet the entrainment was hardly smaller than in the previous year. The next attempt to solve the problem was to invert the phases, i.e. to disperse the major organic phase in the minor aqueous one. The mechanical changes, necessary for the phase inversion, were made only in the two critical stages, namely the end of both the purification and washing batteries, so that the solvent leaves the batteries with small entrainment. After suitable new turbine-pump-mixers (TPM) were designed and installed, both stages operated in aqueous continuous dispersion. The entrainment dropped below 0.5 % and the problem was practically solved. In other stages of these batteries the entrainment was between 1-2 %, and it was possible to live with it. In the extraction battery, where the phase ratio was near to 1:1, even 3 % of entrainment had hardly any influence on the process. During the remaining two years, the aqueous entrainment did not increase, and the phase inversion in the critical stages solved the problem.

### ***Entrainment of solvent***

Solvent entrainment was similar to the aqueous entrainment: it started with values about 100-150 ppm solvent in the raffinate, that are reasonable for mixer-settlers but too high for any SX process. The raffinate was sent to a continuous horizontal packed coalescer, where most of the entrained solvent was separated, leaving about 30 ppm to the waste. Over time, the entrainment went up to 300 ppm. Most of it was adsorbed onto the silica silt or CaF<sub>2</sub> particles, leaving the plant. This solvent was not separated in the horizontal coalescer. A sand filter was added, and it succeeded in decreasing the entrainment to 30 ppm.

### ***Long term durability of the equipment***

The long running-in enabled an excellent verification of the durability of the materials of construction, the reliability of the instrumentation, improvements in the analytical methods, sampling and control schemes etc. Nobody runs a demonstration plant for six year just to validate these parameters, but once such a long running-in period happens, it is an invaluable chance to check all these parameters on an experimental scale. Moreover, if after six years no functional or corrosion problems were detected, it may be considered as a full proof for the equipment. Such a long run minimizes the risk of failure in the commercial plant.

### **The Happy End**

The long story had a happy end: during the last 12 months no new phenomena were discovered, and there was an efficient treatment of the known ones. After six years both the managers and the researchers were convinced that the process is feasible, and the demonstration plant, that fulfilled its task, was shut down.

## **CONCLUSIONS**

The running-in of the CaBr<sub>2</sub> demonstration plant proved that in order to detect all the accumulation phenomena and overcome them, the running-in may take a few years. It supports the approach of making the demonstration plant large enough, so that the value of the product covers most of the operating costs, enabling a long run without excessive costs. It also proved, that once sufficient time is given, there is an economical solution for almost every accumulation problem.

Had the industrial plant been erected without any demonstration plant, its failure is almost certain, as nobody could afford the losses connected with long shutdowns and changes in the plant, caused by the accumulation phenomena.

## PERFORMANCE CHARACTERISTICS FOR A KARR RECIPROCATING PLATE EXTRACTION COLUMN

Angela Stella, H. R. Clive Pratt and Geoffrey W. Stevens

Department of Chemical Engineering, The University of Melbourne, Parkville, Australia

A program for the prediction of mass transfer performance in a Karr reciprocating plate column has been developed for two-phase, phenolic-based systems. Using correlations that have been verified for a 50 mm diameter column, the dispersed phase holdup, droplet size and the continuous phase backmixing coefficient were predicted for 100 and 450 mm diameter columns. Pilot-scale studies, using a solvent-alkaloid-aqueous alkali system were conducted to establish the optimum operating variables, including pulsation characteristics, with a high organic (continuous) to aqueous ratio. A robust model was obtained that enabled the mass transfer performance in a Karr reciprocating plate column to be determined for two-phase systems based on non-linear equilibrium data.

### INTRODUCTION

Since its development, the Karr column [1] has found application in many industries for the separation of the components of mixtures by liquid extraction. The contactor itself consists of a series of reciprocating perforated plates that provide up to 60% open area. Today, the Karr column is used in many areas such as the hydrometallurgical, pharmaceutical and petrochemical industries.

The counterflow of the dispersed phase drops in the continuous phase can induce significant deviations from ideal plug flow, thus leading to a fall in the effective driving force. Factors that contribute to backmixing include: -

- Entrainment of the continuous phase in the wakes of the dispersed phase droplets;
- Circulatory flow of the continuous phase caused by energy dissipation of the droplets;
- Molecular/turbulent eddy diffusion, as well as channelling and stagnant flow effects.

Novotny *et al.* [2], Kim & Baird [3] and Baird & Rao [4] have characterised the performance of various columns predominantly for single-phase operation. Prvcic *et al.* [5] later predicted axial dispersion for a two-phase system in a pulsed, perforated plate extraction column. To date, Stevens and Baird [6] have measured axial dispersion for a single-phase system via continuous tracer injection for a reciprocating plate column. Numerous correlations of mass transfer data to single droplets during formation and coalescence are available in liquid-liquid extraction [7, 8]. Their applicability to droplet swarms in real extractors is not apparent since little is known about the flow patterns of the continuous phase, the effect of throughput, contact area and distributor geometry. Harikrishnan *et al.* [9] have provided a correlation that enabled the prediction of mass transfer coefficients as a function of the dissipation energy for a reciprocating plate column to determinate the effective driving force.

## PROCESS DESCRIPTION

The flowsheet proposed for the alkaloid extraction in a Karr reciprocating plate column is shown in Figure 1. The experiments involved studies of a phenolic alkaloid system, whereby the solute was removed from the solvent mixture into an aqueous alkali solution by solvent extraction. The column consists of a dispersed phase inlet where fresh aqueous alkali was introduced into the column. At the bottom of the column the organic continuous phase was fed from the solvent header that was part of the stream intended to the production columns. The spent solvent was dispensed in the bottom stream that exited the agitated columns. The rich aqueous phase was then sent to the settler whereby the organic phase was later recycled. Further solvent extraction was required to improve the percent of recovery and the loaded liquor was then separated by changes in pH.

## EQUIPMENT AND PROCEDURES

Initial experiments were conducted in a 50 mm diameter column using a phenol - 10% tributyl phosphate/kerosene - water system. Plate frequencies and amplitudes of 2.0 and 3.0 Hz and 0.5 and 1.2 cm, respectively, were studied. The perforated plates with an open area of 45% had a hole size of 12.7 mm and plate spacing of 50 mm. The pulsing unit, driven by a variable speed motor, provided the reciprocating motion via a central shaft. The shaft supported the Teflon plates, which were fixed by three tie rods and positioned on a triangular pitch around the plate. Drainage was used to determine the dispersed phase holdup, while the drop size was found using a photographic technique. Pulse injection of a colour tracer, Waxoline Blue at the continuous phase inlet and measurement of the concentration response at two locations further down the column enabled the degree of continuous phase backmixing to be determined [10].

This was followed by work using an alkaloid system in 100 and 450 mm diameter columns, each constructed from 5m long Pyrex glass and stainless steel tubes. High-density polyethylene plates imparted a reciprocating motion by a variable speed motor with an adjustable yoke coupled to the motor. The plate geometry and plate spacing remained constant for all column diameters studied. Experiments involved the determination of the mass transfer coefficient, which was correlated in terms of the dispersed phase holdup, drop size and the continuous phase back mixing parameter.

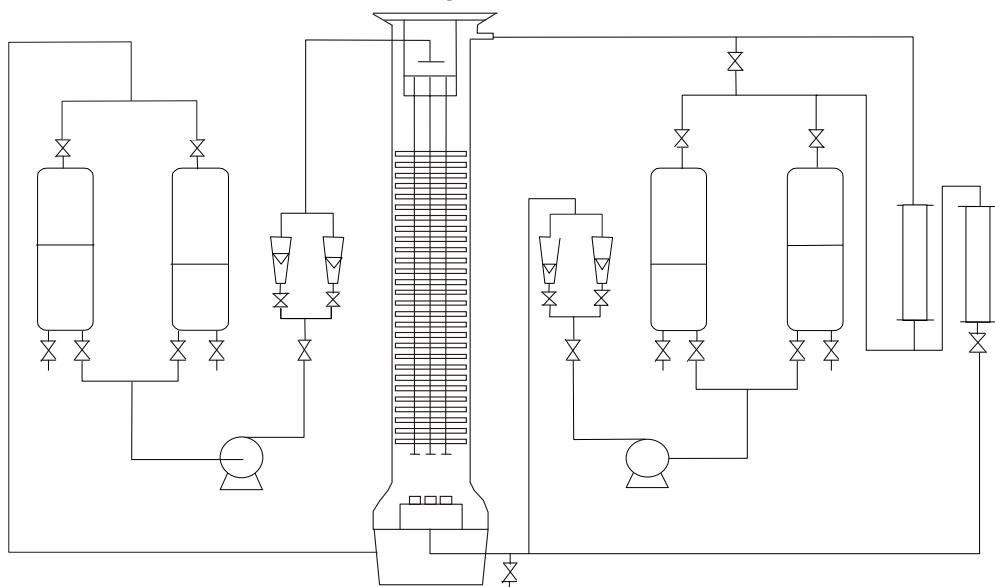

Figure 1. Schematic flow diagram for the alkaloid extraction in a reciprocating plate column.

## RESULTS

### Phenol Solvent Extraction

The properties of the feed and extractant solution for the phenol study are given in Table 1.

*Table 1. Typical properties for the phenol system.*

Element	Symbol	Properties
Dispersed phase	d	Tap Water
Continuous phase	c	10% TBP/Kerosene
Solute	—	Phenol
Interfacial tension	$\gamma$	11.8 mN/m
Continuous phase density	$\rho_c$	809 kg/m <sup>3</sup>
Continuous phase viscosity	$\mu_c$	1.76 cP

The holdup and Sauter mean droplet diameters were measured during mass transfer. Holdup data were in good agreement with predicted measurements using the Kumar & Hartland correlation [11], assuming plates wetted by the dispersed phase as given by,

$$x_d = [k_1 + k_2(Af)^{3.0}] V_d^{0.81} (V_d + V_c)^{0.32} \Delta \rho^{-0.98} \dots \dots \dots (1)$$

where  $k_1$  and  $k_2$  are  $7.2 \times 10^3$  and  $3.2 \times 10^6$  respectively. The relative deviation between predicted and experimental holdup values was  $\pm 10\%$ . Measurements of the Sauter mean diameter of the droplets enabled the predicted data to be expressed as a function of the pulsation intensity,  $Af$  (cm/s) for mass transfer in the direction from the continuous to the dispersed phase, thus,

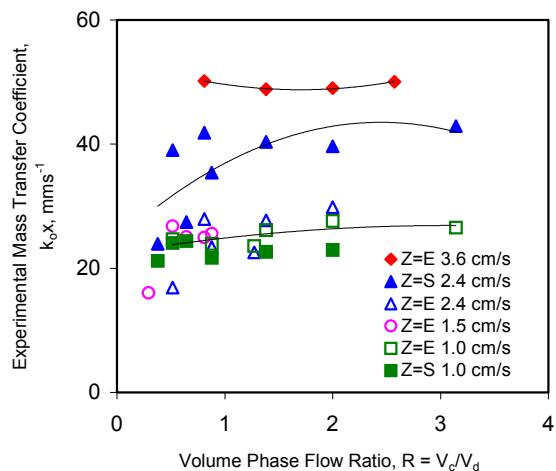

$$d_{32} = -0.591(Af) + 3.434 \dots \dots \dots (2)$$

### Extraction

Extraction equilibria for the system were significantly improved due to the presence of tributyl phosphate in the solvent phase. The conditions were optimised by maintaining the pH of the extraction circuit between 6.0 and 7.5, and using a variable organic to aqueous volume phase ratio, (O:A). Increasing the phase ratio to 2.5 resulted in a lower backmixing coefficient and thus greater affinity for extraction.

### Stripping

Sodium hydroxide, of pH in excess of 13.0, effectively enabled the phenol to be stripped. Typical mass transfer coefficients based on the backflow model are shown in Figure 2.

*Figure 2. Overall mass transfer coefficients obtained in the 50 mm diameter Karr column.*

## Alkaloid Solvent Extraction

The alkaloid system involved the comparable stripping of a phenolic alkaloid in a solvent solution with aqueous caustic soda using 100 and 450 mm diameter columns. The operating condition was to load the organic phase as fully as possible with alkaloid, using a high volume solvent to aqueous phase ratio and to collect samples from the spent solvent and aqueous phase outlets.

Measurements of the dispersed phase holdup were conducted in the 100 mm column to verify the correlated results for the 50 mm diameter column. The drop size, as for the phenol system, was derived using *equation 2*, while the continuous backmixing coefficient was found based on the model developed for a two-phase system in a pulsed, perforated plate extraction column [12]. Various phase flow ratios and pulsation velocities were used to determine optimal operating conditions.

Various single drop models were considered based on the assumption that the continuous organic phase was the governing resistance for mass transfer. Thorsen and Terjesen [13], for continuous phase mass transfer, and Rozen and Bezzubova [14], for dispersed phase mass transfer, were investigated as possible predictive techniques to determine the overall mass transfer coefficient. The resulting models for mass transfer coefficients for each phase,

$$k_c = \frac{D_c(-178 + 3.62 Re^{0.5} Sc_c^{0.33})}{d_{32}} \quad \dots \dots \dots \quad (3)$$

where  $D_c$  and  $D_d$  represent the molecular diffusivities of the continuous and dispersed phase respectively.

## ***Stripping***

When considering the effect of the pulsation frequency, it was evident that an optimum mass transfer rate was reached at 180 rpm and gradually fell with increasing agitation. Interpretation of this result was derived from analysis of the individual film coefficients. Table 2 shows the effects of the continuous and dispersed phase mass transfer coefficient for the various pulsation frequencies. Approach of high frequencies with increasing backmixing, resulted in the formation of rigid droplets of high specific interfacial area. This contrasted the presence of circulation eddies within the droplet at much lower frequencies. An optimal pulsation frequency for the 100 mm diameter column was determined at 180 rpm, with a pulsation velocity of 3.6 cm/s. As presented in Figure 3, the capacity for alkaloid mass transfer as derived using the back-flow model [15], peaked in the frequency range of 2.0 and 3.0 Hz as supported by earlier results [16].

Table 2. Hydrodynamic characteristics for various pulsation frequencies.

Property	Value obtained in 100 mm diameter column			
A, cm	1.2	1.2	1.2	1.2
f, rpm	120	180	210	240
$\alpha_c$	0.01	0.05	0.07	0.10
d <sub>32</sub> , mm	2.0	1.3	1.0	0.60
x <sub>d</sub> , %	3.5	9.9	15.2	22.0
k <sub>c</sub> , (eqn. 3), m/s	$1.7 \times 10^{-4}$	$1.5 \times 10^{-4}$	$1.1 \times 10^{-4}$	$8.1 \times 10^{-6}$
k <sub>d</sub> , (eqn. 4), m/s	$2.1 \times 10^{-8}$	$2.0 \times 10^{-8}$	$1.9 \times 10^{-8}$	$1.7 \times 10^{-8}$
R	16.7	16.7	16.7	16.7

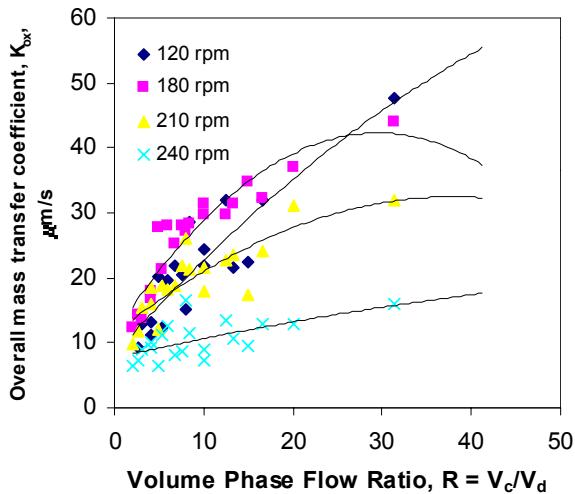

Figure 3. Experimental overall mass transfer coefficients for the 100 mm diameter column.

Results from the 450 mm diameter column confirmed an increase in backmixing with a lower phase flow ratio. The pH of the aqueous alkali was maintained at 13.0 to ensure that the alkaloid remained in solution. The percent of entrainment for Column 1 was measured as 0.74%, while a much lower value of 0.16% was found for Column 2. Table 3 gives the hydrodynamic and performance characteristics at a phase flow of 14.0 and 6.0 for Column 1 and 2 respectively. It shows the effect of the different volume ratios has on both the measured dispersed phase holdup and the predicted value for the continuous phase backmixing coefficient. By doubling the phase flow ratio, the extent of backmixing was significantly reduced. Figure 4 confirms that under negligible backmixing, as was the case in the 100 mm diameter column, the simple plug flow relationship is valid [17].

Table 3. Characteristics of the 450 mm diameter columns.

Column	Column 1	Column 2
A, cm	1.2	1.05
f, rpm	180	180
$\alpha_c$	0.4	1.5
$d_{32}$ , mm	0.9	0.95
$x_d$ , %	3.8	3.0
$K_c$ , m/s	$1.0 \times 10^{-4}$	$1.1 \times 10^{-4}$
$K_d$ , m/s	$1.9 \times 10^{-8}$	$1.9 \times 10^{-8}$
R	14.0	6.0

## CONCLUSIONS

Prediction of the hydrodynamic and mass transfer performance for a two-phase system in pilot-scale reciprocating plate columns was enabled via development of a program. Its viability was extended to existing production columns, wherein the optimum operating conditions were found. More importantly, comparisons were drawn between the performance coefficient found using the backflow model and that based on plug flow operation.

The present work highlights the effect of the phase flow ratio on the backmixing coefficient and the underlying result on the mass transfer coefficient. The optimised alkaloid circuit achieved stripping efficiencies of better than 95%, with losses to the raffinate of below 0.007 g/l, from a feed containing 2 g/l. This work has intended to enhance present understanding of the factors that control the performance of a Karr column and draw conclusions on the optimum throughput permissible and mass transfer efficiency.

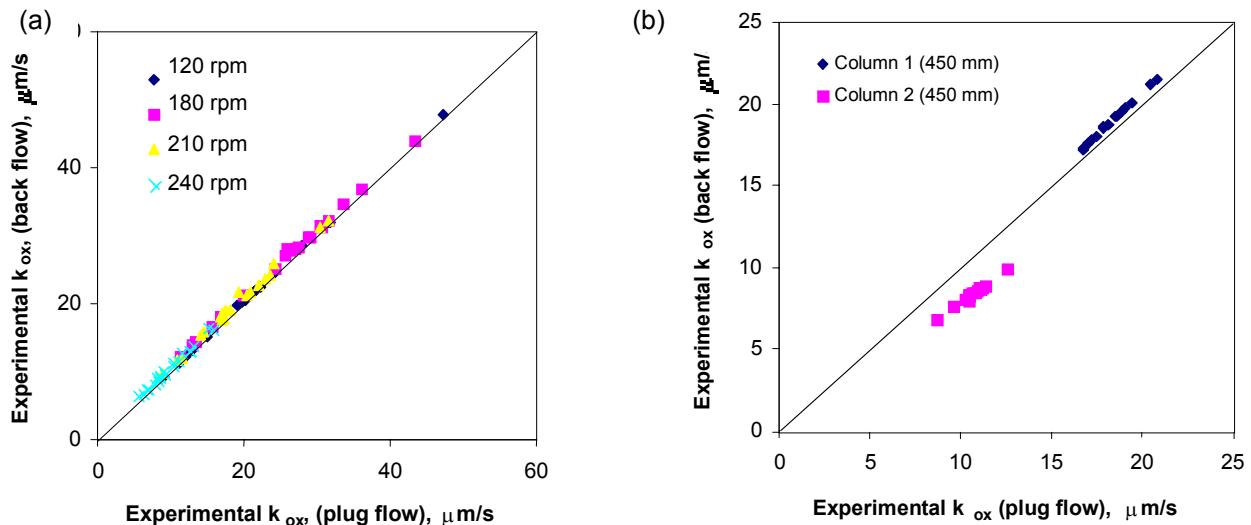

Figure 4. Overall mass transfer coefficient derived using the (non-ideal) back flow model and simple plug flow relationship for (a) 100 and (b) 450 mm diameter columns.

#### ACKNOWLEDGEMENTS

This paper is published by permission of GlaxoSmithKline. The process simulation was modelled using the software program *Mathematica*. Shell Australia and GlaxoSmithKline are thanked for providing the extractants used in this work. Successful completion of the pilot-plant studies was made possible with the significant contribution from Prof. G. W. Stevens and Prof. H. R. C. Pratt from The University of Melbourne.

#### NOMENCLATURE

A	amplitude, m
d	dispersed phase, m
$d_{32}$	Sauter mean drop diameter, mm
D	molecular diffusivity, $\text{m}^2/\text{s}$
E	mass transfer in the direction of the dispersed to continuous phase
f	frequency, 1/s
k	mass transfer coefficient, m/s
$k_o$	overall mass transfer coefficient, m/s
R	volume phase flow ratio, $V_c/V_d$
Re	Reynolds number, $d_{32}V_t \rho_c/\mu_c$
S	mass transfer in the direction of the continuous to dispersed phase
$Sc_c$	Schmidt number for the continuous phase, $\mu_c/(\rho_c D_c)$
$Sc_d$	Schmidt number for the dispersed phase, $\mu_d/(\rho_d D_d)$
V	superficial velocity, m/s
$x_d$	fractional holdup of dispersed phase
Z	pulsation velocity, Af, cm/s

### Greek Symbols

$\alpha_c$	backmixing ratio of continuous phase
$\gamma$	interfacial tension of phases, N/m (kg/s <sup>2</sup> )
$\mu$	viscosity, kg/ms
$\rho$	density, kg/m <sup>3</sup>

### Subscripts

c	continuous phase
d	dispersed phase
x	x-phase (continuous phase in present case)
y	y-phase (dispersed phase in present case)

## GETTING THE BALANCE RIGHT – SOME PRACTICAL DESIGN CONSIDERATIONS FOR SOLVENT EXTRACTION CIRCUITS

Geoff Laing

Bateman Engineering, Perth, Western Australia

On scheduled commissioning and effective operation of a solvent extraction circuit relies on getting the design of both the core contact equipment and the peripheral plant right. Experience has shown that poor performance of new plants is frequently a result of 'utility' systems that do not match the requirements of the circuit, rather than the mass transfer equipment itself. Both the operator/owner and designer need to understand the 'complete requirements' for the circuit to get the balance of the design right. This paper reviews generic issues, frequently overlooked or altered during cost cutting exercises, which have a significant impact on plant performance.

### INTRODUCTION

The performance of a solvent extraction plant is affected by numerous factors ranging from the fundamental mass transfer characteristics of the system to the layout of the plant. Successful commissioning and operation of a solvent extraction circuit relies on getting all the detail right during the design stage. However, getting the detail right all too often becomes a process of trial and error during the commissioning and early operation of the plant. To satisfy the financial constraints of a project and design the optimum circuit a balanced approach to the plant specification needs to be adopted.

Naturally, the most complex issues receive the greatest attention at the piloting and design phases. However, it is not uncommon that the 'simpler issues' result in poor performance of such plants. Problems are often associated with ancillary equipment required to filter, heat, store etc liquors rather than the solvent extraction units themselves. Both the ancillary units and materials of construction tend to be the main focus of cost cutting exercises in the latter stages of design. Often the case is that the solvent extraction plant is given a higher priority than the utility equipment servicing that plant. This equipment must be considered part of the solvent extraction circuit and allocated the same level of importance as the contact equipment. This paper documents a list of factors, in addition to the extraction, scrubbing, and stripping detail, to be considered for any solvent extraction plant. These issues should be considered both prior to any piloting campaign, to enable a suitable test program to be established and then again during the detailed design. The discussion is generic, covering a range of issues relevant to conventional mixer settler type circuits.

## EVALUATING THE CIRCUIT REQUIREMENTS

Successful inclusion of a solvent extraction circuit in a hydrometallurgical flowsheet requires that the selected process operate under appropriate conditions. Suitable equipment will minimize the risk to both the organic reagents and the surrounding unit operations. The selection of appropriate equipment will depend on numerous factors such as the position of the solvent process in the overall flowsheet, the complexity of the aqueous solutions, likely deviations from normal conditions, solvent sensitivity, solvent cost, etc. Illustrated below is a generic block diagram of a solvent extraction process with some of the peripherals that may be necessary for smooth operation of the plant. Certain of the peripheral units are discussed in some detail in the following sections. While the contact equipment is not dealt with *per se*, details of selected issues within each of the extraction, scrub and strip circuits are also addressed.

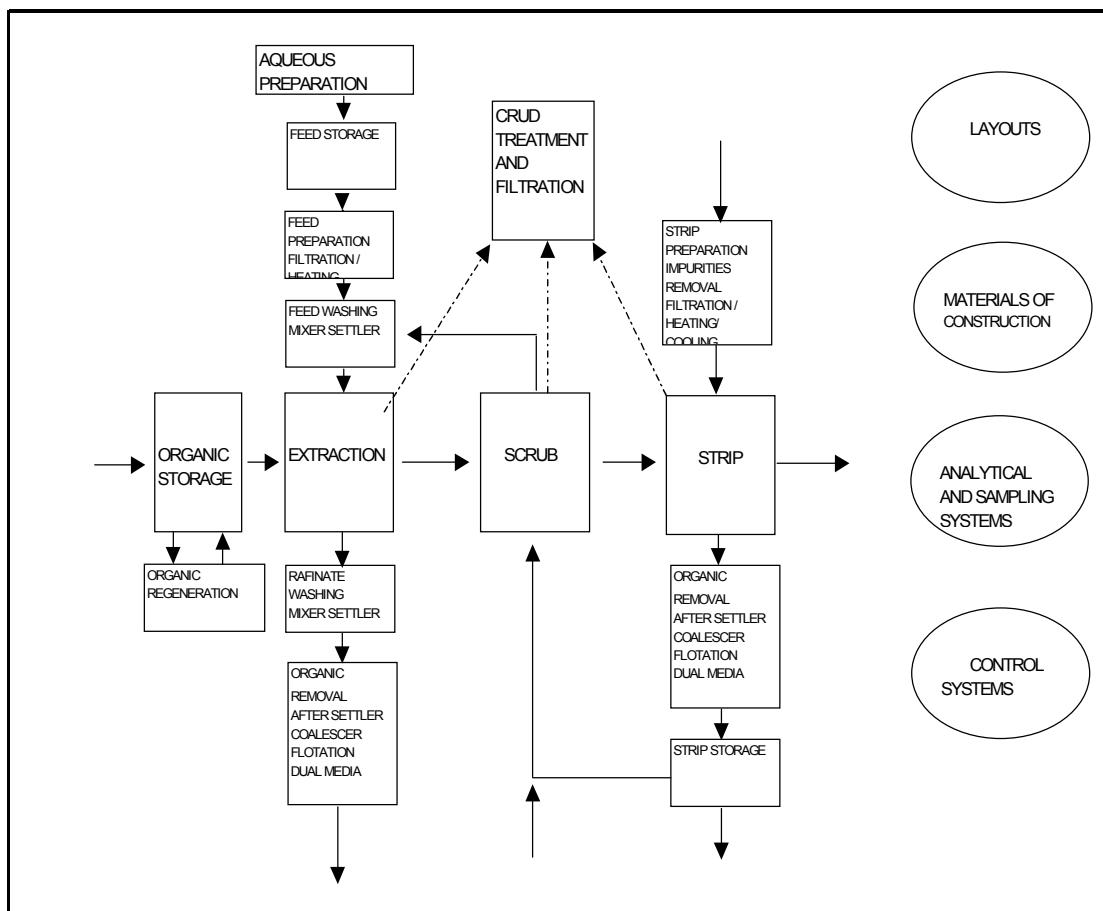

Figure 1. Typical solvent extraction circuit.

During the design of the process the risk associated with including a solvent extraction step in the flowsheet should be evaluated and quantified. The following factors should be considered in the evaluation.

- *Position of the solvent extraction plant in the process flowsheet:* - There are a number of issues to be considered. Firstly, the type of aqueous solution to be contacted with the solvents, this is discussed in more detail in the following point. Secondly, the likelihood of contamination to or from other solvent extraction circuits. Processes using more than one solvent in a series of circuits require careful consideration. Thirdly, the requirement to protect other unit operations linked with the solvent extraction circuit particularly with regard to organic contamination.

- *Exposure of the solvent to undesirable components:* - The more complex the aqueous feed to a solvent extraction circuit the greater the potential risk. The so-called direct solvent extraction circuits result in high exposure while circuits treating refined (relatively pure) process streams present relatively lower exposure. This is especially true in the case where the aqueous solution may vary considerably in composition particularly with regard to trace elements. A refined process stream having a well-defined composition presents far less risk.
- *Resilience of the solvent:* - The ranges of available solvents have quite different resistance characteristics to similar conditions and as such may have very different life expectancies. Understand whether solvent replacement will be to make up physical losses or to replace degraded material.
- *Cost of the solvent:* - Prices range by orders of magnitude, the organic inventory may represent a substantial portion of the plant capital, and replacement, a significant portion of operation.

The following example demonstrates two applications at opposite ends of the spectrum. Risk factors are on a scale of 1 to 5.

*Table 1. Risk ratings of two hypothetical solvent extraction plants.*

	<b>Case 1</b>	Risk	<b>Case 2</b>	Risk
Aqueous feed composition	Complex solution direct from a leach circuit	4	Refined solution containing well defined components	2
Downstream unit operations	Raffinate to second SX circuit in series. EW on strip circuit	5	Raffinate to effluent. Precipitation on strip circuit	2
Stability of solvent	Organic molecules susceptible to oxidation and poisoning by trace elements	4	Stable non oxidizing solvent composition easily regenerated	1
Cost of solvent	High cost, low availability solvent	4	Low cost solvent	1
Skill of potential operators and analytical staff	Poor skill, long term training required	5	Skilled staff from similar type operation	2
<b>Overall Risk</b>	<b>Very High</b>	<b>22/25</b>	<b>Low</b>	<b>8/25</b>

The numbers assigned to the above example are notional, however they demonstrate how a circuit may be evaluated in terms of the requirement for ancillary, or protective equipment. The cost of ancillary plant for case 1 may be similar to the cost of the contact equipment itself while that in case 2 may be only a small portion of the overall capital cost. Detailed understanding of the circuit requirements and realistic assumptions of operating conditions will minimize the need for retrofits and loss of production.

## **SOLVENT EXTRACTION PLANT FEED LIQUOR**

The feed solution to the solvent extraction (SX) plant must be compatible with the solvents and suitable for the selected equipment. This requires that potential solvent poisons, scaling compounds and solids be reduced to levels such that continuous, long-term operation of the plant is achieved. Removal of poisons and scale forming components will require suitable specialized processes. While it is beyond the scope of this paper to discuss such operations design of the SX circuit should make provision for "slippage" from such circuits. This may

involve developing a suitable operating strategy for such an event or provision of sufficient feed storage capacity to isolate the SX plant until the excursion has been rectified. Removal of solids requires some form of filtration system. Suitable filtration capacity for the unsteady state condition should be provided for. Designing to average expected solids loading may result in substantial plant downtime from crud formation because of solids breakthrough to the SX circuit.

## **CONTROL SYSTEMS – FLOW AND INTERFACE LEVEL**

Flow measurement and control within the solvent extraction circuit is critical to maintaining a stable and efficient operation. All instruments should be such that they may be removed for inspection and cleaning with the plant operational. The type of instrument should also be carefully reviewed in terms of suitability to the liquor being measured and constituents (e.g., dissolved solids, suspended solids, organics) that may be present in such liquors. Control valves should provide very smooth changes in flow, thus minimizing the likelihood of setting up cyclical patterns. As most solvent extraction applications rely on either gravity or inefficient pump mixers for liquor transfer, reduction in line size for flow measurement and control valves must be carefully reviewed. Cost savings realized by reducing valve sizes may be very attractive, however, they may cause long-term problems for the operator.

Interface level control in settlers may be affected in a number of ways. While the weir type system is most commonly utilized a level control loop acting on the aqueous discharge from the settler may also vary the interface. The interface is measured by float type instrument. The preferred method of operation will depend on the process as each system has both advantages and disadvantages. The factors governing the choice of level control should include not only steady state operation but how the system will react dynamically and under shutdown conditions. Overflow systems do not normally seal completely, and as a result, settler levels may change under reduced or zero flow conditions. The consequence of a settler level dropping may be severe as the separation of organic and aqueous may be lost and organic may be drawn into the aqueous system. The ability to 'freeze a circuit' on shutting down has very significant advantages. The ability to see an interface may be useful as a 'manual check' of instrumentation measurements. Sight glasses are obviously the most simple and efficient way to check an interface and should be considered where practical. They should also be accessible for in-situ cleaning. Automatic level control may be advantageous particularly in the situation where minimizing organic inventory is critical based on the high cost of the extractant. Once the method of level control has been selected, the task of engineering a fail-safe system needs considerable attention. Redundant valves, instruments and storage tanks should be allocated to ensure that slugs of organic are not lost from the system.

## **MEASUREMENT OF PROCESS DATA**

As temperatures and pressures in SX systems are typically benign, measurement of process data is relatively simple. However, this is complicated by the fact that instruments need to be resistant and may even need to operate in both aqueous and organic media. The equipment must be both robust and located in a suitable position for the required duty. As the processes are atmospheric, care should be taken to ensure that instruments can be withdrawn from tanks during operation for calibration and maintenance purposes.

## **MATERIALS OF CONSTRUCTION**

While this is an area that normally gets significant attention during the design of the plant, the materials of construction are frequently subject to change when the cost containment phase of a project arrives. Experience has demonstrated that compromising on materials of construction particularly in terms of settlers seldom pays off. Substitution of steels, fiberglass and polyconcrete with cheaper plastic materials may reduce the life expectancy of the plant to unacceptable levels. The effects of solvents on rubbers, plastics and the glues used to hold them together may not be adequately demonstrated in piloting trials! Prudent design will allow for some mechanical type cleaning of all surfaces in the plant.

## **CRUD HANDLING SYSTEMS**

From the outset, the crud handling system should be considered an integral part of a solvent extraction circuit, having equal importance to the contact equipment. Depending on the anticipated severity of the crud problem the system may be designed to operate continuously or in a batch wise fashion. As the formation of crud may occur rapidly and extensively the system should have sufficient capacity to store significant quantities of crud which may then be treated at a reasonable rate. Filtration systems should be sized conservatively providing for the poorest fluxes, as the types of crud formed may vary during the course of operation. Removal of crud from settlers may be achieved by a number of methods. In most cases, access to the settler, by the operator, is necessary to identify the location of the crud and in some instances physically remove the crud with a 'vacuum cleaner' type system.

The treatment system should include sufficient tankage to perform the necessary steps for separation of the crud from the organic and aqueous phases. This normally includes 'washing in diluent' followed by settling and filtration through an absorbent clay. There may be special requirements for acid treatment, etc.

## **TANKAGE AND STORAGE CAPACITY**

Solvent extraction circuits are normally coupled to a number of other unit operations that may operate quite independently of the circuit. Volumetric balance around the circuit may only be achieved by the inclusion of significant storage buffer around the plant. Dynamic scenarios should be considered when specifying storage capacity. The storage facilities should not be designed to accommodate two opposing requirements, that of the solvent extraction plant and that of the down/upstream unit operation. Generally, solvent extraction plants respond poorly to stop start situations and may take considerable time to settle down to steady state. Operating errors are far more likely to occur during start-up or shutdown of the plant. Adequate storage will in many cases provide the necessary buffer to prevent having to go through frequent start-up or shutdowns.

Design of tankage around a solvent extraction circuit should allow for the possibility of both aqueous, organic or both ending up in the vessel. Materials of vessels should be suitable for all liquors in the circuit and tanks should be designed in such a way that operators can easily determine the quantities of each phase in a particular tank. Pump discharge arrangements should be carefully designed to facilitate decanting of either phase from any tank without affecting the operation. While storage tanks should not be expected to perform the duties of after settlers, suitable design of feed systems may assist in facilitating significant phase separation in the vessel by minimizing the amount of agitation that occurs within the vessel.

## **ORGANIC RECOVERY FROM AQUEOUS AND STRIP LIQUORS**

The system of organic removal should include stages that remove organic within the SX circuit (such as a pH adjustment step) followed by recovery of 'bulk' organic (for upset conditions) followed by recovery of normal arisings from steady state operation. The equipment for example would include a mixer settler for pH adjustment, followed by an after settler to recover slugs of material, followed by coalescers, dual media filters and carbon columns. Suitable instrumentation should be included on the final settler or after settler to warn operators of organic in the aqueous stream. The plant should also be designed to operate organic continuous in the final stages (of extraction or stripping) to minimize organic entrainments in the aqueous stream. An organic wash stage in which aqueous is contacted only with diluent to reduce losses of extractant or to clean up the aqueous feed stream may be necessary.

Organic entrainments tend to be consistently high during a plant startup and having the facility to put the plant onto recycle may be an effective method of controlling entrainments until the plant 'settles down'. When the organic removal requirements have been specified, the media usage in the various units may be predicted. Time should be taken to design user friendly systems for change-out of media and in the case of high consumption there may be justification to look at regeneration methods for carbon and cleaning of media.

## **PIPING SYSTEMS**

Piping systems in solvent extraction plants need to be carefully designed as in many instances, the process relies on gravity or inefficient pump mixers to transport the liquors. The process engineer responsible for the design of the plant must be actively involved in the piping design and plant layout. Plant layouts should obviously allow for efficient operation of the equipment. Compressing of plant footprints to save on piping costs is a practice that should be avoided. Pipe sizing should be done on the basis that there will be some degree of scale formation on the surfaces – scale even adheres to plastic pipes. Restrictions in piping runs should be kept to a minimum and reduction in line diameters for installation of valves and instrumentation should be avoided.

## **ORGANIC REGENERATION**

A side stream that allows for treatment of the solvent externally to the main circuit may be necessary. This for example may include a high concentration acid strip to remove components that are not stripped under the normal stripping conditions. In the assessment of whether such a circuit is necessary prediction of likely excursions from steady state in upstream processes will be important

Where there are two or more solvent extraction processes in series, solvent, slipped from the primary circuit may need to be recovered from the secondary circuit in a side stream. This should be considered a last resort option, as fail-safe mechanisms should be included in the primary circuit to prevent the occurrence of organic slippage.

## **NEUTRALIZING OR pH ADJUSTMENT REAGENT ADDITION**

The mechanism of introducing the base to the process liquors is important and will result in operational problems if not properly designed. There are many options available ranging from injection of an aqueous solution of the base into the primary mixers to pre-equilibration of a pure organic stream by ammonia gas. Individual options are beyond the scope of this paper, however, in general terms the following should not be overlooked.

The use of strong and concentrated bases may result in the formation of an emulsion with certain extractants (notably Cyanex 272). Strong bases may also cause precipitation of metal species in localized high pH regions that may lead to the formation of cruds. Therefore, consider the strength of the reagent used and the mixing available (which tends to be mild and kept to a minimum) to introduce the material to the process. The neutralizing reagent may be added to the process based on the pH of the aqueous phase. In organic continuous systems it may not be possible to measure the pH in the mixer requiring some phase separation to take place before a measurement may be obtained. The location of the pH instrument is important, as lag time in the control loop should be minimized.

## SAMPLING AND ANALYTICAL

Like other hydrometallurgical processes, the successful operation of a solvent extraction plant is dependant on accurate and efficient analyses of representative samples. The multi component systems in solvent extraction plants make the sampling and analysis more challenging. Detailed design of plants should include allocation of the required sample points to effectively achieve the above. In certain configurations the aqueous phase may not be accessible to operators, for example when level control valves are used for interface control, in which case sample points in transfer lines may be necessary. Multiple sample points in mixer tanks and storage tanks should also be considered, as mixtures may not be homogeneous.

The analytical requirements will depend on the selected process and particularly the requirement to monitor organic composition, quality and entrainment values. Typically, the aqueous analytical requirements will fit in with the remainder of the process. In general terms the determination of entrainments and monitoring of solvent condition and quality, is non-trivial and may require special techniques or assistance from external organizations. The sample composition may also be time dependant requiring immediate attention. The requirements to accomplish the above should be quantified as early as possible and provision made for the associated equipment and training of relevant staff prior to commissioning of the circuit.

## CONCLUSIONS

Solvent extraction circuits are a combination of mass transfer equipment and appropriate process plant to maintain the specified conditions in the feed, discharge and within the circuit. Provision of a successful plant requires that the entire circuit be considered throughout flowsheet development, plant design and construction. Operators/owners and designers must avoid the trap of committing the majority of the resources to the mass transfer problems at the expense of potentially fatal 'side issues'. A balanced approach will ensure that the peripheral equipment services the solvent extraction equipment as required.

## ACKNOWLEDGEMENTS

## ORGANIC RECOVERY WITH COMATRIX™ FILTRATION

William A. Greene

SpinTek Filtration, LLC

This paper outlines a new method of coalescing and filtering electrolyte and raffinate streams that improves the performance and enhances the ability to recover the organic phase. Different methods of floatation have been tried in the last few years as a roughing coalescer to a media filter and this paper will present a new concept in treating electrolyte or raffinate. A 400 m<sup>3</sup>/h system has been successfully operating in Australia for over three years, with excellent results demonstrating the viability of the technology.

### INTRODUCTION

Most copper solvent-extraction (SX) plants today operate with a filter in the electrolyte stream to act as a coalescer for the small amounts of organic phase left entrained after settling and to filter out suspended solids. This practice has been adequate, but the loss of organic phase through the backwash step and the large quantities of waste generated during this backwash process have been the topic of studies to reduce the operating costs. Some smaller SX-EW plants do not have the funds to install these filters and are attempting to reduce the organic content by means of a flotation column alone with the capability to retrofit a filter at a later date should it be necessary.

We developed a two-stage coalescing filter, the CoMatrix™, to address these issues. This unit consists of a Matrix™ coalescing plate section in the upper zone of a pressure tank followed by a deep dual media bed. The combination allows operation at flow rates of 61 m<sup>3</sup>/h/m<sup>2</sup> (25 gpm/ft<sup>2</sup>), which is five times the flow rate of conventional filters, with a capital cost usually half that of conventional filters. The backwash volume is about one third that of conventional filters, with improved performance. The coalesced organic is recovered in the upper zone as a clean stream that is not tied up in the backwash waste tank requiring treatment for recovery.

### COMATRIX TOWER DESIGN

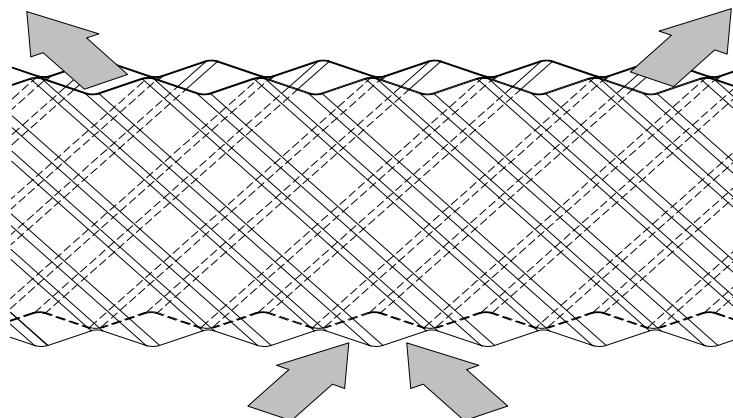

The conventional electrolyte filter, SX filter, is designed to operate at 12.3 m<sup>3</sup>/h/m<sup>2</sup> (5 gpm/ft<sup>2</sup>) in a pressure vessel containing a media bed. This bed consists of two active layers, a 300 mm (12") layer of fine anthracite above a 300 mm (24") bed of fine garnet.

The anthracite is crushed coal that has irregular surfaces to perform the coalescing portion of the filtration. The fine garnet is more uniform and performs the conventional filtration similar to a sand filter and removes suspended solids like fine clays. The organic phase in the feed stream coats on the surfaces of the anthracite and some of the organic is coalesced

in large enough droplets to rise to the upper zone of the tank. This bed becomes saturated in about 12 h of operation when exposed to normal levels of organic entrainment, requiring a backwash cleaning cycle to remove the material in preparation for the next cycle. This is a time-consuming process and a few steps are necessary to adequately clean the media. These are to lower the liquid level in the tank to a level just above the media and introduce air at  $55 \text{ m}^3/\text{h/m}^2$  ( $3 \text{ scfm/ft}^2$ ) for 10 minutes to completely scour and loosen the particles from the media. The entire bed is then backwashed at  $24\text{-}29 \text{ m}^3/\text{h/m}^2$  ( $10\text{-}12 \text{ gpm/ft}^2$ ) for 5-7 minutes to flush the particles from the bed and reclassify the media back into the two zones of heavier garnet on the bottom and lighter anthracite on top. There are many variations to this basic operation, depending upon each plant's operational preferences. Some of these consist of displacing the entire volume of the tank to recover the electrolyte and the use of water for backwashing. The entire sequence usually takes about 30 minutes.

The CoMatrix Tower is quite different from the SX filters, having a packed section 2.1 m (7') deep in the upper zone to perform the coalescing of usually 70% of the inlet organic. The openings in the Matrix plates are 12 mm (1/2") to reduce the possibility of fouling from crud. Just below the packing and before the anthracite/garnet media is a "quiet zone". This quiet zone allows organic that has coalesced but passed through the Matrix plates to rise back up through the plates and into the upper head of the tank. The CoMatrix automatically senses the presence of coalesced organic in the vessel head and discharges it from the filter for recovery.

The Matrix plates are made of PVC or polyethylene that is hydrophobic and acts as an excellent media for organic coalescing. The design of the plates is illustrated in Figure 1 and consists of corrugated plates at opposing angles that allow liquid to easily flow from one channel to the next, and do not limit the effective area of the tank as would be the case with conventional parallel plates. The arrows show that the direction of flow of the organic coalesced is opposite the flow of the main influent stream. These matrix plates are welded together, allowing for easy installation and removal, and are strong enough for a person to stand on during maintenance.

*Figure 1. Matrix plate design.*

The practice of coalescing liquids on plates has been used for some time and relies on supplying an increased surface area of a material compatible with the liquid being coalesced that has corrugations. These create low turbulence areas in the upper area of the corrugation for the lighter liquid to collect. These droplets have only a little vertical distance to rise to reach this area rather than an open tank. This area allows other droplets to combine with each other to form larger droplets that will then rise to the upper zone without the worry of being carried downward with the flow of electrolyte. This phenomenon is illustrated in Figure 2. The added benefit is that any organic that is carried down to the media bed, through the

plates, has already been partially coalesced which greatly reduces the load on the anthracite coalescing section of the media bed.

This organic can then combine with other organic droplets on the top of the anthracite bed and will rise back up to the plate zone and through the plates to the upper section of the tank. The result is a large reduction in the loading on the anthracite, allowing for an increased operating velocity. We should point out that velocity is very important to proper operation of the CoMatrix and that operation at lower flow rates does not improve performance. In our initial testing, we found that when we increased the flow rate from  $24 \text{ m}^3/\text{h/m}^2$  to  $61 \text{ m}^3/\text{h/m}^2$  ( $10 \text{ gpm/ft}^2$  to  $25 \text{ gpm/ft}^2$ ), we actually recovered more organic and had little effect on the loading of the media bed below.

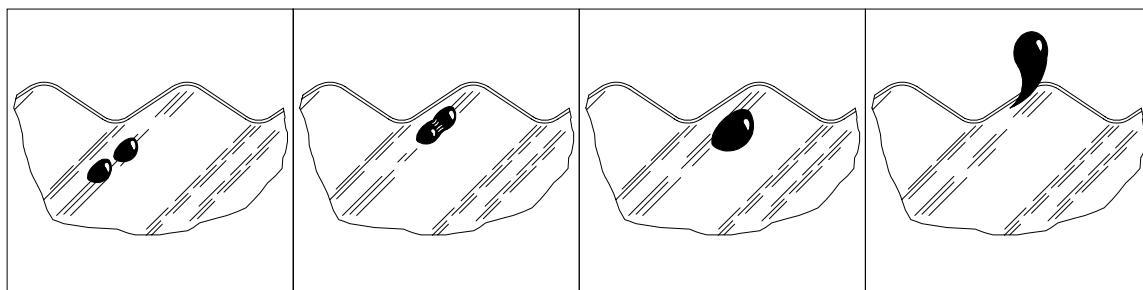

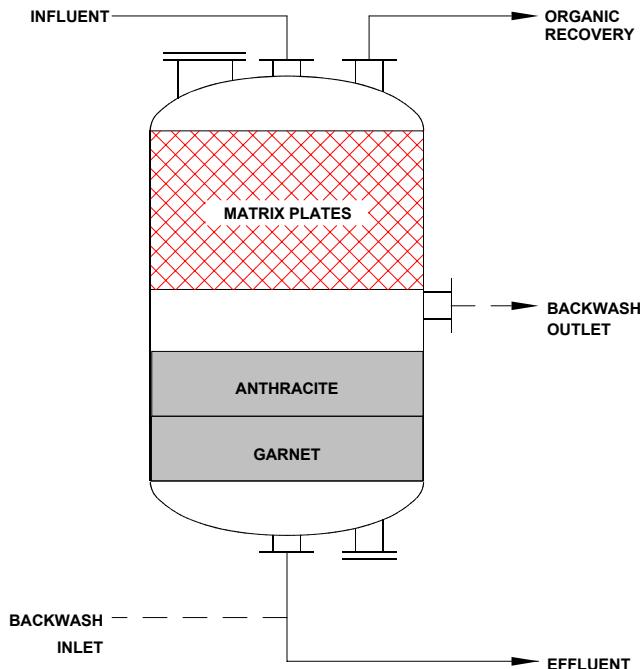

Figure 2. Coalescing droplets on Matrix plate surface.

The material of which the Matrix plates are made is crucial to performance. The PVC or polyethylene plates are hydrophobic upon which the non-aqueous organic adheres.

An important factor in coalescing is the micron size of the droplet. When using plates or air flotation, the size is more critical than when using an anthracite bed since the contact through a media bed offers far more surface area and more potential liquid contact. Generally a droplet size ranging from 10 micron and larger coalesces well in Matrix plates with 100% efficiency obtained at 30  $\mu\text{m}$  sizes and larger. When the size drops to 10  $\mu\text{m}$ , the efficiency is lower.

The media bed consists of anthracite as in the SX filters except that the level is increased to 600 mm (24") from 300 mm (12") for the anthracite. The garnet remains the same since the amount of suspended solids is not the controlling factor in a filtering cycle. The depth between the anthracite bed and the plates is high enough to allow for the air scour/backwash cleaning cycle to take place below the plates. A backwash distributor is installed below the plate section with laterals for proper collection of the backwash waste and allows the bed to expand sufficiently to remove the loosened particles. A cross section of the CoMatrix is shown in Figure 3.

The plates are not disturbed during the backwash step as they operate better with the organic coating left in place. The performance of the plates improves during the first cycle when the CoMatrix is initially placed into service. This is due to an organic coating being formed on the Matrix plates. New entrained organic will touch this organic coating on the plates and themselves coalesce. When sufficient organic droplet size is obtained on the plates, droplets will break free from the plates and rise to the top of the vessel.

*Figure 3. CoMatrix Tower design.*

### COMATRIX TOWER TESTING

Testing was performed at a few plants in Arizona that operated existing SX filters and provided excellent models of well-run plants with organic levels normally around 30 ppm. Our test unit was 300 mm (12") in diameter and was installed parallel to the existing SX filters. The test unit has an area of 0.074 m<sup>2</sup> (0.8 ft<sup>2</sup>) and operates at 76 l/m (20 gpm). The feed was taken from the same pumps that supplied the SX filters and the performance was equal to the SX filters except that we were able to recover a pressurized stream of clean organic from the top of the CoMatrix tower as a result of the plate performance. We consistently obtained non-detectable organic (centrifuge test) from the lower portion of the media bed and we monitored the organic level at points within the tank to verify the recovery amounts in the Matrix plate zone.

Subsequent cycling of the CoMatrix demonstrated that the effluent from the filter maintained non-detectable organic levels (centrifuge test) and 1-2 ppm by Freon extraction.

The CoMatrix's operating cycle was 8 hours compared to 12 hours for the SX filter but the CoMatrix processed 333 % more electrolyte over the time period. Figure 4 shows the performance cycle for a typical electrolyte stream with 30 ppm (30 mg/l) organic. The upper Matrix plate section recovered 20 ppm or 66% of the inlet organic and the anthracite/garnet bed removed the remaining 10 ppm. Subsequent cycles obtained the same performance. An important factor was the reduction in backwash volume when using the CoMatrix.

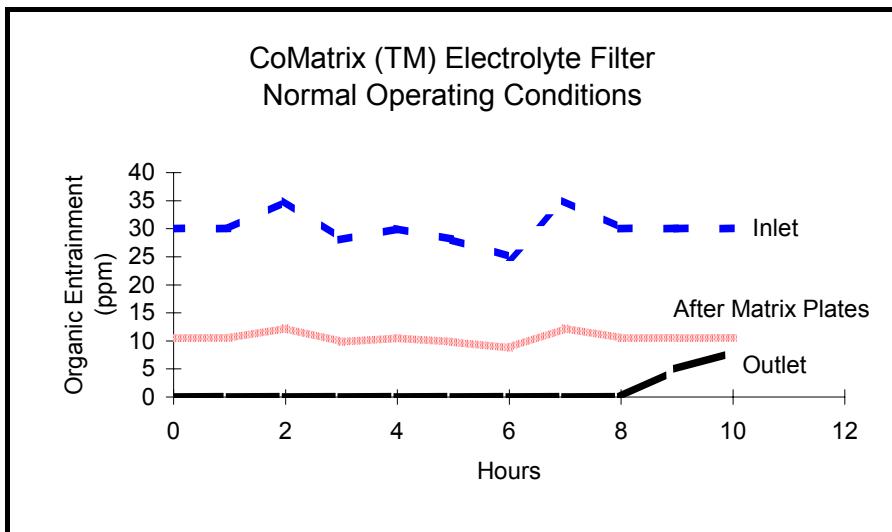

Figure 4. CoMatrix performance.

In an attempt to simulate an upset condition, we operated the CoMatrix from the effluent weir of the E1 settler and fed the unit with an average of 800 ppm organic. Figure 5 illustrates the performance when operated at these high levels. We were able to achieve the same non-detectable level (centrifuge test) of organic in the effluent of the unit and recovered about 75% of the organic in the upper Matrix plate zone. The service cycle in this case was 6 h, compared to 8 h at lower entrained organic levels

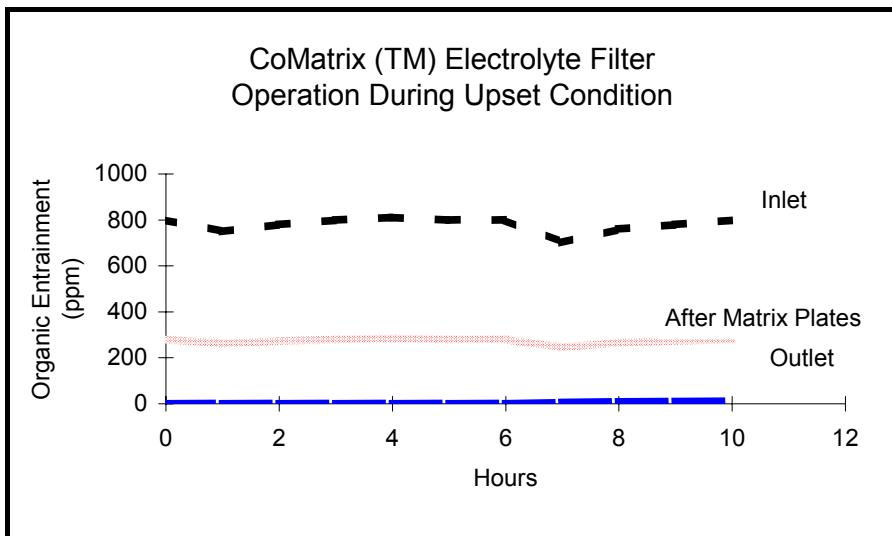

Figure 5. CoMatrix Tower performance.

## **BACKWASH COMPARISON**

Using the service cycle referenced in Figure 5 we can see that the CoMatrix tower will process 333% more electrolyte than a conventional SX filter. We must also compare the amount of backwash required to clean media beds. In actual operation, a 636 m<sup>3</sup>/h (2,800 gpm) electrolyte flow requires five 3.65 m (12') diameter filters while only a single 3.65 m (12') CoMatrix is required.

Using this comparison, in a one-year period, the backwash volume is 156,000 m<sup>3</sup> (41.2M gal) for the SX filter and 47,000 m<sup>3</sup> (12.4M gal) for the CoMatrix tower, or a savings of 70%. In addition, there is 70% less backwash waste to process to recover the organic.

Since the CoMatrix Tower recovers approximately 2/3 of the organic in a concentrated stream, less recovery time is lost for the retrieval of the organic. On a 636 m<sup>3</sup>/h (2800 gpm) electrolyte stream with 30 ppm of organic present, this represents 113 m<sup>3</sup> (30,000 gallons) each year of recovered organic that is not recovered as part of the backwash water. The remaining 38 m<sup>3</sup> (10,000 gallons) of organic recovered is part of the backwash water similar to conventional SX filters.

## **FULL-SCALE OPERATION**

We have installed several small CoMatrix filters on pilot-plant streams with the same results. In addition, a full scale 400 m<sup>3</sup>/h CoMatrix system has been in operation at an Australian copper mine with excellent results. In over three years of operation, the filter consistently produces an electrolyte stream containing 1-2 ppm (Freon extraction) entrained organic phase.

The performance of this large-scale CoMatrix will be the subject of a newly published report.

## **CONCLUSIONS**

We have demonstrated the CoMatrix through pilot studies and the operation of a full-scale 400 m<sup>3</sup>/h (1,760 gpm) unit. The benefits of this system are:

- Coalesces up to 70% of the entrained organic phase prior to the media bed;
- Allows for clean recovery of the coalesced organic phase;
- Improves the performance of the media bed;
- Flow rate of 61 m<sup>3</sup>/h (25 gpm/ft<sup>2</sup>) reduces organic less than 2 mg/l;
- Reduces the backwash flow rate to 20% that of SX filters;
- Reduces the backwash volume by 70% compared to SX filters;
- Reduces the cost of equipment significantly;
- Matrix plates alone are comparable to flotation columns without the need for air introduction that can emulsify the entrained organic phase.

## METAL EXTRACTION PRODUCTS

**The Market Leading supplier of solvent extraction reagents for copper:** AVECIA's Acorga Metal Extraction Products business specializes in the supply of metal extractants to the mining industry. Acorga products have been used successfully in solvent extraction (SX) for the recovery of copper for over 20 years. We discovered and patented nonyl salicylaldoxime extractants for the recovery of copper over 20 years ago and this is now the basis of virtually all copper SX products in use around the world. In addition, Acorga introduced the first successful modified products to the industry and maintain our position as the industry's experts on reagent modification.

## METAL EXTRACTION PRODUCTS

### Contact Us!

If you're beginning or considering a solvent extraction operation, call us or visit our website at [www.acorga.com](http://www.acorga.com). Our Acorga extractants are of uncompromising quality and our technical expertise can be an invaluable asset to any operation. Our experienced scientists are located in every major copper mining center in the world and their wealth of experience is available to assist customers in maximizing production and reducing costs.

## METAL EXTRACTION PRODUCTS

### PRODUCTS

Solvent extraction (SX) is a chemical purification and concentration operation with wide use for production of pure copper metal. Acorga solvent extraction reagents provide a wide range of physical and chemical properties.

**Those "state-of-the-art" technical features of Acorga® reagents include:**

- **highest available Cu:Fe selectivity**
- **excellent hydrolytic stability**
- **excellent kinetics, even when treating solutions at temperatures as low as 3 degrees centigrade**
- **excellent extract efficiency over a wide pH range**
- **highest Cu recovery at low pH**
- **high recovery from concentrated feeds**
- **proven results against solids providing superior protection against crud.**

### Product Range

Product Data Sheets and MSDSs are available from any of our offices or on-line at [www.acorga.com](http://www.acorga.com).

## METAL EXTRACTION PRODUCTS

### Technical Service

At Avecia Metal Extraction Products, we have one very specific but far-reaching goal - to maximize the recovery of metal values at the lowest possible cost. It's a goal that directly benefits our customers, some of whom we've worked with to achieve flow rates of 120-130% of plant design. Stretching capacity like that can only mean a significantly better return on their mine investments.

To achieve results like this requires no small commitment from a reagents supplier. That's why we have chemical engineers, metallurgists, and chemists located in every major copper mining center in the world to provide our customers with all the technical support they need. We stay on-site with them for as long as it takes to help them use the reagents and equipment in a way that maximizes productivity and profitability.

Our technical support often begins even before a customer has broken ground for their solvent extraction facility. In fact, many of our relationships start at the feasibility studies stage, working with the engineering firms that design our customers' plants.

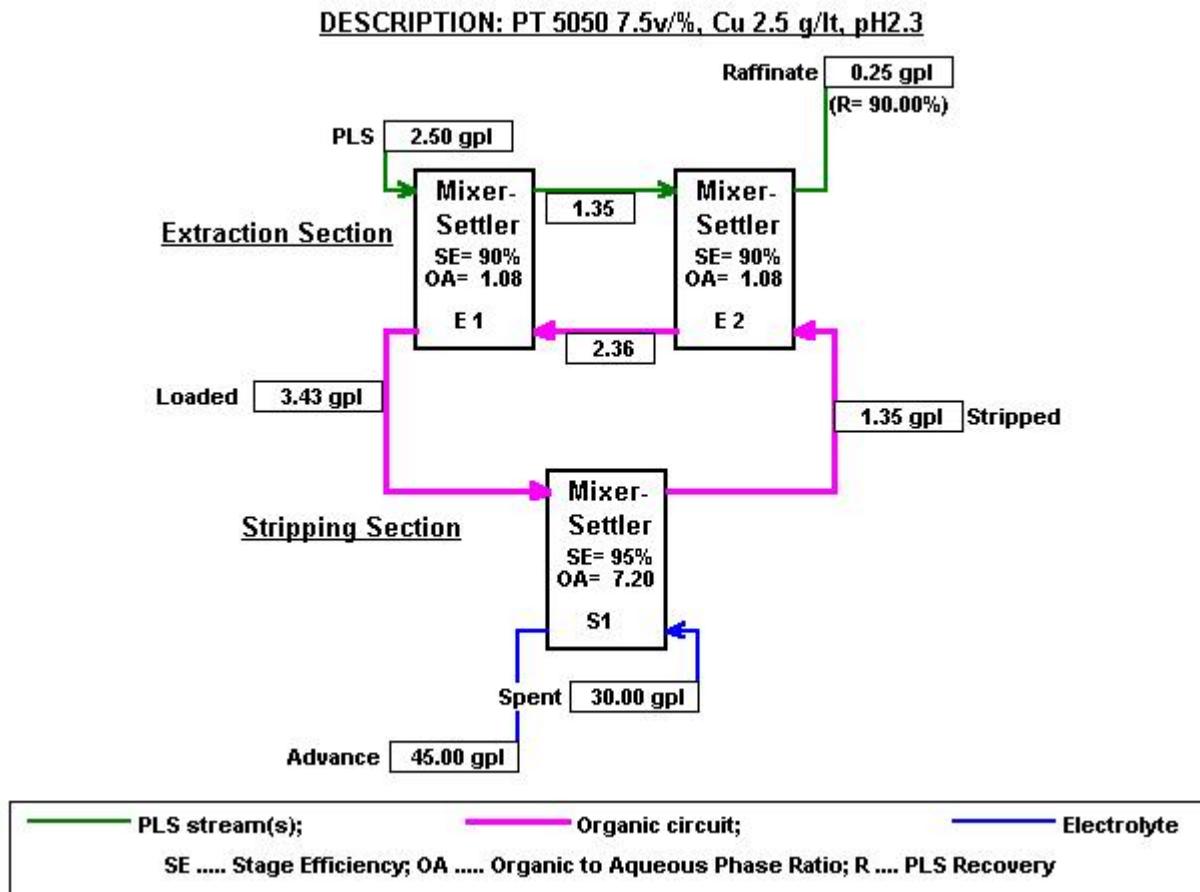

#### Minchem and MEUM computer process modeling:

When it comes to process optimization, we wrote the program. Using computer software programs for process optimization is nothing new to many industries. And it's not new to SX/EW. Thanks to the international scope of the computing and engineering expertise within Avecia, there's MINCHEM - the solvent extraction industry's first, and still most sophisticated, software program. MINCHEM is more than just a flowsheet/design package. It's Windows based system that allows Avecia to design solvent extraction circuits virtually on demand. With minimum information from mining companies or their engineering firms, we are able to evaluate circuit layouts, flow options, recovery options, reagent inventory, and make-up requirements. The end result - the achievement of optimum parameters to maximize plant performance.

What's more, MINCHEM's invaluable capability is available to customers, on their site, at no charge. The MINCHEM End User Module (MEUM), a streamlined version of the software, is user-friendly and enables customers to manipulate data as rapidly as binary file data exchange, via the Internet. For added customer value, the package includes expert system technology and data base and plant control capability.

MINCHEM/MEUM software, the only reagent supplier proprietary program in the industry, and only available from Avezia, is one more example of the unrivaled service capability the metallurgical Industry receives from the SX/EW leaders.

## METAL EXTRACTION PRODUCTS

### Manufacturing and Quality

Acorga products are manufactured at our world-class facility in Mt. Pleasant, Tennessee USA. It is the largest, most modern copper solvent extraction reagent plant in the world. Our patented manufacturing process insures consistently high-quality products, unmatched in the industry. In addition, our investment in and commitment to Safety, Health and the Environment insures our position as we enter the 21<sup>st</sup> century. As an example, our Mt. Pleasant plant recently celebrated 4 consecutive years of operation without a lost time accident.

Location:	Mount Pleasant, Tennessee, USA
Number of employees :	170
Main Activities:	'Acorga' metal extractants; 'PTZ' Stabilizer for acrylics 'Cosmocil' ; 'Almacryl' toner resin; Phosphines; 'Baquacil'
Contact:	PO Box 152, Mt. Joy Road, Mt. Pleasant, TN 38474 Phone: (615) 379 3257 Fax: (615) 379 7124

### **Never a quality rejection and we fully intend to keep it that way.**

Many factors contribute to a company's ability to maintain a leadership position throughout an industry's existence. Not the least of them is consistent product quality. And where some companies might define consistent quality as having "minimum" rejections, we define it as having zero. The Avecia standard for quality has become the industry's benchmark. How have we done it? And how will we continue to do it in the years to come? Quite simply, our manufacturing systems are fundamentally better than any other supplier in the SX industry.

Our unique, patented technology provides us with a "window" in which virtually all of the product we make is of exceptional quality. And our state-of-the-art process controls keep it that way. In-process and end-process quality control procedures simply don't allow us to make a bad batch. In all our years of supplying SX reagents to the copper mining industry, we've never had a quality rejection. Can any of our competitors make that claim? Ask them. Are we proud of that fact? You bet we are.

How important is consistent reagent supply in the SX/EW industry? At Avecia, our goal is to make sure it's something our customers can take for granted. We achieve this by being stationed in every major copper mining country in the world, and by applying decades of experience in cost-effectively servicing world markets.

In addition, our customer service staff is set up with in-home computers so they can respond to customers' needs, even if weather or some other condition prevents them from reporting to work. In both the U.S. and Chile, we also have a 24-hour emergency response system in place.

Also, where needed, we establish local warehouses to ensure uninterrupted supply to customers in remote locations.

When it comes to transportation of product, as part of a world class specialty chemical company, we are well versed in the world's regulatory requirements. Accordingly, we not only meet, but generally exceed those requirements. Avecia is also a member of SOCMA, a Responsible Care® partner association.

With our remote inventory Telemetering, we're there even when we are not.

In 1994, we introduced the first, and still the only, telemetering system in the industry to monitor a customer's bulk reagent supply. We know exactly how much is needed and when. Result: product always arrives in plenty of time.

The constant monitoring of bulk reagent levels is the logical "first step" in maintaining constant reagent supply. Avecia customers benefit from automatic (and accurate) 24-hour telemetric monitoring of their site's inventory - information which is analyzed and acted upon by the Avecia customer service support team. Instantaneously. The net result: reagent inventories become one less thing to worry about in an already demanding industry.

**In April 1999, MEP Business of Avecia was granted the prestigious Queen's Award for Environmental Achievement** for the development of a unique patented chemical process for producing Acorga metal extraction reagents. The award recognizes MEP's environmental improvements over older reagent manufacturing processes.

This unique process, developed by MEP's Research and Process Development staff in Manchester, UK, has enabled MEP to reduce effluent components by up to 85 percent. It is also significant that the composition of the effluent from the new process is essentially benign inorganic salts.

Development of the new process was key to justifying investment in MEP's world-scale production facility at Mount Pleasant, Tennessee, USA, where the process technology has been in commercial practice since commissioning of the Acorga plant in late 1994. The efficient and environmentally superior process reduces production costs (which we have passed along to our customers) and ensures our long-term viability, as our environmental compliance is fully assured.

## METAL EXTRACTION PRODUCTS

### Research and Innovation

Most of the improvements in copper solvent extraction reagents over the past 20 years have come out of our Research programs—e.g. 5-nonyl salicylaldoxime (the basis of virtually all copper SX reagents today) and ester-modified reagents.

Research and innovation - two words, one mission. By its very nature, Avecia is a company driven by research and innovation. Our key skill areas include all of the key chemistry disciplines - organic, physical, coordination, analytical - and molecular design. Expertise in these disciplines enables us to continually evolve and improve our copper SX/EW products. And to continue to invent new technologies, such as our low-cost route for oximes.

Additionally, we are constantly augmenting our knowledge base through our linkage with leading edge thinkers at universities pre-eminent in the metals recovery field.

Our Analytical department has been a pioneer in developing techniques for SX solution analysis. Avecia provides the most accurate and responsive analytical services available which is invaluable when your operation is experiencing a problem and days can mean millions of dollars to your bottom line.

# The MCT Redbook

## The MCT Redbook

is an introduction to the chemistry of metals recovery using LIX® reagents

Cognis LIX® Reagents fall into five different chemical classifications:

- **Ketoximes** such as [LIX® 84-I](#)
- **Aldoximes** such as [LIX® 860N-I](#)
- **Beta-Diketones** such as [LIX® 54-100](#)
- **Non- Modified Extractants**, which include [LIX® 984N](#), a 50:50 blend of [LIX® 84-I](#) and [LIX® 860N-I](#).  
Cognis supplies many different mixtures according to each customer's needs.
- **Modified Extractants**, which include [LIX® 622N](#), a blend of [LIX® 860N-I](#) and TDA, and [LIX® 664N](#).

Products manufactured for the MCT by Cognis Ireland Ltd. include:

<a href="#">LIX® 54-100</a>	<a href="#">LIX® 622N</a>
<a href="#">LIX® 664N</a>	<a href="#">LIX® 84-I</a>
<a href="#">LIX® 84-IC</a>	<a href="#">LIX® 860N-I</a>
<a href="#">LIX® 860N-IC</a>	<a href="#">LIX® 973N</a>
<a href="#">LIX® 973N-C</a>	<a href="#">LIX® 984N</a>
<a href="#">LIX® 984N-C</a>	

Cognis Alamine® and Aliquat® Products are manufactured at Cognis Corporation. Alamine® is the trade name for a series of tertiary amines produced with various alcohol raw materials. For example, Alamine® 336 is a tertiary amine chemical produced from C8 – C10 straight chain alcohol.

Products for Solvent Extraction include:

- [Alamine® 300](#) is tri-n-octyl amine.
- [Alamine® 304-1](#) is tri-n-laurylamine.
- [Alamine® 308](#) is tri-iso-octyl amine.
- [Alamine® 336](#) is tri-n-octyl/decyl amine.

**Aliquat®** is the trade name for a series of quaternary amines, made for Alamines. An example is Aliquat® 336.

- [Aliquat® 336](#) is a quaternary ammonium product made by methylation of Alamine 336.

The gold and silver ion exchange reagents include: [AuRIX® 100](#), [LIX® 79](#) and LIX® 7820.

To learn more about products manufactured by Cognis, go to <http://www.cognis-us.com/cognis/default.htm> or call (520) 622-8891

## MCT Redbook

Cognis Corporation  
Mining Chemicals Technology  
Division

Specialist in Applied  
Chemistry

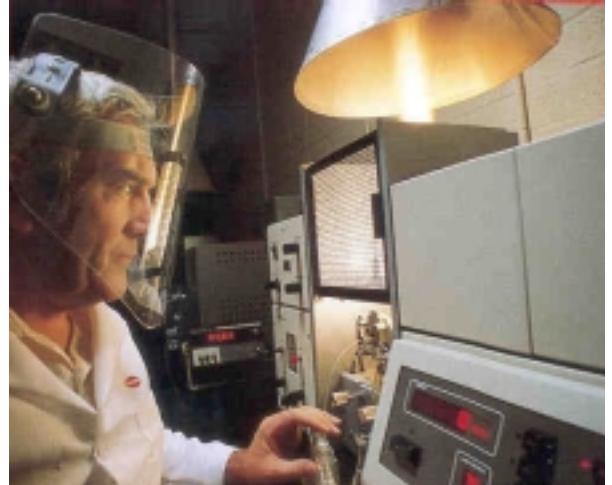

**Cognis.**  
**Meeting the needs of the mining industry,  
worldwide, for more than 40 years.**

Cognis has long been the acknowledged leader in solvent extraction technology. We provide technical support for plant operations, innovative solutions to the challenges of metals recovery and, of course, the best and most effective reagents in the world today. Our products are used on six continents, in more than 30 countries, at over 80 plants...for one very basic reason: they simply work better.

**Product Quality. Customer Service.  
Our highest priorities.**

Cognis products are designed to exhibit specific performance characteristics for specific metallurgical applications. Because we know that plant requirements vary from site to site, we offer more than 25 basic reagents and dozens of derivatives, all of which have a long and impressive track record. We are dedicated to production of the highest quality products because we believe that comprising quality, in the end, means compromising productivity.

That's also why Cognis engineers believe in the highest levels of customer service, and why we remain, continually, "at your service." To answer questions, to analyze plant performance, to help clients solve their unique problems. We work hard to make metals recovery more efficient *and* more profitable, for everyone.

## Introduction

An increasing demand for metals in general, and higher purity metals in particular, decreasing ore grades and more stringent environmental regulations have driven, and will continue to drive, research into finding more effective and efficient methods for processing the ores available to us, and recycling previously used metals. Hydrometallurgy has provided, and will continue to provide, many of the new processes and solvent extraction technology will certainly play an important role in many of these new processes.

Solvent extraction as a simplified technique to purify and recover a metal goes back to at least 1842 when Peligot extracted uranyl nitrate into ethyl ether<sup>1</sup>. The chemical literature has hundreds of references to the use of solvent extraction as a technique in analytical chemistry and a large amount of fundamental knowledge in solvent extraction, particularly in the areas of solution chemistry and organic based extractants, comes from analytical chemistry<sup>2</sup>.

Solvent extraction technology has been applied on a commercial scale to the recovery of uranium, vanadium and molybdenum for about forty years<sup>3</sup> and to copper and nickel for almost thirty years<sup>4</sup>. For this same length of time Cognis Corporation, (formerly General Mills Chemicals, Inc.), has been committed to the development of solvent extraction technology in general, and solvent extraction reagents in particular. This commitment has resulted in the development and successful marketing of the LIX®, Alamine® and Aliquat® Reagents used by numerous, commercially successful metal recovery operations around the world. These reagents are noted for the wide range of conditions in which they operate and for their pollution free flowsheets. It is within the realm of technical feasibility that one day the hydrometallurgist could have an unlimited selection of commercially available chemical reagents at his disposal in order to make efficient and economic separations of virtually all metals in solution.

It is important for the reader to understand that solvent extraction is only one unit process in a series of unit processes needed to win metal from ore. For this reason solvent extraction must be compatible with, and complimentary to, the leaching process

which precedes it and the final metal recovery process which follows (Figure 1). The success of the whole operation then is dependent of the success of each individual unit process.

This booklet is designed to familiarize the reader with some of the basic concepts of solvent extraction technology as well as with the LIX, Alamine and Aliquat Reagents and systems marketed by Cognis Corporation. More detailed information about specific reagents, metals, or process systems is available on request.

# Description of the Solvent Extraction Process

Solvent extraction (SX) is applicable in any instance where it is desirable to selectively remove or extract a species from one solution into another. This can apply either to the removal of a valuable component from contaminants or to the removal of contaminants from the valuable component. The solution originally containing the desired species and the solution into which this species or the contaminants are to be extracted must be immiscible to effect separation.

In metal recovery operations the valuable component is normally a metal ion or a metal ion complex contained in an aqueous solution. This aqueous solution is mixed with an immiscible organic phase containing the active extractant at which time the active extractant transfers the desired component from the aqueous phase into the organic phase. The aqueous / organic mixture, which is called a dispersion, then passes from the mixer to a settler where the phases disengage. The "loaded organic" phase, now containing the extracted metal, is then transferred from the extraction section to the stripping section where the extracted metal is stripped from the organic phase. The "stripped organic" is then recycled back to extraction. In most instances, stripping the extracted species from the loaded organic is accomplished by mixing the loaded organic with an aqueous solution. After the stripping operation final metal recovery takes place from the aqueous solution. The recovery of metal directly from the loaded organic phase is also possible, but, currently not commercially in use<sup>5,6</sup>. Because the solvent extraction process resembles metal extraction with solid ion exchange resins, it is sometimes called liquid ion exchange.

Figure 2 shows a typical counter-current, mixer-settler solvent extraction unit. An individual mixer-settler is known as a stage. In some systems specific problems make it desirable to add one or more organic "wash" or "scrub" stages in order to prevent the transfer of deleterious species from extraction to strip or vice versa.

Solvent extraction as part of an overall metal recovery process has three main objectives:

1. The purification of a metal(s) from unwanted impurities either by extracting the desired metal(s) from the impurities or by extracting the impurities from the desired metal(s).
2. The concentration of metal in order to reduce downstream processing costs.
3. The conversion of the metal values to a form which simplifies eventual recovery.

In any given solvent extraction process one, two or all three objectives may be accomplished.

These objectives can usually be met by choosing the proper reagent and operating under the optimum conditions. A variable number of mixer-settler stages, adjustable flow rates and the ability to use wash stages allows the optimization of operating conditions as well as design flexibility.

## I. EXTRACTABLE METAL SPECIES

If a metal is to be extracted from impurities or vice versa it is important to know what species are present in solution. With respect to metals, the extractable species can be divided into four categories:

1. Metal cations such as  $\text{Cu}^{2+}$ ,  $\text{Ni}^{2+}$ , and  $\text{Co}^{2+}$
2. Complex metal anions, for example  $\text{UO}_2(\text{SO}_4)_3^{4-}$ , and  $\text{Mo}_8\text{O}^{4-}$
3. Complex metal cations such as  $\text{MoO}_2^{2+}$
4. Neutral metal specials like  $\text{UO}_2(\text{NO}_3)_2$

The examples above represent metal species which are recovered by solvent extraction in commercial metal recovery plants. There are many others.

## II. REAGENT REQUIREMENTS

It is obvious that if a metal species is to be transferred from an aqueous leach solution into an organic solution, there must be some chemical interaction which causes this to happen. The component in the organic phase, which chemically interacts with the metal, is properly called the extractant, but is commonly called the reagent.

At the present time there are organic extractants known for virtually all metals in one form or another<sup>7</sup>. As stated previously, this body of knowledge is due in large part to analytical chemists, however, the requirements for a successful extractant in analytical chemistry are different than the requirements for a reagent to be successful in large scale metal recovery operations, especially as they relate to process continuity and economics. In order for a reagent to be commercially successful it must:

- a. Extract the desired metal(s) selectively from the metal-containing solution.
- b. Be strippable into a solution from which eventual metal recovery can take place.
- c. Be stable to the circuit conditions so it can be recycled many times.
- d. Be nonflammable, nontoxic, noncarcinogenic, etc.
- e. Be soluble in an inexpensive organic diluent or be able to function as the diluent.
- f. Load and strip metal at a rate fast enough to allow for the use of economical mixing times.
- g. Not promote stable emulsions.
- h. Not transfer deleterious species from strip to extraction.
- i. Have an acceptable cost.

Normally, reagent behavior with respect to the above list is not a black and white, pass or fail situation. No one reagent is the best with respect to all of the properties in the list; rather, successful reagents possess a good balance of all of the properties in the list.

There are misconceptions about the selectivity of reagents which merit discussion. It should be realized that no reagent is selective for only one metal under all conditions, but that many reagents are selective for only one metal under certain conditions. Selectivity is dependent upon conditions and the challenge is to match the conditions presented by a given leach solution to the selectivity characteristics of the reagents available. A perfect match is not always possible and is, in fact, rare. Most of the time, the researcher either settles for a reagent which, even though not perfect, functions well, or he tries to alter the leach procedure to give a leach solution from which a reagent will be more selective. In order to do this successfully, the chemistry of extraction processes must be understood.

## Type of Extractants

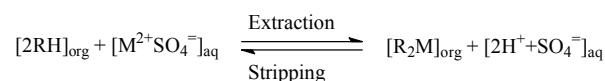

There are five classes of metal extractants as characterized by structure, extraction mechanism and the metal species extracted: chelation, organic acids, ligand substitution, neutral or solvating and ion pairing. Cognis markets chelation reagents and ion pairing reagents and has research interests in ligand substitution reagents.

### I. Chelation Extractants

#### A. GENERAL COMMENTS

Chelation refers to "claw" which is a graphic description of the way in which the organic extractant binds the metal ion in that the extractant chemically bonds to the metal in two places in a manner similar to holding an object between the ends of the thumb and the index finger. Upon bonding with the metal ion the extractant releases a hydrogen ion into the aqueous solution from which the metal was extracted. The simplified equation shown below is for the extraction of a +2 metal cation:

One of the important parameters controlling the equilibrium position of this reaction is the acid content of the aqueous phase. A graphic representation of this behavior is referred to as a pH isotherm, with some typical pH isotherms for the reagent LIX 84

shown in Figure 3. These pH isotherms can be used to predict the extraction characteristics of the reagent with respect to the metals shown under a variety of conditions. For example, at pH 2.0 copper(II) is strongly extracted, ferric iron is slightly extracted, while nickel(II) and cobalt(II) are not extracted. However, at pH 5 all four of these metals would be strongly extracted, except that this fact is not always important for iron(III) since it is only slightly soluble at pH 5.

It is important to realize that in order to make a direct comparison of the pH isotherms of two different reagents with the same metal, or of two different metals with the same reagent, the pH isotherms must be determined under exactly the same conditions.

A tabular method to express these extraction characteristics is shown in Table I.

**Table I Relative Extraction Power of LIX® 84-I for Metals at pH 2.0**

Metal	Relative Extractive Power
Cu(II)	Very strongly extracted
Fe(III)	Slightly extracted
Mo(VI)	Somewhat strongly extracted
V(V)	Slightly extracted
Zn(II)	Nil
Sn(II)	Nil
Ca(II)	Nil
Mg(II)	Nil
As(III)	Nil
Al(III)	Nil
Fe(II)	Nil
Si(V)	Nil
Co(II)	Nil
Ni(II)	Nil

\*The chemistry of Mo(VI) and V(V) is complex on the acid side, however, these metals do not present a problem to copper extraction.

The investigator screens the reagent against the metals most likely to be found in the aqueous feed solutions of interest under conditions similar to those expected in the solvent extraction process. This is normally referred to as selectivity data and holds only at the conditions under which it is determined. These conditions include the metal and reagent concentration, the oxidation state of the metal, the pH of the aqueous feed solution, and the organic-aqueous contact time. From Table I it is obvious that Cu(II) is the only metal listed which is strongly extracted by LIX 84 at pH = 2, and that only Fe(III) would present any potential problems to the preparation of a pure copper solution from a "normal" feed at pH = 2. This data is in agreement with the pH isotherms shown in Figure 3.

The extraction of metals from ammoniacal solution is also an area of interest, thus, the extractive behavior of some metals from ammoniacal solutions has been examined. In general, these data are expressed as ammonia dependent extraction isotherms, several of which are shown for LIX 84-I in Figure 4. The tendency for extraction to decrease with increasing ammonia concentration can readily be explained by the extraction/stripping equation for a typical +2 metal cation shown below:

In essence, the ammonia in solution functions as a coordinating ligand and competes with the organic extractant for the metal ion. The reaction is reversible and stripping with ammonia might be practical in some situations. The number of ammonia molecules coordinated to the metal will vary depending on the conditions; four being a favored number.

By looking at extraction isotherms and selectivity data, it is possible to develop metal separations schemes. For example, a look at the pH isotherms of LIX 84-I with Cu(II) and Ni(II) (Figure 3) suggests that a good Cu-Ni separation can be made with LIX 84-I by controlling the pH in the extraction stages. All of the copper can be extracted at low pH (1.5 to 2.0) before the system is adjusted with ammonia to higher pH (9.0 to 9.5) where the nickel is extracted. This type of scheme has been used on a commercial scale at the S.E.C. Corporation in El Paso, Texas, for the recovery of copper and nickel from a refinery bleed stream<sup>8</sup>.

The LIX 84-I ammonia dependent extraction curves in Figure 4 show that copper(II) is more strongly extracted from an ammoniacal solution than is nickel. Thus copper-nickel separations from ammonia leach solutions should be possible and indeed have been studied for a similar reagent<sup>9</sup>. The study concentrated on a flow scheme where copper is preferentially extracted from an ammonia solution containing copper and nickel before the nickel is extracted. A high copper / nickel ratio on the copper loaded organic is obtained by using an extra extraction stage in which copper crowds nickel from the loaded organic, i.e., the copper in an ammoniacal copper and nickel containing solution, when contacted with an organic loaded with nickel, will replace some of the loaded nickel. After the copper and nickel are loaded in separate extraction operations, each "metal loaded organic" is washed and then stripped to give a copper-rich and a nickel-rich electrolyte, respectively. Circuit complexity, overall operational ease and the number of stages required are dependent upon the aqueous feed.

A different separation scheme on the same type of feed has been reported<sup>10</sup> and has also been studied in this laboratory<sup>11</sup>. This scheme involves the coextraction of nickel and copper with the same organic stream, then washing followed by pH controlled,

selective stripping of each metal, to give copper-rich and nickel-rich electrolytes, respectively. This flow scheme is based on the ammonia isotherms, which show that copper and nickel are strongly extracted from ammoniacal solutions by LIX 84-I, and the pH isotherms, which show that while LIX 84-I loads copper very well at a pH of 2.5 to 3.0, nickel is readily stripped at that pH.

It is well indeed, that the study of pH isotherms, selectivity data and ammonia isotherms leads to the conceptual development of metal separation processes. However, this type of data does not tell in a detailed way how to do a given metal separation, nor the way the circuit must be set up in order to do the separation in the most effective and least costly manner. For this type of information some research effort is required.

## B. Laboratory Evaluation Program for a Copper Leach Solution

Assuming a metal containing solution is available, what is the next step? The first thing is that the contents of the solution must be known, (metals, pH, NH<sub>3</sub>, etc.) as well as whether that solution is typical of the feed solution to be treated. The evaluation of a feed solution, which is not typical of the solution to be treated, can at times be a wasted effort. Once the solution contents are known, judgments about which metals can be separated should be made based on the extraction isotherms available. If data on some of the contained metals is not available, the reagent(s) to be used should be screened against these metals. At this point it should be known which metals are considered desirable to recover, and which metals are possible to recover via solvent extraction, under the given set of conditions. The circuit development work can now begin with the realization that all parts of the total metal recovery scheme must fit together in a workable manner.

For example, consider a solution obtained from a typical copper leach operation containing 2.5 g/l Cu(II) and 1.30 g/l total Fe at a pH of 1.80. The overall goal of the laboratory evaluation program is to determine the conditions required so that about 90% copper recovery is realized. It is also important to generate data on copper over iron selectivity.

From experience it is known that LIX 984, a mixed aldoxime-ketoxime reagent, is a good reagent for the leach liquor under discussion. Previous work tells us

that in a 2 extraction - 1 strip stage circuit, where ~ 90 % copper recovery was obtained, LIX 984 transferred about .24 to .30 g/l Cu per volume percent reagent. Since the leach liquor of interest has a pH of 1.8 assume that LIX 984 will transfer in the middle to lower end of the range. The following simple calculation then gives the reagent concentration, which should be suitable:

$$\begin{aligned} 2.50 \text{ g/l Cu} \times (0.90) & / 0.26 \text{ g/l Cu per v/v\% reagent} \\ & = 8.7 \text{ v/v\% reagent} \end{aligned}$$

An organic solution containing 8.7 v/v% LIX 984 in a suitable diluent is prepared and then vigorously contacted once for about three minutes in a separatory funnel with the feed solution at an organic /aqueous (O/A) ratio of about 1. After the phases have separated and the aqueous phase is discarded the copper loaded organic phase is vigorously contacted twice, for about one minute each contact, with fresh pregnant strip solution (the aqueous solution expected to exit the strip stage of the circuit, 50 g/l Cu and 140 g/l H<sub>2</sub>SO<sub>4</sub> in this case), also at an O/A=1. This results in an organic solution which closely approximates the stripped organic (S.O.) to be expected in the actual continuous circuit operation. The newly prepared stripped organic and the leach solution are now equilibrated at various organic to aqueous volume ratios by vigorous shaking for 3-10 minutes in separatory funnels or by rapid stirring in mixer boxes. After phase separation the respective organic and aqueous layers are filtered and saved for analysis. The organic layer is analyzed for copper (and perhaps iron) and the aqueous layer for copper only. The data is shown in Table II and is plotted as illustrated in Figure 5.

Stripping isotherm data is generated in a similar fashion by equilibrating the stripping aqueous phase (S.E.), in this instance a typical copper electrowinning tankhouse electrolyte containing ~30 g/l Cu and 170 g/l H<sub>2</sub>SO<sub>4</sub>, with copper loaded organic (L.O.) at various O/A ratios (Table II, Figure 6).

**Table II. Equilibrium Extraction and Stripping Data for LIX® 984**

Analysis in g/l Cu

**Extraction**

O/A	Organic	Aqueous
10/1	2.04	0.07
5/1	2.28	0.09
2/1	2.96	0.17
3/2	3.26	0.26
1/1	3.70	0.51
1/2	4.19	1.24
1/5	4.35	1.94
S.O.	1.80	
Leach Solution		2.50

**Stripping**

O/A	Organic	Aqueous
10/1	1.76	51.3
5/1	1.38	43.2
2.5/1	1.21	37.7
1/1	1.07	33.8
1/2	1.01	32.3
1/4	0.98	31.2
L.O.	3.90	
S.E.		30.7

Isotherms are unique to the conditions under which they are generated. If one of the parameters is changed, for example, the reagent concentration, the copper concentration of the respective organic or aqueous phase, the pH of the leach liquor, the acid concentration of the strip liquor, etc., then a different isotherm will be generated. In instances where the change in one or two of the parameters is very small it may not be necessary to run a second isotherm.

Properly generated extraction and stripping isotherms represent equilibrium conditions and, as such, predict the best extraction and the best stripping which can be obtained. These isotherms can be used to set the staging in a circuit. Consider, for example, the extraction isotherm in Figure 5 and suppose that the stripped organic entering into the last extraction stage contains 1.80 g/l Cu and that the advance flowrates of the leach solution and the organic phase are equal. Knowing this, an operating line can be constructed by starting at the point where the stripped organic intersects the isotherm and

drawing the line up and to the right with a slope equal to the ratio of the organic/aqueous flow rates (one in this instance) until the operating line intersects the vertical line representing the copper content of the feed. Next, a horizontal line to the isotherm curve and then a vertical line to the operating line are drawn creating a "step". This process is repeated, creating a second step and completing a two stage "McCabe-Thiele" diagram. Each triangle represents a single stage of extraction. In this system, a raffinate of 0.22 g/l Cu and a loaded organic of 4.24 g/l Cu are predicted in two stages of extraction.

Even though the McCabe-Thiele diagram shown in Figure 5 does not represent true equilibrium, but only a first approximation, it is still quite useful. For example, if a third stage of extraction were to be added to the McCabe-Thiele diagram in Figure 5, (note the dotted line) a near perfect equilibrium McCabe-Thiele diagram would result. In addition, a more accurate two stage McCabe-Thiele extraction diagram can be drawn by taking the two stage McCabe-Thiele construction as shown in Figure 5 and choosing as the point from which a new operating line is to be drawn a distance about 1/2 way between the isotherm line and the raffinate line. When this is done, and then a second two stage McCabe-Thiele diagram constructed as described above, a raffinate of about 0.15 g/l Cu and a loaded organic of 4.17 g/l Cu are predicted. The construction of a true equilibrium McCabe-Thiele diagram is an iterative process. With the example under discussion the second step of iteration is all that is needed to produce a near equilibrium McCabe-Thiele diagram. This will not always be the case.

The construction of an equilibrium McCabe-Thiele diagram depicting one stage of stripping is very simple (Figure 6). A horizontal line is drawn from the loaded organic line (3.90 g/l Cu) to the isotherm line at the value of the pregnant electrolyte (P.E.) desired, 51 g/l Cu in this case. Then a vertical line is dropped from the point where the P.E. line intersects the isotherm to the horizontal axis. This gives the stripped organic (S.O.) to be expected (1.77 g/l Cu). Next, the strip electrolyte (S.E.) line, 30.7 g/l Cu, is drawn horizontally from the vertical axis of the graph to the S.O. line. The line connecting this point with the intersection of the loaded organic and pregnant electrolyte lines is the operating line. The slope of the operating line ( $2.13/20.3 = .105$ ) is equal to the ratio of the advance strip aqueous flow to the

advance organic flow needed to obtain the desired pregnant strip solution.

A two stage McCabe-Thiele strip diagram, constructed as described above for extraction, predicts a stripped organic of 1.12 g/l Cu when building a pregnant electrolyte of 51 g/l Cu and operating at an O/A of 7.3/1.

One of the important decisions the designer or builder of an SX plant must make is to decide on the staging requirements. The capital cost of a stage must be weighed against the benefits the stage provides. For example, consider the benefit of a second strip stage for the example cited above. Two stages of stripping will give a stripped organic of 1.12 g/l Cu and result in a net copper transfer for the organic (the difference between the loaded and stripped organic) of about 2.78 g/l Cu, while one stage of stripping gives a copper net transfer of about 2.13 g/l Cu. Because of the difference in net copper transfer, a one strip stage circuit requires a reagent concentration about 1.3 times greater than a two strip stage circuit in order to have equal copper extraction performance. Therefore, the organic losses expected in a one strip stage plant should be about 1.3 times greater than those in a two strip stage plant. By comparing the capital cost for a second strip stage with the increased operating cost (due to higher reagent usage) for the one strip stage plant, a purely economic decision on the strip stage requirements can be made.

In recent times most companies have opted to treat dump leach liquors in 2 extraction - 1 strip (2E-1S) stage plants rather than 2E-2S or 3E-2S plants. For this reason, a 2E-1S circuit was set up and operated at the advancing O/A ratios shown in the McCabe-Thiele diagrams in Figures 4 and 5. A mixer retention time of 2.6 minutes was used simply because most copper SX plants have two or three minute mixers, depending on the leach solution conditions, mixer design and company philosophy.

In order to run a circuit properly, resulting in good metallurgy and maximum information, several things are important. Flow rates must be accurately set and continually monitored. Mixer dispersions should have an O/A ratio near one in order to get proper mixing, thus, recycles should be employed where needed. The mixing turbines must rotate fast enough for good mixing, but, not so fast that heavy entrainment results<sup>12</sup>. Another important feature of

running a good circuit is frequent sampling with rapid and accurate analyses. This allows the operator to monitor the circuit closely, easily observing circuit behavioral differences as operating parameters are changed. Once an operator has changed operating conditions, the circuit should be allowed to run until circuit equilibrium is established. When a circuit is in equilibrium it means that there is a good metal balance and a good metal-acid balance across the whole circuit, as well as in each stage. Thus, the metal extracted from the aqueous phase in an extraction stage is equal to the acid equivalent gained by that same aqueous phase, and also equal to the metal loaded by the organic in that stage. In a stripping stage the metal stripped from the organic phase is equal to the metal gained, and to the acid equivalent lost, by the strip aqueous phase in that stage.

Obviously, in order to balance metal and acid values, solution analyses and solution flow rates must be known. Furthermore, solution samples for a given stage should be taken from the rear of the respective settler for that stage. When possible it is best to pull samples at those points easiest to access and least likely to upset the circuit.

It is important to realize that circuit behavior will reflect the interdependence of the extraction stripping operations. For example, a loss of stripping efficiency will result in a higher stripped organic which in turn leads to a higher raffinate. The circuit must then be operated with a slightly higher reagent concentration in order to maintain copper recovery or a slightly lower recovery must be accepted.

Because of the design of mixers currently used in copper solvent extraction plants, metal transfer in a stage is usually about 85 to 95% of theoretical. For this reason, the values predicted by equilibrium McCabe-Thiele diagrams for the aqueous and organic phases exiting a given stage are seldom realized in an operating circuit. For example, compare the organic and aqueous values which are predicted by the McCabe-Thiele diagram in Figure 5 with the values generated in a continuous laboratory circuit using the same aqueous, organic and strip aqueous solutions (Table III, Figure 7).

The circuit produced a raffinate of 0.28 g/l Cu and a loaded organic of 4.08 g/l Cu as compared to the raffinate of 0.22 g/l Cu and the loaded organic of 4.24 g/l Cu predicted by the first approximation McCabe-Thiele extraction diagram (Figure 5). The

stripped organic of 1.80 g/l Cu is close to the 1.77 g/l Cu predicted by the McCabe-Thiele strip diagram (Figure 6).

**Table III. Circuit Profile Data with 8.7 v/v% LIX® 984 in Escaid 110**

Sample	Organic g/l Cu	Aqueous g/l Cu	Organic g/l Fe	Aqueous g/l Fe
Extraction Stage One	4.08	0.0020	1.31	
Extraction Stage Two	2.88	0.0038	0.28	
Strip Stage	1.80	N.D.	51.2	0.026
Strip Aqueous			30.7	0.010
Leach Aqueous			2.50	1.30

The natural question arises: Why perform the work required for an equilibrium isotherm when the circuit will not produce the predicted results? There are several good reasons. First of all, generating an isotherm helps to develop a "feel" for the system. Secondly, if the system has any unusual metallurgical behavior characteristics, the isotherm will usually reflect them. Thirdly, a good idea of the actual circuit results can be obtained by drawing in the operating line as previously described. However, instead of filling in the horizontal and vertical lines to reflect 100% mixer efficiency, draw the horizontal lines in to represent only 95% efficiency. When this is done using Figure 5, a two stage raffinate of 0.28 g/l Cu is predicted - a value identical to that realized in the circuit operation.

The feed chosen for the above example is typical of many copper leach operations and represents one of the simplest feeds to treat. Copper recovery is very good, the selectivity for copper over iron is high (in the above circuit it is about 1100/1 on a transfer basis), and there is little tramp metal contamination. More complicated feed solutions are evaluated in a manner similar to that described above, but, the extraction and stripping isotherms and the staging in the circuit can be, and often are, more complicated. Thus, the initial circuit may have to be modified several times before the best recovery scheme is worked out.

### C. Computer-Generated McCabe-Theile Diagrams for Copper

Cognis has developed a computer program, called Isocalc®, which will generate isotherms for the extraction of copper from typical sulfuric acid leach solutions. This computer program is based on the equilibrium constants for the extraction of copper from aqueous acidic sulfate solutions with the Cognis reagents LIX 84-I, LIX 984, LIX 622 and LIX 860-I, respectively, according to the equation on page 3. The program also incorporates the effects of sulfate buffering, the initial pH of the leach liquor, the reagent concentration and the stripping conditions for the loaded organic.

After generating an isotherm, the program will use that isotherm to calculate McCabe-Thiele extraction diagrams under specified conditions. Finally, the program will calculate and print mass balances across both the extraction and stripping stages.

This program is useful for:

- a) predicting reagent behavior under varying conditions,
- b) comparing the performance of one reagent with another under varying conditions,
- c) predicting metallurgical changes as conditions in a circuit are changed, for example, staging, the pH of the leach liquor, reagent concentration, mixer efficiency and stripping conditions.

However, the computer program only predicts those circuit behaviors associated with the copper extraction \_ stripping equilibrium. It does not predict copper over iron selectivity nor does it address the physical properties of a circuit such as:

- d) phase separation - how fast the aqueous/organic dispersion exiting a mixer separates into organic and aqueous phases,
- e) entrainment - the very small droplets of one phase carried in the other phase after primary phase separation has taken place,
- f) crud generation - the term crud or gunk is used to describe an interfacial material which is present in almost all solvent extraction circuits. This material usually contains finely divided solids

(either carried into the circuit with the leach liquor or precipitated in the circuit), some stable emulsion, bulk leach solution and/or bulk organic, colloidal silica and at times bacteria. Crud is a very difficult thing to describe as crud in one plant may be quite different from crud in another plant.

The Isocalc program should be used in conjunction with, but, not as a total substitute for, laboratory evaluations. As such, it can save a lot of time by very quickly providing information on "what if" type questions. This is particularly true early in a project.

A version of the program is available for Cognis customers, but, it is not available for general distribution. Under certain conditions your Cognis solvent extraction specialist will be happy to run Isocalc programs for your projected sulfuric acid copper leach solutions.

## D. Commercial Applications for Copper Recovery

### 1. Sulfuric Acid Leach Solutions

The use of chelation type extractants in liquid ion exchange has enjoyed its greatest commercial success for the recovery of copper from dilute sulfuric acid leach solutions which are generated from the leaching of oxide and/or sulfide ores using a variety of leaching techniques including dump, heap, in-situ, vat, thin layer and agitation. The leach-SX-EW technology begins with leaching and Cognis advises that companies considering this technology thoroughly investigate the leaching characteristics of their ore. Money spent up front in leaching studies usually pays handsome dividends.

Typical leach solutions may contain less than 1 g/l Cu up to about 35 g/l Cu over a pH range of 1.1 to 3.0. The leach solution may also contain up to 50 g/l chloride and a host of other impurities depending on the ore, available water and evaporation rate. Typical sulfuric acid leach solutions successfully treated by solvent extraction are summarized in TABLE IV.

**Table IV. Typical Sulfuric Acid Leach Solutions**

Type	Cu (g/l)	pH
Dump, Heap, In-situ	< 1 to 6	1.3 to 2.2
Ferric Cure, Thin Layer	3 to 6	1.5 to 2.2
Vat	5 to 50	1.6 to 2.0
Agitation	1 to 35	1.4 to 2.0

Other common constituents: Fe, Mo, Mn, Al, Mg, Na, K, sulfate ions and at times chloride ions.

Typical solutions from which high purity copper is electrowon contain from 30 to 38 g/l Cu and 140 to 180 g/l H<sub>2</sub>SO<sub>4</sub>. Most copper tankhouses coupled with SX in the acid sulfate system will have copper and acid concentrations in these ranges.

At the present time (December 1996) there are forty seven commercial operations that recover copper from dilute sulfuric acid leach solutions and there are several plants under construction with several others planned. Actual operating costs for one of the largest of these, the tailings leach plant of the Chingola Division, Zambia Consolidated Copper Mines, Ltd., in Zambia, Africa<sup>13</sup>, and one of the smaller, the Cyprus Bagdad Copper Company plant in Bagdad, Arizona<sup>14</sup>, have been published. The advantages of solvent extraction-electrowinning (SX-EW) over the cementation process for the recovery of copper from these types of leach solutions is well documented in these papers. These papers also demonstrate the applicability of solvent extraction on a very large scale, since ZCCM produces over 7,000 tons per month of high quality cathode copper, and on a smaller scale, as Cyprus Bagdad produces about 1100 tons per month of superior quality cathode copper. In addition, the ability to forecast fairly accurate operating costs for the SX-EW operation, as reported in the above papers, is a great advantage to the parties involved during feasibility studies.

### a. Commercial Copper Solvent Extraction Reagents

Even though a large number of molecules with a wide variety of extractive functionality's have been proposed as extractants to be used for the recovery of copper from sulfuric acid leach solutions, only the

hydroxy oximes have been used in commercial copper SX-EW plants. The basic structure for these copper extractants is shown in Figure 8.

The extractants of the general structure can be subdivided into two distinct classes based on their structure and properties: the ketoximes, which are normally copper extractants of moderate strength and the salicylaldoximes, which are very strong copper extractants. The strength of a copper extractant is based on the degree to which the copper extraction stripping equilibrium previously shown is driven toward extraction by the reagent. In simple terms, very strong copper extractants extract substantial amounts of copper at pH values less than 1.0, while moderate strength copper extractants are most useful above a pH of 1.6-1.8.

Another class of extractant combines a salicylaldoxime with a ketoxime in an approximate 1/1 mole ratio. This "third" class is not based on structure, but rather on the distinct and advantageous properties the mixtures exhibit. These patented mixtures<sup>15</sup> are classified as strong copper extractants and as such are useful at pH values as low as ~1.2.

**Ketoximes:** A ketoxime was the first hydroxy oxime extractant to be used commercially for the extraction of copper from dilute sulfuric acid leach liquor<sup>2</sup> and ketoximes were used exclusively for about 11 years. The most outstanding feature of the ketoximes, as represented by LIX 84, is the good physical performance they display under a wide variety of conditions, especially with respect to solutions that are known to be sensitive to certain organic solutions. One example would be agitation leach solutions which contain colloidal silica, some solids and/or residual flocculent. A second example are leach solutions containing dissolved organics, often present due to rotting vegetation. The ketoximes show excellent phase separation, low entrainment losses to the raffinate, and do not promote excessive crud formation. Because ketoximes are only moderately strong copper extractants and kinetically slow at cold temperatures, the number of copper SX plants using a ketoxime extractant exclusively is limited. However, in the circuits which are designed to use ketoximes, the operator enjoys a low cost, trouble-free copper extractant.

**Salicylaldoximes:** The salicylaldoximes were developed to overcome the perceived shortcomings of the ketoximes. Their outstanding characteristics in-

clude rapid copper transfer kinetics and high extractive strength. However, the salicylaldoximes by themselves are such strong copper extractants that they are most often used in combination with an equilibrium modifier or with a ketoxime so that they can be efficiently stripped with an acidic copper solution from which high quality copper can be electrowon.

The use of equilibrium modifiers leads directly to certain shortcomings in that some modifiers are known to accelerate reagent degradation. It has also been reported that equilibrium modifiers contribute significantly to the amount of crud generated in some solvent extraction circuits<sup>16</sup>. Another problem sometimes associated with modified reagents is the contamination of electrolyte due to the excessive entrainment of leach liquor in the loaded organic stream. Finally, nonylphenol is known to have deleterious effects on certain materials of construction.

As a group salicylaldoximes are less stable than ketoximes and within the salicylaldoxime subgroup, the nonyl derivative is less stable than the dodecyl derivative. In operating circuits at normal temperatures, reagent degradation with 5-nonylsalicylaldoxime has been calculated to be equal to about 10% of the total reagent makeup. Actual degradation results on operating circuits have not been published, however, for some plants they are known to be higher than the calculated value depending on the modifier, the temperature and the acid content of the aqueous stripping solution. With heated circuits, reagent degradation could be even more significant and should be determined experimentally. Still, overall reagent loses are quite low in a well operated plant so the loses due to degradation are not excessive in any case.

In spite of their shortcomings, modified salicylaldoxime reagents such as LIX 622 have been quite successful in commercial circuits which are designed for their use, and where the leach liquor is compatible with the reagent.

**Ketoxime-Salicylaldoxime Mixtures:** The properties of ketoxime-salicylaldoxime mixtures containing no added modifier, such as LIX 984 and LIX 984N, reflect the most desirable characteristics of the components: the extractive strength and fast kinetics of the salicylaldoximes combined with the proven, excellent physical performance and stability of the ketoximes<sup>16</sup>.

Although the extractive strength of the mixtures is not quite as high as the modified salicylaldoximes, it is considerably greater than the ketoximes. Copper transfer kinetics are a little slower than salicylaldoximes, but are still very fast.

One interesting feature of these mixtures is the greater than expected copper transfer these mixtures give because of their lower than expected stripped organic value. It is felt this property results from the ketoxime component of the mixture functioning as a modifier for the salicylaldoxime component in the strip stages of the circuit. The mixtures were introduced to the industry in 1982 and are now the most widely used copper extractant system in the world. Since the ketoxime and salicylaldoxime components can be mixed in any ratio, a reagent mixture can be tailored to the demands of almost any leach liquor. Indeed, these mixtures could prove in time to be a universal reagent system for acid sulfate copper leach solutions since, in most instances, a properly tailored mixture will function both physically and chemically very well with virtually any leach solution of this type.

Since all three reagent classes of oxime extractants are commercially successful it follows that each class of extractant meets the reagent requirements previously given. In reading the successful reagent requirements it is obvious that they are somewhat general in nature. For example, the first requirement says that the reagent must extract the desired species selectively (in this case copper), but, it says nothing about how much copper must be extracted, nor the degree of selectivity the reagent must have. In fact, it is virtually impossible to be more specific because each leach liquor, each plant and each reagent is unique. Whereas a given reagent requirement may be critical in one situation, in another it can be relatively unimportant. What should be understood is that all three classes of hydroxy oxime reagents possess the successful reagent requirements to such an extent that all three classes are commercially successful, yet, no one reagent is the best for each and every copper leach liquor or copper solvent extraction circuit.

## b. Cognis Copper Solvent Extraction Reagents

Cognis produces three (3) oxime extractants: 5-nonylsalicylaldoxime, 5-dodecylsalicylaldoxime and 5-nonyl-2-hydroxyacetophenone oxime. These three oximes form the basis for a wide range of reagents which are derived by blending the oximes in a variety of ways, for example, with diluent, with one another or with a modifier, to give LIX Copper Solvent Extraction Reagents with properties that best fit the particular leach solution and plant design under consideration.

Furthermore, there are operating copper SX plants which purchase the individual reagent components separately and mix these components in a way that best meets the individual needs of the particular leach solution, plant or season. The ability to purchase the reagent components gives copper SX plant operators great flexibility in the operation of their plant to meet changing conditions, for example, summer versus winter operation, while still maintaining excellent physical properties.

Cognis makes available both normally formulated reagents and concentrated reagents. The concentrated reagents contain the same oximes as the normally formulated reagents. However, because the concentrated reagents are formulated with less diluent in order to save packaging, shipping and handling costs, the concentrated reagents are more viscous than normally formulated reagents and they do not flow well at temperatures less than about 5°C.

Table V shows the contents for some of the oxime copper extractants available from Cognis. If you would like more information about Cognis oxime copper solvent extraction reagents, or if you would like to discuss the extraction of copper from dilute sulfuric acid leach solutions in more depth, contact your local Cognis representative.

The oxime copper extractants marketed by Cognis Corporation, either alone or mixed, are highly selective for copper over iron when mixed with almost all copper leach solutions. As a result minimum tank-house bleeds are needed for iron control.

**Table V. Composition of some Hydroxy Oxime Copper Extractants, available from Cognis**

<u>Extractant/Catagory</u>	<u>Composition</u>
LIX® 84 /Ketoxime	A mixture of predominantly 2-hydroxy-5-nonylacetophenone oxime with a small amount of 5-dodecylsalicylaldoxime in a high flash point hydrocarbon diluent needed for handling purposes.
LIX® 860 /Aldoxime	A mixture of predominantly 5-dodecylsalicylaldoxime with a small amount of 2-hydroxy-5-nonylacetophenone oxime in a high flash point hydrocarbon diluent needed for handling purposes.
LIX® 860N /Aldoxime	A mixture of predominantly 5-nonylsalicylaldoxime with a small amount of 2-hydroxy-5-nonylacetophenone oxime in a high flash point hydrocarbon diluent needed for handling purposes.
LIX® 984 /Mixture	An equivolume mixture of LIX 84 with LIX 860.
LIX® 973 /Mixture	A 7 / 3 volume blend of LIX 860 with LIX 84.
LIX® 622 /Salicylaldoxime	A mixture of 5-dodecylsalicylaldoxime and tridecanol in a high flash point hydrocarbon diluent.

## 2. Ammonia Leach Solutions

The extraction of metal from ammoniacal leach solutions is a second commercial application for chelation type extractants. Ketoximes, such as LIX 84, and the beta-diketone reagent LIX 54 have both been used. In one example, a ketoxime was used as the extractant for a leach liquor derived from the ammonia leaching of copper sulfide concentrates in a process termed the "Arbiter Process"<sup>17</sup>. In another example, LIX 54 is used as the extractant for copper from a leach liquor derived from the ammonia leaching of copper-lead dross<sup>18</sup>.

LIX 54 was designed for the extraction of copper from ammoniacal leach liquors. Its ease of stripping, low ammonia loading, fast kinetics, good phase separation, high copper loading, and low viscosity when fully loaded, make it ideally suited for this task<sup>19</sup>. However, LIX 54 is not applicable to sulfuric acid leach solutions since it does not extract copper well below pH ~3.0.

## E. COGNIS CHELATING REAGENTS AND SOME OF THEIR POSSIBLE USES

**LIX 54:** A beta-diketone based reagent, used for the selective extraction of copper from ammoniacal leach solutions, which strips with very low concentrations of residual sulfuric acid and operates at a high net copper transfer<sup>18,19</sup>. It may be possible to strip copper from this reagent using concentrated ammonia solutions.

**LIX 63:** This hydroxy oxime has been proposed for germanium recovery<sup>20</sup>, for copper recovery from typical tankhouse electrolytes<sup>21</sup>, in synergistic mixtures with other reagents for cobalt and nickel recovery<sup>22, 23, 24</sup> and for the separation of molybdenum from uranium in dilute sulfuric acid solution.

**LIX 84:** This ketoxime based reagent requires about 150 g/l H<sub>2</sub>SO<sub>4</sub> for copper stripping and contains no added modifier. It is widely used for copper recovery from dilute sulfuric acid leach solutions, and has application for the recovery of copper and nickel from ammonia solutions<sup>9, 10, 11, 25</sup>.

**LIX 87QN:** A ketoxime based reagent developed specifically for the extraction of nickel from ammonia, followed by a stripping operation using a concentrated solution of ammonia and carbon dioxide<sup>26</sup>.

**LIX 860:** This aldoxime based reagent, containing no added modifier, has been proposed as a reagent for the coextraction and selective stripping of copper and zinc<sup>27</sup>. In addition, this reagent when coupled with a copper sulfate crystallization circuit can be used to extract copper efficiently at pH values less than 1.0.

Whereas the above list is impressive, it should not be considered as limiting. Cognis is constantly working on the development of new chelating functionalities, while Cognis, and others in the industry, are continually working on new applications for existing chelation type extractants.

## F. CAPITAL COSTS FOR COPPER SX-EW

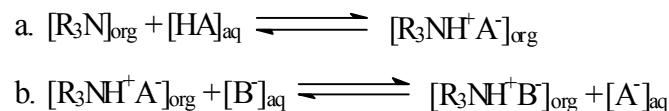

It is difficult to set out a formula by which to predict capital costs for solvent extraction-electrowinning plants. Raw material costs, local labor markets, the type of construction, the nature of the feed and the final plant designs are variables important in predicting capital costs. Cognis Corporation does try to keep current in these areas and will do some preliminary capital cost analysis for people interested in solvent extraction. To this end, Cognis has developed its Metcalc® computer program, which can be used in conjunction with the Isocalc program previously discussed, or by itself. The Metcalc program is not available for distribution, but, Cognis technical representatives will be happy to run the program according to customer needs.

## II. ION-PAIR EXTRACTANTS

A second class of extractants is based on the principle of ion association; whereby a large, positively charged organic moiety causes the extraction of a large, anionic metal complex into the organic phase, with concomitant expulsion of a small common anion to the aqueous phase. Cognis Corporation markets two classes of compounds which fall into this general classification.

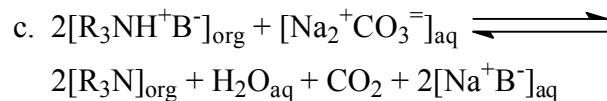

## A. ALAMINE® SERIES

The Alamine Series of Reagents all contain a basic nitrogen capable of forming amine salts with a wide variety of inorganic and organic acids. The amines which find the widest use in metals recovery processing by solvent extraction are the tertiary amines of the general formula R<sub>3</sub>N, where R can represent a variety of hydrocarbon chains. The equations below are representative of the extraction chemistry of the Alamine Series of Reagents:

Equation a represents simple amine salt formation while equation b represents true ion exchange. The extent to which B<sup>-</sup> will exchange for A<sup>-</sup> is a function of the relative affinity of the two anions for the organic cation and the relative stability of the anions in the aqueous medium. Since tertiary amines can form salts with a wide variety of acids, the choice of reagents for a liquid ion exchange process is quite large, i.e., the bisulfate salt, the chloride salt, etc., of any of the Alamine Reagents.

Amine type extractants can be stripped with a wide variety of inorganic salt solutions such as NaCl, Na<sub>2</sub>CO<sub>3</sub>, and (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>. The choice of stripping agent depends on the overall recovery process, but in general, basic stripping agents which deprotonate the amine, give the best stripping in the fewest stages. The equation below shows the stripping action of Na<sub>2</sub>CO<sub>3</sub> on an amine salt:

The greatest commercial acceptance for Alamine type reagents has been in uranium recovery processes, however, any metal capable of forming anionic complexes in aqueous solutions is a candidate for extraction by an amine type extractant. Figure 9 shows some of the extraction data which has been generated using Alamine 336 and/or similar amines<sup>28</sup>. The data is far from all-inclusive, but, it does show the wide variety of metal-aqueous systems which are amenable to treatment with amine type extractants.

## B. ALIQUAT® SERIES

The Aliquat Series of Reagents is based on the methyl chloride quaternization of a respective Alamine reagent. Because a quaternized amine is always positively charged, anion extraction with Aliquat Reagents is not pH dependent like it is with the tertiary amines. As a result, some basic metal leach solutions may be successfully treated by Aliquat type reagents without pH adjustment. The biggest disadvantage of using an Aliquat reagent is that these reagents will not deprotonate, therefore, stripping is usually more difficult than with the parent amine type reagent.

## C. LABORATORY EVALUATION PROGRAM FOR ION-PAIR EXTRACTANTS

Laboratory evaluation programs with amine type extractants are carried out much like those described earlier for chelating type reagents. Even though amine systems tend to be more complicated than chelating systems for a variety of reasons:

- a. the large number of aqueous anionic systems where an amine extractant may be applicable,
- b. the large variety of potential stripping agents as compared, for example, to copper loaded chelates, where stripping with sulfuric acid is the norm,
- c. the three variables: pH, the oxidation state of the metal and the concentration of the anion contributing to the anionic metal complex, all of which are important in metal separation schemes with amines,

The goals of the laboratory evaluation program remain the same; to develop the best conditions for the extraction, stripping and final product recovery consistent with the overall metallurgical flowsheet.

An example which illustrates the importance of the variables cited above is the separation of Co, Fe and Ni from an acidic chloride solution. Refer to Figure 10 and note that Ni(II) is only slightly extracted at 200 g/l chloride ion, Co(II) and Fe(III) are strongly extracted at 150-200 g/l chloride ion and Fe(III) is strongly extracted at 50 g/l chloride ion. As a result, an excellent Co, Ni, and Fe separation can be effected by taking an alloy of the metals into a con-

centrated HCl solution, oxidizing the iron to ferric, co-extracting the Co(II) and Fe(III) while leaving the Ni in the original solution, and then selectively stripping the Co(II) from the Fe(III) with water. This flowsheet has been studied in our laboratory. Several slightly different flowsheets have also been reported<sup>29, 30</sup>. The best flowsheet for this type of feed is dependent upon the relative amounts of Co, Ni and Fe present.

In general, the use of organic phase modifiers, normally polar organic molecules such as long chain alcohols, is required with amines in order to keep the amine metal complexes soluble, prevent third phase formation and/or to have acceptable phase separation.

## D. PRESENT AND POSSIBLE FUTURE USES OF AMINE EXTRACTANTS

One of the best ways to illustrate the value of amines as ion-pair metal extractants is to list the high purity amines commercially available from Cognis Corporation and some of their known uses:

1. Alamine®300 (tri-n-octylamine): cobalt extraction from chloride leach solutions<sup>31</sup>.
2. Alamine®308 (tri-isooctylamine): cobalt-nickel separation from hydrochloric acid liquors<sup>32</sup>.
3. Alamine®336 [tri-(C<sub>8</sub>C<sub>10</sub>)amine]: uranium recovery from sulfuric acid leach liquors<sup>33</sup> or sulfuric acid resin eluate solutions<sup>34, 35</sup>, cobalt-nickel separations from hydrochloric acid<sup>36</sup>, iron extraction from aluminum chloride solutions<sup>37</sup>, vanadium extraction<sup>38</sup>, chromium extraction<sup>39</sup>, platinum group metals separations<sup>40</sup> and tungsten recovery.
4. Alamine®310 (tri-isodecylamine): uranium and vanadium extraction from acidic sulfate leach liquors and platinum group metals separations<sup>40</sup>.
5. Alamine®304 (trilaurylamine): uranium and molybdenum extraction from acidic leach liquors, the advantage being that the molybdenum amine complex is highly soluble.
6. Aliquat®336 [tri-(C<sub>8</sub>C<sub>10</sub>)methylammonium chloride]: vanadium extraction<sup>38</sup>, separation of platinum group metals<sup>40, 41</sup>, rare earth extrac-

- tions<sup>42</sup>, rhenium recovery<sup>43</sup>, and arsenic extraction from refinery electrolytes<sup>44</sup>.
7. Aliquat®336 Nitrate: the nitrated salt of Aliquat 336, a specialty product for rare earth separations.

Future uses for these types of reagents may lie in the areas of:

- a) reclaiming metals from spent catalysts<sup>45</sup>,
- b) niobium, tantalum, titanium and zirconium separations<sup>46</sup>,
- c) inorganic acid purification<sup>47</sup>,
- d) separation of cobalt, copper and zinc from nickel<sup>48</sup>.

### III. NEUTRAL OR SOLVATING TYPE EXTRACTANTS

A third class of extractants are known as neutral or solvating type extractants. Extractants of this class are basic in nature and will coordinate to certain neutral metal complexes by replacing waters of hydration, thereby causing the resulting organo-metal complex to become aqueous insoluble, but, organic soluble. Solvating extractants have an atom capable of donating electron density to a metal in the formation of an adduct, and are classified according to that ability:

trialkylphosphine oxides > trialkylphosphates > ketones > alcohols > ethers.

It takes little imagination to see that the above list is only a brief representation of the organic compounds which could function as solvating extractants. In general, extractions with solvating extractants are limited by: 1) the metal's ability to form neutral complexes with anions, 2) the co-extraction of acid at high acid concentrations, and 3) the solubility of the organo-metal complex in the organic carrier.

An important extractant of this type is tri-n-octylphosphine oxide (TOPO),  $(\text{C}_8\text{H}_{17})_3\text{PO}$ . The extraction characteristics of TOPO with a wide variety of metals have been investigated<sup>49</sup> and are summarized (Figure 11). The most important commercial application of TOPO in solvent extraction is its synergistic combination with di-2-ethylhexyl-

phosphoric acid (D2EHPA) for the extraction of uranium from wet process phosphoric acid<sup>50, 51</sup>.

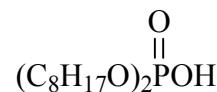

Other important extractants in this class are tributyl-phosphate (TBP), di-butyl butylphosphonate (DBBP) and 2,2'-dibutoxy diethyl ether (trade name dibutyl carbitol).

It is of interest to note that all of the equilibrium and phase modifiers commonly used come from this class of extractants. This is no surprise since both require a group having the ability to donate electron density and in some cases to be a hydrogen bond acceptor and/or donor.

Cognis Corporation does not currently market reagents of this type.

### IV. ORGANIC ACID EXTRACTANTS

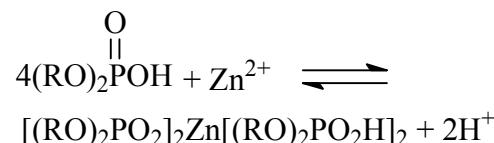

A fourth class of extractant is the so-called acid extractants. The chemistry of this type of extractant has some characteristics which resemble chelating extractants and some which are similar to neutral or solvating extractants. Di-2-ethylhexyl-phosphoric acid (D2EHPA), shown below, is representative of this class of extractant.

Di-2-ethylhexylphosphoric acid (D2EHPA)

Reagents which belong to this class are the organophosphoric, -phosphonic and -phosphinic acids, their respective mono- and di-thio derivatives, organosulfonic acids and carboxylic acids.

The following equation shows the dual behavioral characteristics:

Note that two of the D2EHPA molecules lose a proton much like a chelating extractant while two other D2EHPA molecules solvate the zinc similar to solvating type extractants. The pH extraction char-

acteristics of D2EHPA with respect to several metals is shown in Figure 12.

One of the more interesting characteristics of the extraction behavior of non thio acid extractants is their strong affinity for iron(III) over other base metals. This is unfortunate since it limits the use of these reagents for two reasons:

1. Insufficient selectivity for most base metal systems,
2. Iron is so strongly extracted that stripping the iron can be a problem.

In spite of these limitations the acid extractants have found some actual and proposed use for metal recovery. D2EHPA has been used for the recovery of uranium<sup>3, 52</sup>, vanadium<sup>3, 52</sup>, and zinc<sup>53</sup>. All three types of acidic organo-phosphorous compounds have been used for the selective extraction of cobalt over nickel<sup>54, 55</sup>. There are remarkable selectivity differences for cobalt over nickel between certain types of these compounds resulting from very interesting and subtle chemical and steric differences.

## Reagents in Development, Gold

At the time this edition of the Red Book was published, development work on several new extraction reagents and/or metal recovery processes was taking place in our laboratories. A brief discussion about one of these developments follows. Inquiries from interested parties about the progress of these developments are invited.

### GOLD EXTRACTION

Cognis is developing a reagent for the extraction of gold from typical cyanide leach solutions which can be stripped with an aqueous solution of 2-4 w/v% NaOH and .5 w/v% of NaCN. The selectivity of this reagent for metal cyanide complexes has the following order:

The recovery of gold from clarified cyanide leach solutions may offer certain advantages over existing gold recovery processes, particularly:

1. Where very high gold recovery is needed or,
2. In the case of leach solutions carrying either high levels of copper or organic compounds which foul carbon.

In addition, the gold inventory carried in the SX-EW recovery process is less than that in typical carbon in column or Merrill Crowe recovery processes.

The functionality is also available as a solid ion exchange resin called Aurix® 100<sup>57</sup>. This resin has shown excellent gold extraction kinetics and high gold loading in laboratory and pilot plant tests. It has also been shown to be resistant to breakage in typical resin in leach or resin in pulp applications. Aurix 100 may show significant advantage over activated carbon for gold extraction from preg robbing pulps or from bio-leach liquors which foul carbon.

## SOLVENT EXTRACTION DILUENTS

The discussion to this point has been centered around the reagents used for metal extraction, yet, in many commercial SX plants the diluent used as a carrier for both the reagent and the reagent metal complexes is present in far larger amounts than the reagent. Furthermore, the diluent can alter both the chemical and physical properties of an SX system. Given this, a brief discussion on diluents is appropriate.

In many cases, the role of the diluent on the chemistry of the system is minor, and the choice of diluent is made simply on economics and on the diluents physical properties such as phase separation, flash point and the solubility of the reagent and the reagent metal complexes. It is fortunate that with many of the large SX systems, for example, the copper-oxime system, the above holds true. In other cases, where the diluent has a major role in the chemistry of the system, the choice of diluent depends on both chemical and physical properties. In either case, efforts to choose a proper diluent, and to monitor the quality of continuing supplies of the diluent, is important. These efforts must be included as part of any good laboratory evaluation program.

It should be noted that in this discussion, the function of the diluent is assumed to be separated from that of the modifier. In real systems this is not a valid assumption, but, solvent-modifier interactions are complex and for reasons of brevity this topic will not be discussed.

## CONCLUSION

The potential of solvent extraction is well documented by the wide variety of metal containing solutions, which are amenable to recovery, purification, and concentration, by solvent extraction. However, much work in both reagent synthesis and process development remains. Cognis plans to continue as an industry leader in this field via its vigorous research and development program. This program includes close working relationships with existing and potential customers in a joint effort to solve problems of common interest in metals recovery. Efforts in the area of technical service to existing

and potential customers have made a significant contribution to our overall success in solvent extraction. Cognis realizes it does not have all the answers nor it is aware of all the problems. But, Cognis firmly believes that by cooperating with the customer we can become aware of, and help find solutions to, many of these problems. Cognis' 40 years of experience in solvent extraction is an important asset to our problem solving ability.

Cognis Mining Chemicals Technology is supported by our parent company, the \$3 billion Cognis GmbH, a specialty chemical company of international importance, headquartered in Roermond, Netherlands. An innovator in applied chemistry, Cognis GmbH is a major producer of industrial chemicals for the worldwide market.

Our Cork Ireland facility, the only certified ISO-9000 SX plant in the world, is also well known for its environmentally friendly products, such as solvent free adhesives and phosphate free detergents as well as a host of other specialty chemicals.

As a member of the Chemical Manufacturers Association, Cognis has been instrumental in the implementation of Responsible Care Initiative, and remains totally committed to the efficient, safe and responsible development of useful products the serve industry and the home.

### Cognis products and technical support will help you

- Yield high quality metals
- Secure more convenient and safer reagent handling
- Reduce reagent consumption
- Produce cleaner circuits
- Generate greater efficiencies
- Build better plant performance and throughput
- Lower cost of production
- Convert "waste ore" to a valuable resource
- Yield greater potential profits

### Solvent Extraction Technical Services

- On-site personnel training
- New plant start-up assistance
- Feasibility studies/design analysis
- Flow sheet analysis
- Monitoring of reagent behavior
- Physical and chemical analysis

**Cognis' development technology provides the world's best selection of efficient solvent extraction reagents for recovery of:**

- Cobalt
- Copper
- Germanium
- Gold
- Molybdenum
- Nickel
- Palladium
- Rhenium
- Silver
- Tungsten
- Uranium
- Vanadium

# **LIX®84-I**

LIX 84-I solvent extraction reagent is water insoluble 2-hydroxy-5-nonylacetophenone oxime in a mixture with a high flash point hydrocarbon diluent. It forms water insoluble complexes with various metallic cations in a manner similar to that for copper which is described in the following equation:

Copper extraction from typical leach solutions is pH dependent. Stripping is accomplished with acid solutions such as a typical barren electrolyte from copper electrowinning.

### **TYPICAL PROPERTIES**

#### **A. Physical Properties:**

Extractant Appearance	Fluid Amber Liquid
Specific Gravity (25°/25°C)	0.90-0.92
Flash Point <sup>1</sup>	Greater than 160°F
Copper Complex Solubility	>30 g/l Cu at 25°C

#### **B. Performance Specifications<sup>2</sup>:**

Maximum Copper Loading	4.7 to 5.0 g/l Cu
Extraction Isotherm Point	≥ 3.65 g/l Cu
Extraction Kinetics	≥ 90% (60 seconds)
Extraction Cu/Fe Selectivity	≥ 2000
Extraction Phase Separation	≤ 60 seconds
Strip Isotherm Point	≤ 0.50 g/l Cu
Net Copper Transfer	≥ 3.30 g/l Cu
Strip Kinetics	≥ 90% (30 seconds)
Strip Phase Separation	≤ 80 seconds

<sup>1</sup>The flash point is determined by Setaflash closed cup.

<sup>2</sup>The performance parameters are determined using the Standard Cognis Quality Control Test dated 6/28/96.

# LIX®860N-I

LIX 860N-I, 5-nonylsalicylaldoxime in a high flash point hydrocarbon diluent, is a very strong copper extractant requiring more than 225 g/l H<sub>2</sub>SO<sub>4</sub> for stripping.

### SUGGESTED USES

LIX 860N-I can be blended with LIX 84-I over a broad range to give copper extraction reagents of variable extractive strength. It extracts copper according to the equation below:

LIX 860N-I will also extract zinc from ammoniacal solutions.

### TYPICAL PROPERTIES

#### A. Physical Properties:

Extractant Appearance	Fluid Amber Liquid
Specific Gravity (25°/25°C)	0.90-0.92
Flash Point <sup>1</sup>	Greater than 160°F
Copper Complex Solubility	>30 g/l Cu at 25°C

#### B. Performance Specifications<sup>2</sup>:

Maximum Copper Loading	5.5 to 5.9 g/l Cu
Extraction Isotherm Point	≥ 5.00 g/l Cu
Extraction Kinetics	≥ 95% (30 seconds)
Extraction Cu/Fe Selectivity	≥ 2500
Extraction Phase Separation	≤ 70 seconds
Strip Isotherm Point	≤ 3.50 g/l Cu
Strip Kinetics	≥ 95% (30 seconds)
Strip Phase Separation	≤ 80 seconds

<sup>1</sup>The flash point is determined by Setaflash closed cup.

<sup>2</sup>The performance parameters are determined using the Standard Cognis Quality Control Test dated 6/28/96.

# LIX® 54-100

LIX 54-100 solvent extraction reagent is a water insoluble reagent, which forms hydrocarbon soluble complexes with various metal cations in a manner similar to that shown below for copper:

### TYPICAL USES

LIX 54-100 was designed and is most commonly used for the extraction of copper from aqueous ammonia leach solutions arising from the ammonia leaching of printed circuit boards, copper scrap, copper alloys, copper/lead dross and certain copper sulfide concentrates.

Because of its low viscosity LIX 54-100 can be operated at copper loadings up to about 35 g/l (35 v/v% reagent) resulting in relatively small solvent extraction circuits when compared to oxime copper extractants.

Copper can be stripped from LIX 54-100 with an aqueous solution whose equilibrium copper concentration is high, but, whose equilibrium acid concentration is low. This allows an operator to tailor the pregnant copper strip solution to the specific needs of the final copper recovery operation.

### TYPICAL PROPERTIES

#### A. Physical Properties:

Extractant Appearance	Fluid Amber Liquid
Specific Gravity (25°/25°C)	0.95-0.99
Flash Point <sup>1</sup>	Greater than 200°F
Viscosity @25°C (Kinematic)	10 centipoise
Copper Complex Solubility	≥ 40 g/l Cu

#### B. Performance Specifications<sup>2</sup>:

Maximum Copper Loading	Not less than 100 g/l Cu
Extraction Kinetics	≥ 95% (30 seconds)
Extraction Phase Separation	≤ 120 seconds
Strip Isotherm Point	≤ 0.10 g/l Cu
Strip Kinetics	≥ 90% (30 seconds)
Strip Phase Separation	≤ 90 seconds

<sup>1</sup>The flash point is determined by Setaflash closed cup.

<sup>2</sup>The performance parameters are determined using the Standard Cognis LIX 54 Quality Control Test dated 6/03/93.

LIX® is a registered trademark of Cognis Group

# LIX®984N

LIX 984N reagent, a 1:1 volume blend of LIX 860N-I and LIX 84-I, is a mixture of 5-nonylsalicylaldoxime and 2-hydroxy-5-nonylacetophenone oxime in a high flash point hydrocarbon diluent which forms water insoluble complexes with various metallic cations in a manner similar to that shown below for copper:

Because this extractant contains no added modifier it may show advantages when used for copper extraction from solutions containing soluble silica or finely divided solids.

### TYPICAL PROPERTIES

#### A. Physical Properties:

Extractant Appearance	Fluid Amber Liquid
Specific Gravity (25°/25°C)	0.90-0.92
Flash Point <sup>1</sup>	Greater than 160°F
Copper Complex Solubility	>30 g/l Cu at 25°C

#### B. Performance Specifications<sup>2</sup>:

Maximum Copper Loading	5.1 to 5.4 g/l Cu
Extraction Isotherm Point	≥ 4.40 g/l Cu
Extraction Kinetics	≥ 95% (30 seconds)
Extraction Cu/Fe Selectivity	≥ 2000
Extraction Phase Separation	≤ 70 seconds
Strip Isotherm Point	≤ 1.8 g/l Cu
Net Copper Transfer	≥ 2.70 g/l Cu
Strip Kinetics	≥ 95% (30 seconds)
Strip Phase Separation	≤ 80 seconds

<sup>1</sup>The flash point is determined by Setaflash closed cup.

<sup>2</sup>The performance parameters are determined using the Standard Cognis Quality Control Test dated 6/28/96.

# LIX® 622N

LIX 622N solvent extraction reagent, which forms water insoluble complexes with various metallic cations, is a mixture of 5-nonylsalicylaldoxime with tridecanol and a high flash point hydrocarbon diluent. Its extraction-stripping reaction with copper can be described by the following equation:

Copper extraction from typical leach solutions is pH dependent. Stripping is accomplished with relatively strong acid solutions such as a typical barren electrolyte from copper electrowinning.

### TYPICAL PROPERTIES

#### A. Physical Properties:

Extractant Appearance	Fluid Amber Liquid
Specific Gravity (25°/25°C)	0.91-0.93
Flash Point <sup>1</sup>	Greater than 160°F
Copper Complex Solubility	>30 g/l Cu at 25°C

#### B. Performance Specifications<sup>2</sup>:

Maximum Copper Loading	5.5 to 5.9 g/l Cu
Extraction Isotherm Point	≥ 4.70 g/l Cu
Extraction Kinetics	≥ 95% (30 seconds)
Extraction Cu/Fe Selectivity	≥ 2500
Extraction Phase Separation	≤ 70 seconds
Strip Isotherm Point	≤ 2.30 g/l Cu
Net Copper Transfer	≥ 2.70 g/l Cu
Strip Kinetics	≥ 95% (30 seconds)
Strip Phase Separation	≤ 80 seconds

<sup>1</sup>The flash point is determined by Setaflash closed cup.

<sup>2</sup>The performance parameters are determined using the Standard Cognis Quality Control Test dated 6/28/96.

# LIX® 664N

LIX 664N solvent extraction reagent, which forms water insoluble complexes with various metallic cations, is a mixture of 5-nonylsalicylaldoxime with a proprietary ester modifier and a high flash point hydrocarbon diluent. Its extraction-stripping reaction with copper can be described by the following equation:

Copper extraction from typical leach solutions is pH dependent. Stripping is accomplished with relatively strong acid solutions such as a typical barren electrolyte from copper electrowinning.

### TYPICAL PROPERTIES

#### A. Physical Properties:

Extractant Appearance	Fluid Amber Liquid
Specific Gravity (25°/25°C)	0.935 - 0.955
Flash Point <sup>1</sup>	Greater than 160°F
Copper Complex Solubility	>30 g/l Cu at 25°C

#### B. Performance Specifications<sup>2</sup>:

Maximum Copper Loading	5.5 to 5.9 g/l Cu
Extraction Isotherm Point	≥ 4.70 g/l Cu
Extraction Kinetics	≥ 95% (30 seconds)
Extraction Cu/Fe Selectivity	≥ 2500
Extraction Phase Separation	≤ 70 seconds
Strip Isotherm Point	≤ 2.10 g/l Cu
Net Copper Transfer	≥ 2.70 g/l Cu
Strip Kinetics	≥ 95% (30 seconds)
Strip Phase Separation	≤ 80 seconds

<sup>1</sup>The flash point is determined by Setaflash closed cup.

<sup>2</sup>The performance parameters are determined using the Standard Cognis Quality Control Test dated 6/28/96.

Cognis Corporation • 2430 North Huachuca Drive • Tucson, Arizona USA 85745-1273  
Telephone: (520) 622-8891 • FAX: (520) 624-0912 • Web site: [www.cognis-us.com](http://www.cognis-us.com)

Information provided in this technical literature is believed to be accurate. However, Cognis assumes no liability and makes no warranty or representation that the information is correct or complete. # LIX® 84-IC

LIX 84-IC solvent extraction reagent is water insoluble 2-hydroxy-5-nonylacetophenone oxime in a mixture with a high flash point hydrocarbon diluent. It forms water insoluble complexes with various metallic cations in a manner similar to that for copper, which is described in the following equation:

Copper extraction from typical leach solutions is pH dependent. Stripping is accomplished with acid solutions such as a typical barren electrolyte from copper electrowinning.

### TYPICAL PROPERTIES

#### A. Physical Properties:

Extractant Appearance	Fluid Amber Liquid
Specific Gravity (25°/25°C)	0.945-0.965
Flash Point <sup>1</sup>	Greater than 170°F
Copper Complex Solubility	>30 g/l Cu at 25°C

#### B. Performance Specifications<sup>2</sup>:

Maximum Copper Loading	4.7 to 5.0 g/l Cu
Extraction Isotherm Point	≥ 3.65 g/l Cu
Extraction Kinetics	≥ 90% (60 seconds)
Extraction Cu/Fe Selectivity	≥ 2000
Extraction Phase Separation	≤ 60 seconds
Strip Isotherm Point	≤ 0.50 g/l Cu
Net Copper Transfer	≥ 3.30 g/l Cu
Strip Kinetics	≥ 90% (30 seconds)
Strip Phase Separation	≤ 80 seconds

<sup>1</sup>The flash point is determined by Setaflash closed cup.

<sup>2</sup>The performance parameters are determined using the Standard Cognis Quality Control Test dated 6/28/96 except the dilution is 7.143 v/v%.

# LIX®860N-IC

LIX 860N-IC, 5-nonylsalicylaldoxime in a high flash point hydrocarbon diluent, is a very strong copper extractant requiring more than 225 g/l H<sub>2</sub>SO<sub>4</sub> for stripping.

### SUGGESTED USES

LIX 860N-IC can be blended with LIX 84-IC over a broad range to give copper extraction reagents of variable extractive strength. It extracts copper according to the equation below:

LIX 860N-IC will also extract zinc from ammoniacal solutions.

### TYPICAL PROPERTIES

#### A. Physical Properties:

Extractant Appearance	Fluid Amber Liquid
Specific Gravity (25°/25°C)	0.945-0.965
Flash Point <sup>1</sup>	Greater than 170°F
Copper Complex Solubility	>30 g/l Cu at 25°C

#### B. Performance Specifications<sup>2</sup>:

Maximum Copper Loading	5.5 to 5.9 g/l Cu
Extraction Isotherm Point	≥ 5.00 g/l Cu
Extraction Kinetics	≥ 95% (30 seconds)
Extraction Cu/Fe Selectivity	≥ 2500
Extraction Phase Separation	≤ 70 seconds
Strip Isotherm Point	≤ 3.50 g/l Cu
Strip Kinetics	≥ 95% (30 seconds)
Strip Phase Separation	≤ 80 seconds

<sup>1</sup>The flash point is determined by Setaflash closed cup.

<sup>2</sup>The performance parameters are determined using the Standard Cognis Quality Control Test dated 6/28/96 except the dilution is 7.143 v/v%.

**LIX®973N**

LIX 973N solvent extraction reagent is a mixture of 5-nonylsalicylaldoxime and 2-hydroxy-5-nonylacetophenone oxime in a high flash point hydrocarbon diluent which forms water insoluble complexes with various metallic cations in a manner similar to that shown below for copper:

Because this extractant contains no added modifier it may show advantages when used for copper extraction from solutions containing soluble silica or finely divided solids.

**TYPICAL PROPERTIES****A. Physical Properties:**

Extractant Appearance	Fluid Amber Liquid
Specific Gravity (25°/25°C)	0.90-0.92
Flash Point <sup>1</sup>	Greater than 160°F
Copper Complex Solubility	>30 g/l Cu at 25°C

**B. Performance Specifications<sup>2</sup>:**

Maximum Copper Loading	5.2 to 5.6 g/l Cu
Extraction Isotherm Point	≥ 4.80 g/l Cu
Extraction Kinetics	≥ 95% (30 seconds)
Extraction Cu/Fe Selectivity	≥ 2300
Extraction Phase Separation	≤ 70 seconds
Strip Isotherm Point	≤ 2.25 g/l Cu
Net Copper Transfer	≥ 2.70 g/l Cu
Strip Kinetics	≥ 95% (30 seconds)
Strip Phase Separation	≤ 80 seconds

<sup>1</sup>The flash point is determined by Setaflash closed cup.

<sup>2</sup>The performance parameters are determined using the Standard Cognis Quality Control Test dated 6/28/96.

# LIX®973N-C

LIX 973N-C solvent extraction reagent is a mixture of 5-nonylsalicylaldoxime and 2-hydroxy-5-nonylacetophenone oxime in a high flash point hydrocarbon diluent which forms water insoluble complexes with various metallic cations in a manner similar to that shown below for copper:

Because this extractant contains no added modifier it may show advantages when used for copper extraction from solutions containing soluble silica or finely divided solids.

### TYPICAL PROPERTIES

#### A. Physical Properties:

Extractant Appearance	Fluid Amber Liquid
Specific Gravity (25°/25°C)	0.945-0.965
Flash Point <sup>1</sup>	Greater than 170°F
Copper Complex Solubility	>30 g/l Cu at 25°C

#### B. Performance Specifications<sup>2</sup>:

Maximum Copper Loading	5.2 to 5.6 g/l Cu
Extraction Isotherm Point	≥ 4.80 g/l Cu
Extraction Kinetics	≥ 95% (30 seconds)
Extraction Cu/Fe Selectivity	≥ 2300
Extraction Phase Separation	≤ 70 seconds
Strip Isotherm Point	≤ 2.25 g/l Cu
Net Copper Transfer	≥ 2.70 g/l Cu
Strip Kinetics	≥ 95% (30 seconds)
Strip Phase Separation	≤ 80 seconds

<sup>1</sup>The flash point is determined by Setaflash closed cup.

<sup>2</sup>The performance parameters are determined using the Standard Cognis Quality Control Test dated 6/28/96 except the dilution is 7.143 v/v%.

# LIX®984N-C

LIX 984N-C reagent, a 1:1 volume blend of LIX 860N-IC and LIX 84-IC, is a mixture of 5-nonylsalicylaldoxime and 2-hydroxy-5-nonylacetophenone oxime in a high flash point hydrocarbon diluent which forms water insoluble complexes with various metallic cations in a manner similar to that shown below for copper:

Because this extractant contains no added modifier it may show advantages when used for copper extraction from solutions containing soluble silica or finely divided solids.

### TYPICAL PROPERTIES

#### A. Physical Properties:

Extractant Appearance	Fluid Amber Liquid
Specific Gravity (25°/25°C)	0.945-0.965

Copper Complex Solubility	>30 g/l Cu at 25°C

#### B. Performance Specifications<sup>2</sup>:

Maximum Copper Loading	5.1 to 5.4 g/l Cu
Extraction Isotherm Point	≥ 4.40 g/l Cu
Extraction Kinetics	≥ 95% (30 seconds)
Extraction Cu/Fe Selectivity	≥ 2000
Extraction Phase Separation	≤ 70 seconds
Strip Isotherm Point	≤ 1.8 g/l Cu
Net Copper Transfer	≥ 2.70 g/l Cu
Strip Kinetics	≥ 95% (30 seconds)
Strip Phase Separation	≤ 80 seconds

<sup>1</sup>The flash point is determined by Setaflash closed cup.

<sup>2</sup>The performance parameters are determined using the Standard Cognis Quality Control Test dated 6/28/96 except the dilution is 7.143 v/v%.

# **ALAMINE®300**

**Alamine 300** is a water insoluble, tri-n-octyl amine which is capable of forming oil soluble salts of anionic species at low pH.

### **APPLICATIONS :**

**Alamine 300** finds use as an agent for producing oil soluble salts of various anions or as a reagent in recovering and/or purifying organic or inorganic species which are capable of forming anions using a process known as solvent extraction.

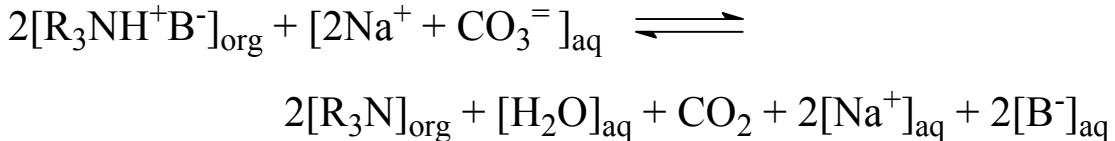

### **CHEMISTRY:**

Since **Alamine 300** contains a basic nitrogen atom, it typically can react with a variety of inorganic and organic acids to form amine salts, which are capable of undergoing ion exchange reactions with a host of other anions. The general reactions are shown below in two steps, protonation and exchange, describe this behavior.

The extent to which  $\text{B}^-$  will exchange for  $\text{A}^-$  is a function of the relative affinity of the two anions for the organic cation and the relative solvation energy of the anions by the aqueous phase.

When used as reagent in solvent extraction, the Alamine® 300 first extracts the target species from an aqueous solution and then must be regenerated ( stripped ) for recovery of the target species and reuse of the reagent. Amine type extractants can be stripped by a wide variety of inorganic salt solutions such as  $\text{NaCl}$ ,  $\text{Na}_2\text{CO}_3$  and  $(\text{NH}_4)_2\text{SO}_4$ . The type of stripping agent used depends on the overall recovery process, but in general basic stripping agents, which reverse the amine protonation reaction, give the best stripping in the fewest stages. The equation below shows the stripping action of  $\text{Na}_2\text{CO}_3$  on the amine salt:

Cognis Corporation • 2430 North Huachuca Drive • Tucson, Arizona USA 85745-1273  
Telephone: (520) 622-8891 • FAX: (520) 624-0912 • Web site: [www.cognis-us.com](http://www.cognis-us.com)

# **Aliquat® 336**

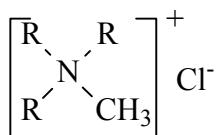

**Aliquat 336** is a water insoluble quaternary ammonium salt made by the methylation of mixed tri octyl/decyl amine, which is capable of forming oil soluble salts of anionic species at neutral or slightly alkaline pH.

### **APPLICATIONS:**

- 1) **Solvent Extraction:** **Aliquat 336** has been used to recover or purify the following ionic complexes: Cadmium, Cobalt, Iron, Molybdenum, the Rare Earths, Tungsten, Uranium, Vanadium and Zinc. **Aliquat 336** has also been used in acid purification.
- 2) **Waste treatment:** **Aliquat 336** has been used successfully to remove and recover acids or their salts or to remove certain heavy metals from wastewater. **Aliquat 336** is also effective in defoaming wastewater containing anionic surfactants.
- 3) **Adhesion promoter and surface curing aid** for fluorocarbon elastomers.
- 4) **Anti-static agent:** for textile fabrics and carpeting.
- 5) **Decolorization and deodorization:** of fermentation broths.

### **Chemistry:**

**Aliquat 336** is composed of a large organic cation associated with a chloride ion, as shown below.

Because the ammonium structure has a permanent positive charge, it can form salts with anions over a wider pH range than primary, secondary or tertiary amines. For this reason, **Aliquat 336** finds application in environments from acid to slightly alkaline pH.

When used as reagent in solvent extraction, the **Aliquat 336** first extracts the target species from an aqueous solution and then must be regenerated (stripped) for recovery of the target species

Cognis Corporation • 2430 North Huachuca Drive • Tucson, Arizona USA 85745-1273

Aliquat® is a registered trademark of Cognis Corporation

and reuse of the reagent. Quaternary ammonium extractants are more difficult to strip than amines. Usually the stripping agent must be more strongly attracted to the quaternary than the anion to be stripped. In some cases, stripping can be accomplished by using a large anion, which will crowd off the anion to be stripped. Chloride ions are frequently effective stripping agents. In certain cases the formation of anionic complexes, and their subsequent extraction, is dependent upon the concentration of the anion contributing to the anionic complex. In other cases, the chloride ion in **Aliquat 336** prevents effective extraction. This is because different anions are bound more strongly than others. It may be desirable to exchange the chloride anion to some other anion. (Request bulletin "Converting **Aliquat 336** chloride to hydrogen sulfate")

### **TYPICAL ANALYSIS:**

% Quaternary salt content .....	90	Acid value .....	0-1.0
Amine value .....	1.0-2.0	Color (Gardner) .....	3-6
% Water.....	5	Appearance.....	amber colored, viscous liquid

### **Chemical and Physical Properties**

# AuRIX® 100

AuRIX 100 ion exchange resin is based on a styrene di-vinylbenzene based macroreticular resin bead functionalized with guanidine groups.

Guanidines are strong organic bases especially suited to the extraction of aurocyanide from typical alkaline cyanide leach liquors. Upon contact with an aqueous solution, the guanidine will extract a proton from water at pH's typically less than 11.5 to form a guanidinium cation, which can then form an ion pair with auro-cyanide resulting in extraction. At pH's above 13, the guanidinium cation gives up its proton to re-form the neutral guanidine group resulting in transfer of the aurocyanide back into the aqueous resulting in stripping. The overall process is described in the following equations:

### Extraction

### Stripping

## TYPICAL PROPERTIES

### A. Physical Properties:

Appearance	Tan Spherical Beads
Resin Bulk Density	
As shipped – wet	620-700 gpl
Dry basis	330 gpl
Moisture Retention (Cl) %	47-53 %
Particle Size (% < 0.60 mm)	0.01

### B. Performance Properties:

Volume Capacity	0.25-0.35 eq/l
Recommended Gold Loading in Extraction	2,000 – 10000 gm/ton
Typical Eluted Resin Values	300 gm/ton Au
Typical Elution Time	12-24 hours
Typical Residence Time per Stage in RIP	15-30 mins

Cognis Corporation • 2430 North Huachuca Drive • Tucson, Arizona USA 85745-1273  
Telephone: (520) 622-8891 • FAX: (520) 624-0912 • Web site: [www.cognis-us.com](http://www.cognis-us.com)

### Selectivity

While quite selective for gold, AuRIX 100 will extract other anionic metal cyanide complexes. The order of extraction is as follows:

The observed selectivity is to some extent dependent upon the pH of the incoming aqueous feed solution as might be expected for an ion pair extraction type mechanism.

### TYPICAL OPERATING CONDITIONS

AuRIX 100 ion exchange resin is ideally suited for recovery of gold from typical alkaline cyanide leach liquors having a pH of 9.0-11.5. AuRIX 100 is well suited for extraction of gold from clear solutions in the Resin-in-Solution(RIS) process and from pulps in the Resin-in-Pulp(RIP) process. Attrition tests in an Anglo American pump cell contactor have shown that no detectable break down of AuRIX resin beads occurred during the processing of 800 tons of pulp.

The resin is shipped as the hydrochloride form. Before beginning any test work to evaluate the effectiveness of AuRIX 100 on a given leach solution, it is recommended that the resin be first converted to the free base form by two contacts with 1 molar sodium hydroxide (2 volumes of aqueous caustic/volume of resin beads) followed by washing with water until the pH of the wash water is neutral. Resin amounts must be determined on a volume measurement basis. Drying the resin beads in an attempt to obtain a dry weight will result in destruction of the resin upon re-exposure to water.

Stripping is achieved by contacting the loaded resin with a caustic solution containing 0.5M sodium hydroxide, 0.5M sodium benzoate and 100 ppm of sodium cyanide at 55-60°C. The gold values are recovered from the eluent by electrowinning.

For assistance in developing a test program for evaluating the application of AuRIX 100 ion exchange resin to a particular leach solution, please contact your Cognis technical representative.

### TOXICITY

Material Safety Data Sheet available upon request.

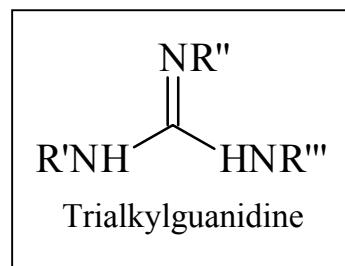

Cognis Corporation • 2430 North Huachuca Drive • Tucson, Arizona USA 85745-1273

# LIX®79

LIX 79 solvent extraction reagent is a water insoluble tri-alkylguanidine in a mixture with a high flash point hydrocarbon diluent. Tri-alkylguanidines are strong organic bases especially suited to the extraction of aurocyanide from typical alkaline cyanide leach liquors. Upon contact with an aqueous solution, the tri-alkylguanidine will extract a proton from water at pH's typically less than 11.5 to form a guanidinium cation, which can then form an organic soluble ion pair with aurocyanide resulting in extraction. At pH's above 13, the guanidinium cation gives up its proton to reform the neutral tri-alkylguanidine resulting in transfer of the aurocyanide back into the aqueous resulting in stripping. The overall process is described in the following equations:

### Extraction

### Stripping

## TYPICAL PROPERTIES

### A. Physical Properties:

Extractant Appearance	Fluid Yellow Liquid
Specific Gravity (25°/25°C)	0.80-0.85
Flash Point <sup>1</sup>	Greater than 155°F
Viscosity (20°C)	4.4 Centistokes
Pour Point	-18°C

### B. Performance Specifications:

Maximum Au(CN) <sub>2</sub> <sup>-</sup> Loading <sup>2</sup>	410 – 430 mg/l
Extraction Kinetics	≥ 95% (30 seconds)

<sup>1</sup>The flash point is determined by Setaflash closed cup.

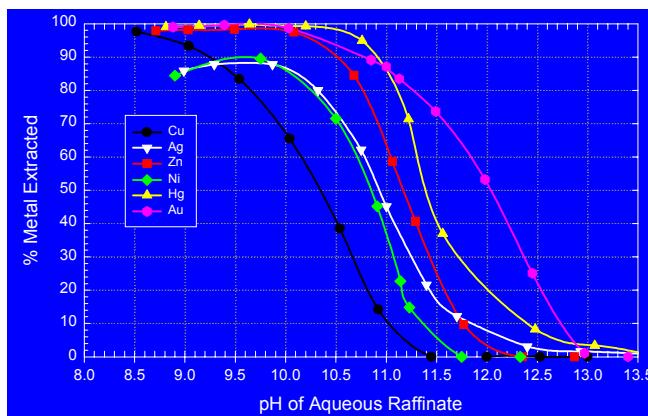

<sup>2</sup>Determined at a reagent concentration of 1.5 v/v% by four repetitive contacts at an O/A of 1/10 of the organic with an aqueous containing 25 ppm of gold as the aurocyanide and 100 ppm of free cyanide as sodium cyanide at a pH = 10.25.

### Selectivity

While quite selective for gold, LIX 79 will extract other anionic metal cyanide complexes. The order of extraction is as follows:

The observed selectivity is to some extent dependent upon the pH of the incoming aqueous feed solution as illustrated by the pH isotherms shown in the figure below:

### TYPICAL OPERATING CONDITIONS

Based on pilot plant experience with actual leach liquors having gold concentrations in the range of 0.65 to 1.3 ppm, it is suggested that initial lab shake out tests be carried out with reagent concentrations in the 10-15%(v/v) range. The reagent should be diluted in a mixture of a typical high quality solvent extraction diluent containing some aromatic character and a highly branched aliphatic alcohol, such as isotridecanol. Best results are typically achieved with an overall concentration of 75 gpl of isotridecanol in the organic phase. When working with diluents having lower levels of aromatic character, it may be necessary to add additional isotridecanol to insure good solubility of the complex in the organic phase.

Stripping is achieved by contacting the loaded organic with a caustic solution containing 0.8-1.0M sodium hydroxide. Depending on the metal values in the strip solution, stripping efficiency begins to fall off at sodium hydroxide concentrations much below 0.8M.

Using 15%(v/v) reagent in a 3Ex2S configuration, raffinates containing less than 0.01 ppm of gold have been achieved with greater than 99% gold recovery from a typical alkaline cyanide heap leach liquor.

**TOXICITY:** Material Safety Data Sheet available upon request.

## CYANEX® Solvent Extractant Database: Description and Documentation

The database of CYANEX solvent extractants contains bibliographic information on all publications from 1967 to the present in which CYANEX SX reagents are discussed. In order to use this database, you must have Microsoft ACCESS\* version 97 or greater. Copy the database file ([SXBIB.mdb](#)) to the ACCESS folder of your PC. Initially the file will be in a "Read Only" format and while you will still be able to search the database and view the results, changes cannot be made. The "Read Only" restriction can be removed as follows: From "Windows Explorer", highlight the database file name, right click and select "Properties" from the drop down menu. In the "General" form, remove the check mark from the "Read Only" box by left clicking on it. Select "Apply" and close the dialogue box.

The data fields consist of the following: Entry Number, Publication Year, Patent Number, Reagent Name, Title, Journal, Author, Patent Assignee, Corporate Source, Country and Abstract. The most useful way to access the data is through the "FORMS", of which, there are ten.

Two of the forms require no user interaction – "All Data" and "All Patents". Opening these forms will list every entry and every entry, which is a patent. All others will require one or two user inputs. The form titles are self-explanatory. For example, "Papers by Author" allows one to search the database for publications by a particular author and "Papers by Reagent" allows one to search for all publications on a particular reagent. "One Abstract Key Word plus Reagent" and "One Title Key Word plus Reagent" allows one to narrow the search somewhat.

When the forms are opened, the user is prompted for the type of entry. Each field has been entered as a string. To avoid not getting any hits, inputs to the prompts should be entered as string segments using "\*" before and after the entry as a multiple character "wild card". For example, there are several papers in the database with William A Rickelton as one or more of the authors. The name is also entered in more than one way. The surest way to retrieve all papers concerning this author is to enter \*Rickelton\*. The only time when it is not necessary to enclose the input with \*'s is when search by publication year.

The SX reagents are entered as CYANEX 272 extractant, CYANEX 301 extractant, etc. However, to retrieve entries for a particular reagent, it is only necessary to use the reagent number bracketed by \*'s. For example, when searching for CYANEX 272 extractant, either \*272\* or \*CYANEX 272\* will achieve the same results.

The one instance in which one **should not** enclose the prompt reply with an "\*" is when searching by "Publication Year" In this case, just enter the year – e.g. 1993 and not "\*1993\*".

The form "Papers by Metal" searches the title strings for the name of the metal supplied by the user input. In some cases, extraneous entries will be retrieved. For example, if the title contains the word "smelting" as well as \*tin\* or "environment" as well as \*iron\*, then those publications will appear as well as those containing "tin" or "iron".

Those users who are proficient in the use of ACCESS\* may modify the forms and associated queries as well as add additional records, provided that you have removed the "Read Only" restriction as indicated above.

While the information included in the database is thought to be reasonably inclusive and accurate, Cytec cannot be responsible for any errors or omissions.

# INTRODUCTION

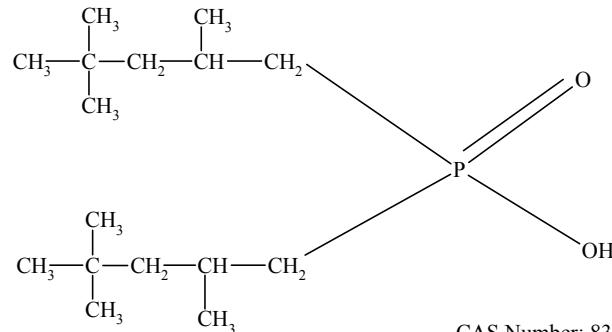

CYANEX® 272 extractant has proven to be the reagent of choice for the separation of cobalt from nickel from both sulfate and chloride media. It is now being used to produce a major portion of the world's cobalt.

Since the active component of CYANEX 272 extractant is a phosphinic acid, metals are extracted through a cation exchange mechanism. Although CYANEX 272 is selective for cobalt in the presence of nickel, a variety of other cations can also be extracted depending upon the solution pH.

CYANEX 272 extractant is totally miscible with common aromatic and aliphatic diluents, and is extremely stable to both heat and hydrolysis.

## Chemical Structure

The active component of CYANEX 272 extractant is bis(2,4,4-trimethylpentyl)phosphinic acid.

CAS Number: 83411-71-6

## Typical Properties

Bis(2,4,4-trimethylpentyl)phosphinic acid :	85%
Appearance	: Colourless to light amber liquid
Specific Gravity at 24°C	: 0.92
Viscosity, Brookfield at 25°C	: 142cp
50°C	: 37cp
Solubility in distilled H <sub>2</sub> O at pH 2.6	: 16 µg/ml
pH 3.7	: 38µg/mL
Boiling Point	: >300°C
Pour Point	: -32°C
Flash Point, closed cup	: >108°C
Specific Heat @ 52°C	: 0.48 cal/gm/°C
Thermal Conductivity	: 2.7 x 10 <sup>-4</sup> cal/cm/sec/°C

## Stability

The hydrolytic stability of CYANEX 272 extractant was examined in several tests which involved equilibrating the reagent with aqueous cobalt-nickel sulfate solutions at pH 5 and 50°C.

The experimental procedure involved contacting the aqueous and organic phases in a stirred vessel for one week and then stripping the organic phase with sulfuric acid. The solvent was subsequently returned to the vessel for a further one week contact with a fresh aqueous solution. The procedure was repeated for a total contact time of four weeks.

Analysis by titration and P<sup>31</sup> NMR failed to detect any degradation of the reagent, nor were any statistically significant changes in cobalt-nickel selectivity observed.

Furthermore, no degradation has been detected in plants which have been operating continuously for as long as ten years.

## Solubility Losses

Losses of CYANEX 272 extractant by distribution to aqueous cobalt-nickel sulfate solutions were determined in a number of shake-out tests. The effect of two variables, pH and aqueous phase salt concentration, was studied.

Aliquots of the organic and aqueous phases were contacted for 5 minutes at 50°C and A/O = 1. After coalescence, the aqueous phases were analyzed for CYANEX 272 extractant using a gas chromatographic procedure. The solvent was composed of 12 v/o CYANEX 272 extractant in Kermac\* 470B diluent. Ammonium hydroxide was used for pH adjustment. The results are given below.

Aqueous Composition (g/l)			Equilibrium pH	CYANEX 272 Extractant Solubility (µg/ml)
Ni	Co	Total Salt Conc.		
100 25	2 25	300 133	3.5	0.5-1.5
			4.6	2
			5.3	2
			6.2	2
5	5	27	4.6	3
			5.5	8
			6.5	25

The solubility losses follow the general pattern expected of an acidic extractant. Distribution to the aqueous phase was found to be proportional to pH and inversely proportional to salt concentration.

As can be seen, the losses are not excessive and this is corroborated by operating plant experience where total annual losses from both solubility and entrainment are approximately 10-15% of the solvent inventory.

## Toxicity

The acute oral (rat) and acute dermal (rabbit) LD50 values for CYANEX 272 extractant are 4.9 g/kg and >2.0 g/kg, respectively. The product produced only limited to mild eye and skin irritation during primary irritation studies with rabbits. The acute LC<sub>50</sub> (96 hr) for the bluegill sunfish and rainbow trout are 46 ppm and 22 ppm, respectively. When CYANEX 272 extractant was assayed for mutagenic potential in the Ames *Salmonella* Test, it was determined to be non-mutagenic.

## Suitability of Construction Materials

**Metals:** Samples of stainless steel (304 and 316), mild steel and aluminum in the form of coupons (approximate dimensions 50mm x 20mm x 3mm) were immersed in capped jars for 8-1/2 months at 50°C (temperature was maintained only during working hours). No corrosion was observed in the three steel samples but aluminum exhibited minimal corrosion at a rate of 1 mil/year.

**Plastics and Rubbers:** Samples of various plastics and rubbers were immersed in CYANEX 272 and kept at 50°C for a total of 424 hours. The following observations were made:

Material	Remarks
Butyl Rubber	Unsuitable. Increase in dimensions and softening.
Teflon fluorocarbon Film**	Suitable. No measured effect.
Polypropylene	Suitable. No measured effect.
Natural and Black Latex	Unsuitable. Complete dissolution in less than 192 hours
PVC Laboratory Grade	Short term suitability. Loss of plasticity in less than 192 hours.
PVC Solvent Grade	Suitable. Only small change in dimensions observed.
Red Gum Rubber	Unsuitable. 100% increase in weight and dimensions and softening.
Viton Fluoroelastomer*	Suitable. No measured effect.
Silicon	Unsuitable. Disintegrated after 56 hours.

# COBALT RECOVERY

## Cobalt-Nickel Selectivity

The results of batch shake-out tests showing the effect of pH on Co-Ni selectivity from both sulfate and chloride media are given in Tables I and 2, respectively.

**TABLE 1 - SULFATE SOLUTION**

Solvent (v/o)	:	12% CYANEX 272 extractant, 5% isodecanol in Kermac 470B diluent
Aqueous (g/l)	:	1.96 Co, 98.0 Ni as sulfates
Temperature	:	50°C
Contact Time	:	5 minutes
A/O	:	1
pH Control	:	NH <sub>4</sub> OH

Co	% Extraction		Equilibrium pH	Separation Factor
	Co	Ni		
21.5	0.04		3.8	700
43.7	0.08		4.2	1000
88.0	0.37		5.3	2000
96.7	1.05		5.7	2700
100	1.81		6.1	

**TABLE 2- CHLORIDE SOLUTION**

Solvent (v/o)	:	10% CYANEX 272 extractant, 5% isodecanol in Kermac 470B diluent
Aqueous (g/l)	:	0.88 Co, 1.76 Ni as chlorides
Temperature	:	50°C
Contact Time	:	5 minutes
A/O	:	1
pH Control	:	NaOH

Co	% Extraction		Equilibrium pH	Separation Factor
	Co	Ni		
2.9	0.1		3.2	40
54.2	0.3		4.0	370
98.1	7.0		5.1	680
99.7	30.0		5.5	680
99.9	72.9		6.2	650

## Calcium Rejection

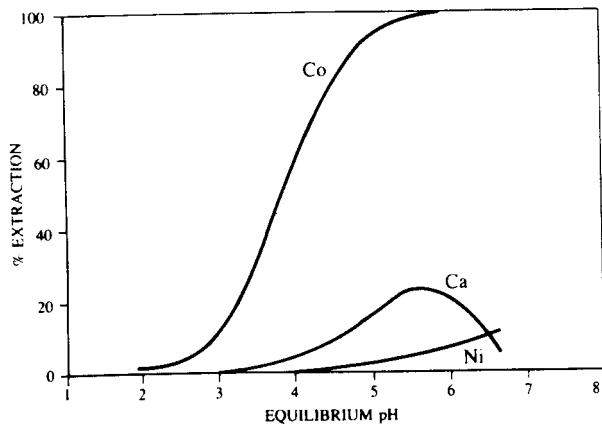

Unlike other organophosphorus cobalt extractants, CYANEX 272 extractant will extract cobalt preferentially to calcium when both are present in the same feed stream. This performance characteristic is demonstrated in Table 3 and Figure 1.

**TABLE 3- CALCIUM REJECTION IN THE PRESENCE OF COBALT AND NICKEL**

Solvent (v/o)	: 15% CYANEX 272 extractant, 10% p-nonylphenol in Kermac 470B diluent
Aqueous (g/l)	: 1.60 Co, 77 Ni, 0.31 Ca as sulfates
Temperature	: 50°C
Contact Time	: 5 minutes
A/O	: 1
pH Control	: NH <sub>4</sub> OH

Co	% Extraction		Equilibrium pH
	Ni	Ca	
3.1	0	0.95	1.99
17.2	0.04	1.24	3.34
54.3	0.17	3.33	3.85
91.7	1.03	12.0	4.84
98.3	3.95	25.7	5.72
100	13.4	5.16	6.63

**FIGURE 1**

## Cobalt Extraction Isotherm

Procedural details and results of our extraction studies are given in Table 4.

**TABLE 4**

Solvent (v/o)	: 12% CYANEX 272 extractant, 5% isodecanol in Kermac 470B diluent.
Aqueous (g/l)	: 5 Co as sulfate
Temperature	: 50°C
Equilibrium pH	: 5.0±0.1
pH Control	: 1N NaOH

A/O	Equilibrium Cobalt Concentration (g/l)	
	Solvent	Aqueous
10	6.32	4.68
5	6.13	4.13
2	5.54	2.58
0.5	2.72	0.06

The actual loading capacity of this solvent was 6 g/l cobalt, whereas the stoichiometric capacity is approximately 10 g/l cobalt.

## Cobalt Loading

Loading studies were carried out at 50°C and pH 6.0 -t 0. 1. The pH was controlled by the addition of ammonia. Other details and results are shown in Table 5.

**TABLE 5**

Solvent (v/o)	: 30% CYANEX 272 extractant in Kermac 470B diluent
Aqueous (g/l)	: 10 Co as sulfate
Theoretical Maximum (g/l)	: Approximately 24
Contact Time	: 5 minutes

A/O	Co in Solvent (g/l)	% of Theoretical Maximum	
		0.5	1.0
0.5	5	21	
1.0	10	42	
1.5	15	63	
3.0	23*	96	
5.0	23*	96	

\*At this loading the solvent was judged to be too viscous for practical use. The 15 g/l solvent did not exhibit this viscosity problem. The maximum practical loading for the conditions cited is probably about 65-75 % of theoretical

It should be noted that the loading capacity of CYANEX 272 extractant will vary depending upon several parameters, notably pH, temperature, and extractant concentration, and may be more or less than the figure cited. For example, with a 15% CYANEX 272 extractant solution at 50°C and pH 5-5 the solvent can be loaded to 100% of the theoretical maximum while remaining sufficiently mobile for practical use.

### Scrubbing Isotherm

As can be seen from the results in Table 6, even if a high quantity of nickel is co-extracted with the cobalt, it can be successfully scrubbed from the loaded solvent.

**TABLE 6**

Solvent (v/o)	: 12% CYANEX 272 extractant, 5% isodecanol in Kermac 470B diluent
Solvent Loading (g/l)	: 1.9 Co, 1.9 Ni
Scrub Feed (g/l)	: 30 Co (as sulfate), initial pH 3.7
Temperature	: 50°C

Equilibrium Concentration in Scrubbed Solvent ( $\mu\text{g/ml}$ )			
O/A	Co	Ni	Co-Ni Ratio
10	3820	4.5	850
5	3790	2.2	1720
2	3740	1.3	2900
1	3730	1.1	3400

### Stripping Isotherms

Stripping from a solvent modified with isodecanol tended to produce hazing. Substituting p-nonylphenol or TBP for the isodecanol essentially eliminated this problem.

Tables 7 and 8 show stripping isotherms obtained with a p-nonylphenol modified solvent.

**TABLE 7 -Using H<sub>2</sub>SO<sub>4</sub>**

Solvent (v/o)	: 12% CYANEX 272 extractant, 10% p-nonylphenol in Kermac 470B diluent
Solvent Loading (g/l)	: 3.26 Co (2 $\mu\text{g/ml}$ Ni)
Temperature	: 40°C
Contact Time	: 5 minutes
Strip Feed (g/l)	: 20.5 Co (as sulfate), 24.5 H <sub>2</sub> SO <sub>4</sub>

O/A	Equilibrium Cobalt Conc. (g/l)	
	Organic	Aqueous
6.67	0.58	38.4
5	0.22	35.7
4	0.19	32.5
3.33	0.03	31.3
2.86	0	29.8
2	0	27.0

**TABLE 8 - USING HCl**

Solvent (v/o)	: 12% CYANEX 272 extractant, 10% p-nonylphenol in Kermac 470B diluent
Solvent Loading (g/l)	: 9.26 Co
Temperature	: 50°C
Contact Time	: 5 minutes
Strip Feed (g/l)	: 19.4 Co (as chloride) 100 HCl

O/A	Equilibrium Cobalt Conc. (g/l)	
	Organic	Aqueous
2	0	37.9
3	0	47.1
5	0	65.7
7.5	0.01	88.8
10	0.35	108.5

### Continuous Separation of Cobalt from Nickel in Sulfate Solution

In continuous countercurrent tests (four extraction and two scrub stages) carried out at Warren Spring Laboratory (Stevenage, U.K.), more than 99.5% of the cobalt in the feed was recovered as a product containing a Co-Ni ratio of greater than 1000 to 1.

The experimental conditions are shown below. A circuit flowsheet and the relevant assays are given in Figure 2.

Solvent (v/o)	: 20% CYANEX 272 extractant (NH <sub>4</sub> salt)*, 10% p-nonylphenol
Aqueous Feed (g/l)	: 2 Co, 100 Ni as sulfates, 20 (NH <sub>4</sub> ) <sub>2</sub> O <sub>4</sub> , pH 5
Scrub Feed (g/l)	: 40 Co as sulfate, pH 3
Temperature	: 50°C
Phase Ratios	: Extraction A/O = 2 Scrubbing O/A = 32
Mixer Residence Time	: 3.5-4 minutes (Based upon total liquid flow)

\*The phosphinic acid contained in the solvent was converted 70% to the ammonium salt by reaction with concentrated ammonium hydroxide solution (S.G. = 0.88). A phase modifier was used since converting more than 50% of the free acid to a salt (NH<sub>4</sub> or Na +) usually requires a modifier to prevent third phase formation.

\*\*A product of Shell Chemical Co.

## Effect of Process Variables on Cobalt-Nickel Separation Factor

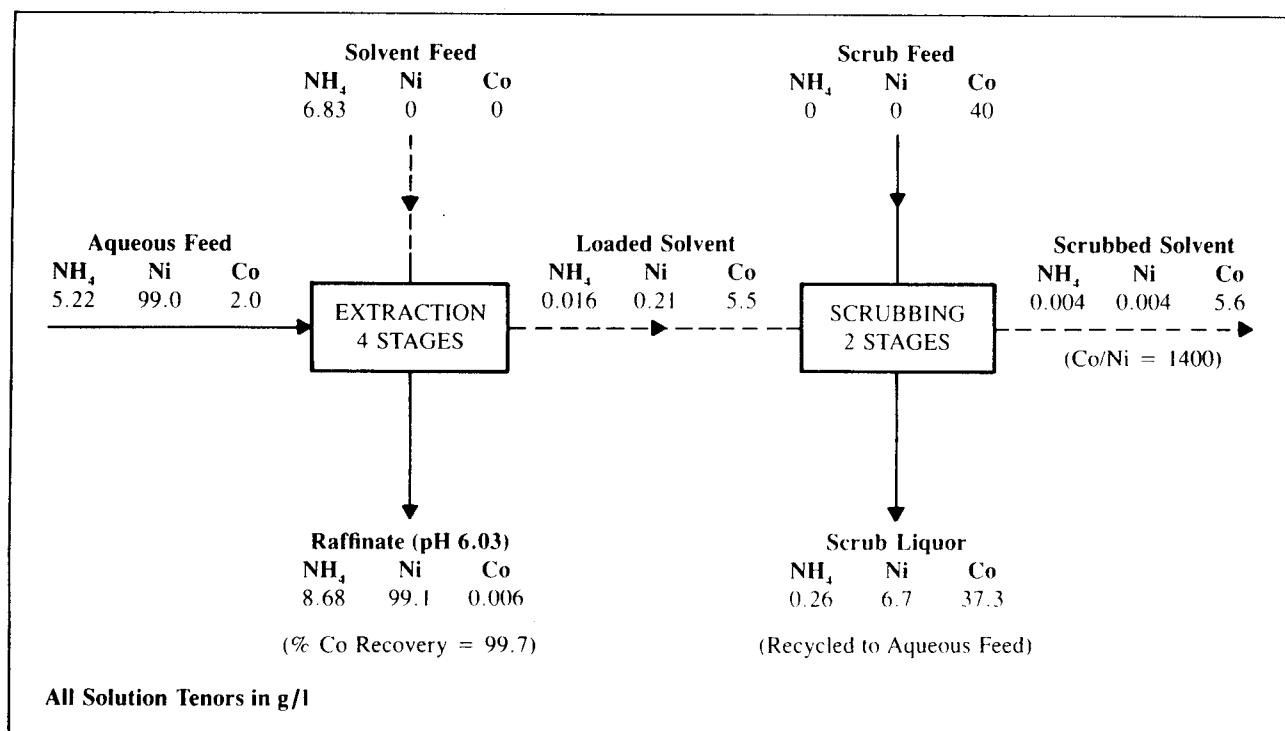

The effect of pH, temperature and diluent aromaticity on the cobalt-nickel separation factor in sulfate solutions was measured in a series of statistically designed tests and the data fitted to the following mathematical model:

$$\log_{10} S = 1.8827 + 0.0332T + 0.01249A + 0.0033PT - 0.002151PA = 0.0003405T^2$$

Where:

S = Co-Ni Separation Factor  
T = Temperature (°C)  
A = % Aromatics in diluent  
P = Equilibrium pH

FIGURE 2—CONTINUOUS TESTING OF CYANEX 272 EXTRACTANT

The effect of these process variables on the separation factor is shown in Tables 9 through 11.

**TABLE 9 - EFFECT OF TEMPERATURE**

Solvent (v/o) :	22% CYANEX 272 extractant in the diluent (95% MSB 210* diluent, 5% Aromatic 150**) diluent).

# OTHER POTENTIAL APPLICATIONS

## Diluent Oxidation and Prevention

Hydrocarbon diluents oxidize readily to carboxylic acids in the presence of a cobalt ( $\text{Co}^{2+}$ ) catalyst. The formation of carboxylic acids, which are active nickel extractants, can seriously reduce the cobalt-nickel selectivity obtained with CYANEX 272 extractant. However, inhibitors such as BHT can be used to prevent this oxidation. Plants following this practice have run for many years without loss of selectivity.

## Recovery from Ammoniacal Solutions

CYANEX 272 can be used to recover cobalt from ammoniacal as well as acidic solutions. The data in Table 13 show that it outperforms other organophosphorus extractants.

**TABLE 13 - EXTRACTION FROM AMMONIACAL SOLUTIONS**

Solvent (v/o)	:	20% extractant, 5% isodecanol in Kermac 470B diluent
Aqueous (g/L)	:	0.97 $\text{Co}^{3+}$ , 0.95 $\text{Ni}^{2+}$ , $(\text{NH}_4)_2\text{O}_4$ for a total $\text{SO}_4^{2-}$ concentration of 16
Temperature	:	50°C
pH Control	:	11.6 with $\text{NH}_4\text{OH}$
Contact Time	:	5 minutes
A/O	:	1
Extractant	% Extracted	Co/Ni Separation Factor
	Co	Ni
CYANEX 272	91.5	15.6
PC-88A	91.4	22.0
D2EHPA	90.4	46.9

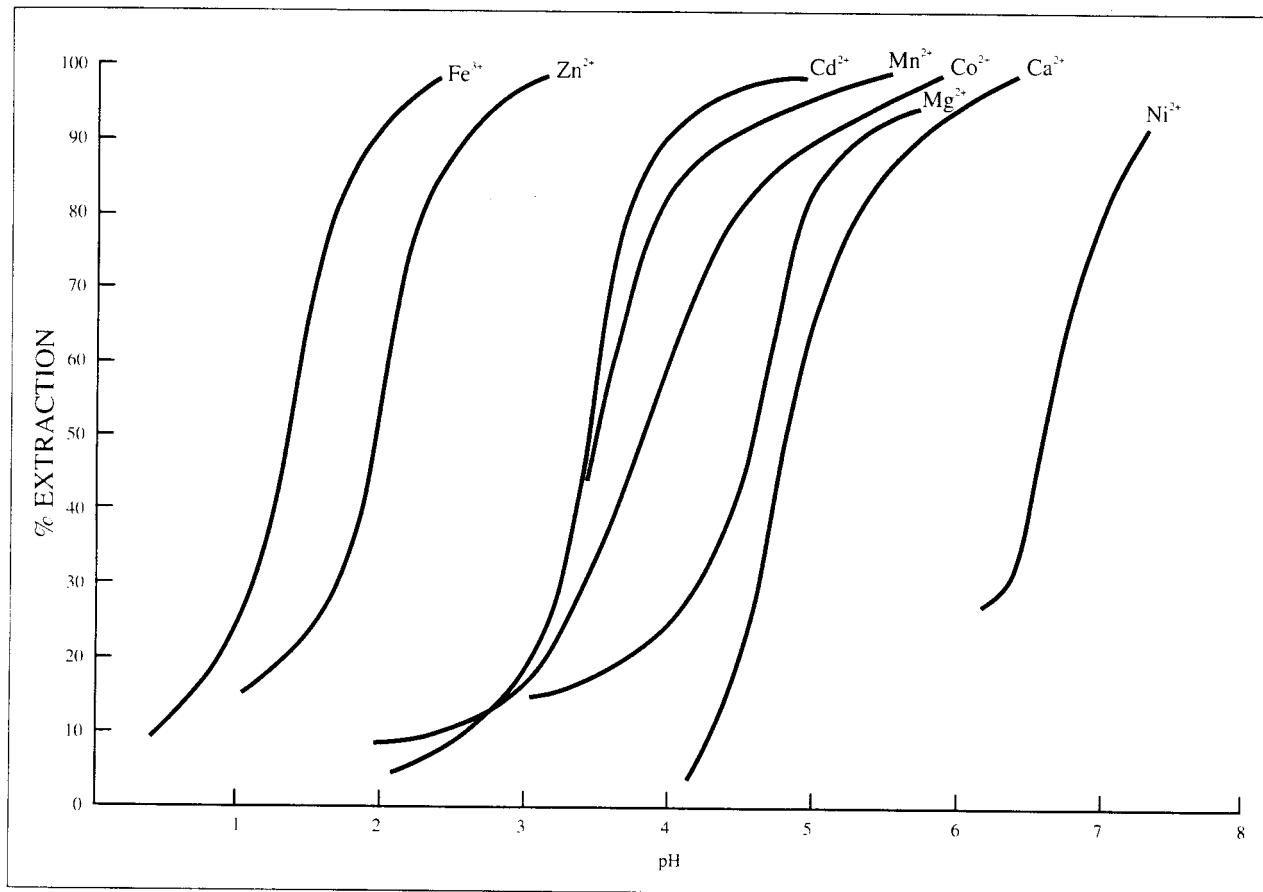

Although CYANEX 272 extractant is designed primarily for cobalt-nickel separations, the data in Table 14 and Figure 3 show that it will extract a variety of metal cations and indicate its potential for other selective separations.

### FIGURE 3 - EXTRACTION OF METALS BY CYANEX 272 FROM SULFATE SOLUTIONS

# ANALYTICAL METHODS

## Analysis for Active Component in CYANEX 272

### Extractant in Organic Solvents

The active component of CYANEX 272 extractant is bis(2,4,4-trimethylpentyl)phosphinic acid. Its concentration in an organic solvent is determined by titration with standard caustic solution.

The extractant contains small quantities of a dibasic impurity (2,4,4-trimethylpentyl phosphonic acid) which also titrates with caustic.

The endpoints are detected potentiometrically.

### Apparatus

pH meter

Magnetic stirrer

Standard laboratory glassware

### Reagents

75 v/o 2-propanol in distilled water

0.1N Standard NaOH solution in 75 v/o 2-propanol

100 g/l H<sub>2</sub>SO<sub>4</sub>

All reagents are AR grade.

### Procedure

1. Contact approximately 50 ml of the solvent to be analyzed with 50 ml of 100 g/l H<sub>2</sub>SO<sub>4</sub> for 5 minutes at 50°C. Separate the phases and allow to stand for 15-30 minutes. Centrifuge the solvent or filter through PS paper\* to remove entrained aqueous.
2. To prepare the analyte solution, pipette a 25 ml aliquot of the solvent and dilute to 200 ml in a volumetric flask with the appropriate diluent (Escaid\*\*, Kermac\*\*\* etc.). Alternatively, the 75 v/o solution of 2-propanol may be used for volume make-up.
3. Pipette 25 ml of the analyte solution into a 150 ad tall-form beaker. Dilute to approximately 50 ml with the 2-propanol solution. Insert the pH electrodes and begin stirring.

\* Phase separation paper available from Whatman Inc., Clifton, NJ.

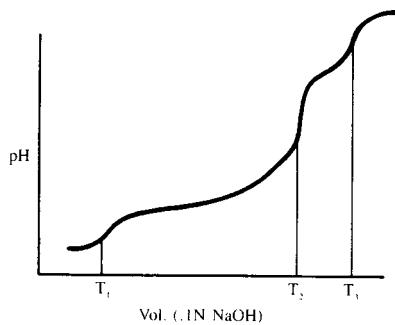

\*\* A product of Exxon Chemical Co., USA

\*\*\* A product of Kerr McGee Refining Corp.

4. Note the initial pH and begin to titrate with 0.1N NaOH. Record the pH as a function of the volume of NaOH added. Three endpoints should be observed. As each endpoint is approached, the incremental addition of NaOH should be reduced to 0.1 ml to facilitate calculation of the titer by the method of second differences.

### Calculation

A typical potentiometric curve is as follows:

The titer  $T_1$  corresponds to the neutralization of sulfuric acid dissolved in the solvent.  $T_2$  represents the neutralization of the phosphinic acid *plus* the reaction of the first of two replaceable hydrogen ions associated with the phosphinic acid. The phosphinic acid is totally neutralized at  $T_3$ .

ml 0.1N NaOH	pH	First Differential	Second Differential
9.8	7.50		
9.9	8.00	50	+40
10.0	8.90	90	+90
10.1	10.70	180	-130
10.2	11.20	50	-40
10.3	11.30	10	

$T_1$  and  $T_3$  may be calculated in an analogous manner.

When all three titers are known, the concentration of bis(2,4,4-trimethylpentyl)phosphinic acid may be determined.

$$\text{bis}(2,4,4\text{-trimethylpentyl}) \text{ phosphinic acid (g/l)} = \frac{[T_2 - (T_3 - T_2) - T_1] \times N(\text{NaOH}) \times 290 \times 1000}{1000 \times \frac{25}{200} \times 25}$$

Similarly the concentration of the phosphonic acid and dissolved sulfuric acid may also be calculated.

$$2,4,4\text{-trimethylpentyl phosphonic acid (g/l)} = \frac{T_2 - T_1 \times N(\text{NaOH}) \times 194 \times 1000}{1000 \times \frac{25}{200} \times 25}$$

$$\text{H}_2\text{SO}_4 (\text{g/l}) = \frac{T_1 \times 49 \times N(\text{NaOH}) \times 1000}{1000 \times \frac{25}{200} \times 25}$$

### NOTES

1. A minimum net titer, i.e.  $[T_2 - (T_3 - T_2) - T_1]$ , of 10 ml is recommended to obtain reproducible results. In this procedure, 10 ml of 01N NaOH is equivalent to approximately 100 g/l concentration of phosphinic acid. Where necessary, the size of the aliquots and dilutions may be varied to ensure a sufficient volume of titrant is consumed.
2. Approximate pH's corresponding to the  $T_1$ ,  $T_2$  and  $T_3$  endpoints are 4, 9 and 11, respectively. However these values may vary depending upon the composition of the solvent. After gaining experience with a system, the NaOH may be added rapidly until the particular endpoint pH is approached and then added in 0.1 ml increments to define the point of inflection in the curve.
3. The concentrations of sulfuric and phosphonic acids in the solvent are usually small and these endpoints may not be observed. In this case  $T_1$  and  $T_3$  should be assigned a value of zero in the calculations. Typically,  $T_1$  and  $T_3 - T_2$ ) will be  $< 0.2$  and  $< 0.1$  ml of 0.1N NaOH, respectively, corresponding to  $< 0.3$  g/l  $\text{H}_2\text{SO}_4$  and  $< 0.6$  g/l phosphonic acid.

$$\text{Then, } T_2 = (10.0 + 0.1) \frac{90}{90 + 130} = 10.04 \text{ ml}$$

## **Analysis for Active Component in CYANEX 272**

### **Extractant in Aqueous Solutions**

The concentration of the active component, bis(2,4,4-trimethylpentyl)phosphinic acid in water is determined by gas chromatography of its silyl derivative.

1. Transfer exactly 10 ml of the aqueous sample into a separatory funnel and acidify with 0.50 ml of 37% hydrochloric acid.
2. Extract this acidified sample with 10 ml of dichloromethane.
3. Concentrate the dichloromethane extract to about 0.5 ml in a Kontes tube concentrator at a temperature of 7-75°C.
4. Dilute the concentrate to exactly 1.5 ml with dichloromethane, add 0.40 ml of Regisil RC-2\*, and silylate at 70-75°C for 10 minutes.
5. Analyze the silylated sample by gas chromatography as described under chromatographic conditions.
6. Calculations:

Bis(2,4,4-trimethylpentyl)phosphinic acid ( $\mu\text{g}/\text{ml}$ )

$$= \frac{A_{\text{Spl}}}{A_{\text{Std}}} \times \frac{C_{\text{Std}}}{10/1.5}$$

Where  $A_{\text{Spl}}$  = area of phosphinic acid peak from sample.

$A_{\text{Std}}$  = area of phosphinic acid peak from standard.

$C_{\text{Std}}$  = concentration (Rg/ml) of phosphinic acid in standard.

\*Regisil-RC-2 is available from Regis Chemical Company, 8210 North Austin Avenue, Morton Grove, Illinois 60053.

### **Chromatographic Conditions**

Instrument	:	Hewlett-Packard 5840 or equivalent
Column	:	10' x $\frac{1}{4}$ " x 2 mm ID glass column packed with 3% SP 2100 on 100/120 mesh Supelcoport
Detector	:	FID
Carrier Gas	:	Helium (20 ml per minute)
Temperatures	:	FID Detector = 300°C Injection port = 250°C Column programmed from 120°C to 270°C at 5° per minute
Sample Injection		
Volume	:	4 microliters
Peak Areas	:	Electronic integration. The compound has
Calibration	:	a retention time of about 15.7 minutes. Calibrate the instrument using standard solutions in dichloromethane containing 2 to 50 micrograms per ml. Then silylate 1.5 ml of this standard solution in the manner described in Procedure 4.

# TECHNICAL PAPERS AND PATENTS

## Technical Papers (listed chronologically)

### 1. Vanadium-uranium extraction from Wyoming vanadiferous silicates

Hayashi, M; Nichols, J.L.; Huiatt, J.L.  
Rep. Invest. - U.S., Bur. Mines RI 8822 Pages 13; (1983)

### 2. Recent developments in the separation of nickel and cobalt from sulfate solutions by solvent extraction

Preston, J.S.  
J.S. Afr. Inst. Min. Metall. 83 6 Pages 126-32; (1983)

### 3. Separation of cobalt and nickel by liquid-liquid extraction and supported liquid membranes with bis(2,4,4-trimethylpentyl)phosphinic acid (CYANEX® 272 Extractant)

Danesi, P.R.; Reichley-Yinger, L.; Cianetti, C.; Rickert, P.G.  
Solvent Extr. Ion Exch. 2 6 Pages 781-814; (1984)

### 4. Extraction equilibria of ammonia with acidic organophosphorus extractants

Inoue, Katsutoshi; Nakayama, Daizo; Watanabe, Yasushi  
Proc. Symp. Solvent Extr. Pages 127-32; (1984)  
(Shizuoka Univ., Hamamatsu, Japan)

### 5. Cobalt-nickel separation by solvent extraction with bis(2,4,4-trimethylpentyl)phosphinic acid

Rickelton, W.A.; Flett, D.S.; West, D.W.  
Solvent Ext. Ion Exch. 2 6; (1984)

### 6. Separation and recovery of cobalt from copper leach solutions

Jeffers, Thomas H.  
J. Met. 37 1 Pages 47-50; (1985)

### 7. Cobalt recovery from copper leach solutions

Jeffers, TH.; Harvey, M.R.  
Rep. Invest. - U.S., Bur. Mines RI 8927 Pages 16; (1985)

### 8. Glycine enhanced separation of cobalt (II) and nickel (II) with bis(2,4,4-trimethylpentyl)phosphinic acid (CYANEX 272® Extractant) by liquid-liquid extraction and supported liquid membranes

Reichley-Yinger, L.; Danesi, P.R.  
Solvent Extr. Ion Exch. 3 1-2 Pages 49-60; (1985)

### 9. Selectivity-structure trends in the extraction of cobalt (II) and nickel (H) by dialkylphosphoric, alkyl alkylphosphonic, and dialkylphosphinic acids

Danesi, Pier R.; Reichley-Yinger, L.; Mason, G.; Kaplan, L.; Horwitz, E.P.; Diamond, H.  
Solvent Extr. Ion Exch. 3 4 Pages 435-52; (1985)

### 10. Determination of the equilibrium constants of organophosphorus liquid-liquid extractants by inductively coupled plasma-atomic emission spectroscopy

Li, Ke An; Muralidharan, S.; Freiser, Henry  
Solvent Extr. Ion Exch. 3 6 Pages 895-908; (1985)

### 11. Some observations on the performance of hollow-fiber supported liquid membranes for cobalt-nickel separations

Danesi, P.R.; Rickert, P.G.  
Solvent Extr. Ion Exch. 4 1 Pages 149-64; (1985)

### 12. Extraction equilibria of ammonia with acidic organophosphorus compounds

Inoue, Katsutoshi; Nakayama, Daizo; Watanabe, Yasushi  
Hydrometallurgy L6 1 Pages 41-53; (1986)

### 13. A composite supported liquid membrane for ultraclean cobalt-nickel separations

Danesi, Pier R.; Reichley-Yinger, L.  
J. Membr. Sci. 27 3 Pages 339-47; (1986)

### 14. Extraction of lanthanide metals with bis(2,4,4-trimethylpentyl)phosphinic acid

Li, Kean; Freiser, Henry  
Solvent Extr. Ion Exch. 4 4 Pages 739-55; (1986)

### 15. A possible use of photoreaction in liquid-liquid extraction of substitution-inert metal complexes.

Extraction of chromium (III) and cobalt (III) complexes

Fu, Xun; Hu, Zhengshui; Liu, Yide; golding, J.A.  
Solvent Extr. Ion Exch. 8 4-5 Pages 573-95; (1990)
- 48. Extraction of divalent metals with bis(2,4,4-trimethylpentyl)phosphinic acid**  
Sastre, A.M.; Miralles, N.; Figuerola, E.  
Solvent Extr. Ion Exch. 8 4-5 Pages 597-614; (1990)
- 49. Improved separation of closely related metal ions by centrifugal partition chromatography**  
Muralidharan, S.; Cai, R.; Freiser, H.  
J. Liq. Chromatogr. 13 18 Pages 3651-72; (1990)
- 50. Analytical utility of coupled transport across a supported liquid membrane**  
Cox, James A.; Bhatnagar, Atul  
Talanta 37 11 Pages 1037-41; (1990)
- 51. Study of uranium removal from groundwater by supported liquid membranes**  
Chiarizia, R.; Horwitz, E.P.  
Solvent Extr. Ion Exch. 8 1 Pages 65-98; (1990)
- 52. The selective recovery of zinc with new thiophosphinic acids**  
Rickelton, W.A., Boyle, R.J.  
Solvent Extr. Ion Exch. 8 6 Pages: 783-97; (1990)
- 53. The significance of diluent oxidation in cobalt-nickel separation**  
Rickelton, W.A., Robertson, A.J., Hillhouse, J.H.  
Solvent Extr. Ion Exch. 9 1/1 Pages 73-84; (1991)
- 54. An improved extractant for separation of ammonia from sour waters by combined stripping and extraction**  
Poole, Loree J.; King, C. Judson  
Solvent Extr. Ion Exch. 9 1 Pages 103-25; (1991)
- 55. Application of supported liquid membranes for removal of uranium from groundwater**  
Chiarizia, R.; Horwitz, E.P.; Rickert, Pg.; Hodgson, K.M.  
Sep. Sci. Technol. 25 13-15 Pages 1571-86; (1990)
- 56. The solvent extraction of europium by some organophosphorus and carboxylic acids**  
Preston, J.S.; Du Preez, A.C.  
Solvent Extr. Ion Exch. 9 2 Pages 237-57; (1991)
- 57. Mechanism of membrane extraction of Molybdenum (VI) with CYANEX® 272**  
CaO, Y and Nakashio, F.  
Huazue Fanying Gongcheng Yu Gongyi, 6, No. 3, Pages 67-73; (1990)
- 58. Organophosphorus compounds in extraction of metal ions**  
Gega, J. and Walkowiak, W.  
Rudy Met. Niezelaz, 36, No. 1, Pages 27-32; (1991)
- 59. Separation of thulium, ytterbium and lutetium by centrifugal partition chromatography with organophosphinic acids**  
Suzuki, Y. et. al.  
Anal. Sci., 7 Pages 249-52; (1991)
- 60. Transport of lanthanoid elements through liquid membrane with organophosphinic acid**  
Nakamura, S. et. al.  
Proc. Symp. Solvent Extr., Pages 45-52; (1991, Japan)
- 61. Solvent extraction of thorium, uranium and some metals from nitrate solution with organophosphinic acid**  
Kenichi, A. et. al.  
Ibid., Pages 181-6
- 62. Solvent extraction characteristics of thiosubstituted organophosphinic acid extractants**  
Sole, K.C. and Hiskey, J.B.  
Hydrometallurgy, 30, No. 1-3, Pages 345-65; (1992)
- 63. Separation of cobalt-zinc, cobalt-manganese and zinc-manganese systems from their binary solutions through supported liquid membrane containing organophosphorus acid as extractant**  
Mohapatra, R. et. al.  
Indian J. Chem., Sect. A., 31A, No. 31A, Pages 389-90; (1992)
- 64. Solvent impregnated resins containing CYANEX® 272. Preparation and application to the extraction and separation of divalent metals**  
Cortins, J. et. al.  
React. Polym., 18, No. 1, Pages 67-75; (1992)

- 65. Comparison of aggregates formed by acidic organophosphorus extractants and metals (nickel and cobalt) in solvent extraction**  
Zhou, N. et. al.  
Process Metals, 7A, Pages 165-70; (1990)
- 66. W/O microemulsions formed by acidic extractants and effect of lanthanides**  
Wu, J. et. al.  
Ibid. Pages 195-200
- 67. The recovery of cobalt and nickel from acidic sulfate solutions in the presence of aluminum**  
Orive, M. et. al.  
Solvent Extr. Ion Exch., 10, No. 5, Pages 787-97; (1992)
- 68. Solvent extraction of iron (111) by bis(2,4,4-trimethylpentyl)phosphinic acid: experimental equilibrium study**  
Miralles, N., et. al.  
Hydrometallurgy, 31, No. 1-2, Pages 1-12; (1992)
- 69. Modification of hollow fibers by impregnation and radiation**  
Belfer, S., et. al.  
Proc. Int. Conf. Ion Exch. (1991).  
Published by Kodansha, Tokyo
- 70. Extraction separation of scandium and iron from hydrochloric acid solutions with bis(2,4,4-trimethylpentyl)phosphinic acid**  
Ma, G., et. al.  
FenxiHuaxe, 20, No.10, Pages 1113-16; (1992)
- 71. Synergistic extraction of iron from sulfuric acid solutions with mixed Kelex 100 - alkyl phosphorus acid extractants**  
Demopoulos, G.P., et. al.  
Solvent Extr. Ion Exch., 11, No. 1, Pages 67-89; (1993)
- 72. Extraction of nickel from aqueous sulfate solution into bis(2,4,4-trimethylpentyl)phosphinic acid, CYANEX® 272. Equilibrium and kinetic studies**  
Golding, J.A., et. al.  
Ibid. Pages 91-118
- 73. The potential for recovery of cobalt from copper leach solutions**  
Sole, K.C.; Hiskey, J.B.  
Proc. Copper 91 - Cobre 91 Int. Symp.,  
Pages 229-43; (1991)
- 74. Extraction rates of terbium, thulium and lutetium with acidic organophosphorus reagents**  
Nakamura, Shigeto; Yamada, Kiyofumi; Akiba, Kenichi  
Proc. Symp. Solvent Extr., Pages 169-74; (1992)
- 75. Extractive separation of copper(II) and zinc(II) using emulsion liquid membrane**  
Cao, Yiming; Goto, Masahiro; Nakashio, Fumiuki  
Mo Kexue Yu Jishu, 12, No. 4, Pages 12016; (1992)
- 76. A spectrophotometric method for the determination of cobalt (11) in organic phases**  
Azimi, A.; Rice, N.M.  
Hydrometallurgy, 32, No.2, Pages 223-32; (1993)
- 77. Simultaneous characterization of extraction equilibria and back extraction kinetics: use of Arsenazo III to characterize lanthanide-bis(2,4,4-trimethylpentyl)phosphinic acid complexed in surfactant micelles**  
Inaba, Kazuho; Muralidharan, Subramaniam; Freiser, Henry  
Anal. Chem., 65, No. 11, Pages 1510-16; (1993)
- 78. Cobalt-nickel separation: the extraction of cobalt (11) and nickel(II) by CYANEX® 301, CYANEX® 302 and CYANEX® 272**  
Tait, Brian K.  
Hydrometallurgy, 32, No.3, Pages 365-72; (1993)
- 79. Solvent extraction of lanthanides by acidic organophosphorus compounds**  
Akiba, Kenichi; Yamada, Hiyofumi; Nakamura, Shigeto  
Nippon Kagaku Kaishi, No. 5, Pages 555-60; (1993)
- 80. Recovery of molybdenum, vanadium, nickel and cobalt from spent hydrodesulfurization catalysts**  
Inoue, Katsutoshi; Pingwei, Zhang; Tsuyama, Hiromi  
Prepr. - Am. Chem. Soc., Div. Pet. Chem., 38,  
No. 1, Pages 77-80; (1993)
- 81. Extraction of rare earth ions with bis(2,4,4-trimethyl pentyl)phosphinic acid**  
Zhang, Xiaofeng; Li, Deoian  
Yingyong Huaxue, 10, No. 4, Pages 72-4; (1993)
- 82. Extraction of metal (titanium, vanadium, molybdenum)oxyz cations by monoacidic phosphates and phosphonates**  
Fu, Xun; et.al.  
Rare Met. (Beijing), 12, No. 2, Pages 142-7; (1993)
- 83. Bioextraction of cobalt from cobaltite**  
Torma, A.E.; Wey, J.E.; Pesic, B.  
Metall (Berlin), 47, No. 7. Pages 648-51; (1993)
- 84. Dissociation constants of organophosphinic acid compounds**  
Maritinez, M.; Miralles, N.; Sastre, A.; Bosch, E.  
Talanta, 40, No. 9, Pages 1339-43; (1993)
- 85. Solvent extraction separation of cobalt(II) from nickel and other metals**  
Gandhi, M.N.; Deorkar, N.V.; Khopkar, S.M.  
Talanta, 40, No. 10, Pages 1535-9; (1993)

86. Solvent-impregnated resins containing di-(2,4,4-trimethylpentyl)phosphinic acid. II. Study of the distribution equilibria of zinc(II), copper(II) and cadmium(II)  
Crotina, J.L.; et. al.  
React. Polym., 21, No. 1-2, Pages 103-16; (1993)
87. Study on rare earth complexes with bis(2,4,4-trimethylpentyl)phosphinic acid  
Li, Qiongqing; et. al.  
JinshuXuebao, 29, No.4, Pages 13251-13257; (1993)
88. Solvent-impregnated resins containing di-(2,4,4-trimethylpentyl)phosphinic acid. I. Comparative study of di-(2,4,4-trimethylpentyl) phosphinic acid adsorbed into Amberlite XAD-2 and dissolved toluene  
Corina, J.L.; et. al.  
React. Polym., 21, No. 1-2, Pages 89-101; (1993)
89. Extraction of thorium(IV) by CYANEXI reagents, PC-88A and their mixtures from aqueous hydrochloric acid media  
Rout, K.C.; Mishra, P.K.; Chakravortty, V.; Dash, K.C.  
Radiochim. Acta, 62, No. 4, Pages 203-6; (1993)
90. Recovery of molybdenum, vanadium, nickel and cobalt from spent dehydrosulfurization catalysts  
Inoue, Katsutoshi; Zhang, Pingwei; Tsuyama, Hiromi  
Prepr. - Am. Chem. Soc., Div. Pet. Chem., 38, No. 1, Pages 77-80; (1993)
91. Thermodynamic function of microemulsions in sodium salt of dialkylphosphoric acid extractant systems  
Fu, Xun; Xin, Huizhen; Hu, Zhengshui; Liu, Zhixiang  
Huaxue Xuebao, 51, No. 12, Pages 1151-6; (1993)
92. Comparative study on kinetic behavior of solvent extraction of  $\text{Co}^{2+}$  and  $\text{Ni}^{2+}$  with organophosphorus extractants  
Zhu, Tun  
HuagongXuebao (Chin. Ed.), 44, No. 3, Pages 343-9; (1993)
93. Vibrational spectra of rare earth complexes of bis(2,4,4trimethylpentyl)phosphinic acid  
Li, Qiongqing; Zeng, Guangfu; Li, Deqian  
Guangpuxue Yu Guangpu Fenxi, 13, No. 6, Pages 19-24; (1993)
94. Sodium salts of D2EHPA, PC-88A and CYANEX® 272 and their mixtures as extractants for cobalt(II)  
Devi, N.B.; Nathsarma, K.C.; Chakravortty, V  
Hydrometallurgy, 34, No. 3, Pages 331-42; (1994)
95. Application of europium(III) extraction with organophosphinic acid to liquid membrane transport  
Nakamura, S.; Sato, A.; Akiba, K.  
J. Radioanal. Nucl. Chem., 178, No. 1, Pages 63-71; (1994)
96. Organophosphinic, phosphonic acids and their binary mixtures as extractants for molybdenum(IV) and uranium(VI) from aqueous HCl media  
Behera, P.; Mishra, S.; Mohanty, I.; Chakravortty, V.  
J. Radioanal. Nucl. Chem., 178, No. 1, Pages 179-92; (1994)
97. Purification of nickel sulfate solutions containing iron copper, cobalt, zinc and manganese  
Senapati, Dabasis; Chaudhury, G. Roy;  
Sarma, PXR. Bhaskara  
J. Chem. Technol. Biotechnol., 59, No. 4, Pages 335-9; (1994)
98. Extraction mechanism of Sc(III) and separation of Th(IV), Fe(III), and Lu(III) with bis(2,4,4-trimethylpentyl) phosphinic acid (A) in n-hexane from sulfuric acid solutions  
Wang, Chun; Li, Deqian  
Solvent Extr. Ion Exch., 12, No. 3, Pages 615-3 1; (1994)
99. Study on transport and separation of Zn(II) from Cd(II) and other metal ions through the emulsion liquid membrane system of CYANEX® 272-Span 80- toluene  
Zou, Changying; Li, Kean; Tong, Shenyang  
Gaochang Xuexiao Huacue Xuebao, 15, No. 2, Pages 185-8; (1994)
100. Synergistic extraction of rare earth elements (III) with BTMPPA and HPMBP  
Sun, Jing; Li, Deqian  
Yingyong Huaxue, 11, No. 3, Pages 49-53; (1994)
101. Extractive spectrophotometric determination of cobalt using CYANEX® 272  
Reddy, B.R.; Sarma, P.V.R. Bhaskara  
Talanta, 41, No. 8, Pages 1335-9; (1994)
102. Solvent extraction of silver by CYANEX® 272, CYANEX® 302 and CYANEX® 301  
Sole, Kathryn C.; Ferguson, Tonya L.; Hiskey, J. Brent  
Solvent Extr. Ion Exch., 12, No. 5, Pages 1033-50; (1994)
103. Effect of the kinetic factors on the efficiencies of centrifugal partition chromatographic separations of tervalent lanthanides with bis(2,4,4-trimethylpentyl)phosphinic acid as extractant  
Inaba, K.; et. al.  
Solvent Extr. Res. Dev., Jpn., 1, Pages 13-29; (1994)
104. Liquid membrane transport of lanthanoid elements using organophosphinic acid  
Nakamura, S., et. al.  
J. Radioanal. Nucl. Chem., 181, No. 2, Pages 281-9; (1994)
105. Kinetics of the extraction of cobalt (II) Using CYANEX® 272  
Liu, Ping; et. al.  
Shandong Daxue Xuebao, 29, No. 3, Pages 320-5; (1994)

- 106. Separation of Zn, Co and Ni using solvent extraction techniques**  
 Cho, E.H. and Dai, P.K.  
*Miner. Metall. Process.*, 11, No. 4, Pages 185-7; (1990)
- 107. Recovery of metals from spent hydrodesulfurization catalysts by liquid-liquid extraction**  
 Zhang, P.; et. al.  
*Energy Fuels*, 9, No. 2, Pages 231-9; (1995)
- 108. Two-phase potentiometric metal extraction titrations of silver (I), copper (II) and cadmium (II) using some cation-exchangers as extractants**  
 Tait, Brian K.  
*Talanta*, 42, No. 1, Pages 137-42; (1995)
- 109. Solvent extraction of copper by CYANEX® 272, CYANEX® 302 and CYANEX® 301**  
 Sole, Kathryn C. and Hiskey, Brent J.  
*Hydrometallurgy*, 37, No. 2, Pages 129-47; (1995)
- 110. Solvent extraction of zinc and cadmium by CYANEX® 272, 301 and 302 extractants**  
 Nayak, Al; et. al.  
*Indian J. Chem. Technol.*, 2, No. 2; (1995)
- 111. Solvent extraction of Sc (III), Zn (IV), Th (IV), Fe (III) and Lu (III) with thiosubstituted organophosphinic acid extractants**  
 Wang, C. and Li, D.  
*Solvent Extr. Ion Exch.*, 13, No. 3, Pages 502-23; (1995)
- 112. Metals recovery from hydrosulfurization catalysts**  
 Delmas, F; et. al.  
*Hydrometall.* '94, Pages 1075-86,  
 Chapman & Hall, London; (1994)
- 113. Sodium salts of D2EHPA, PC-88A and CYANEX®272 and their mixtures as extractants for nickel**  
 Devi, N.; et. al.  
*Scand. J. Metall.*, 23, No. 5/6, Pages 194-200; (1994)
- 114. Application of a new extractant, CYANEX® 272, to liquid membrane separation technology**  
 Zhang, R. and Chen, G.  
*Mo Kexue Yu Jishu*, 15, No. 1, Pages 8-13; (1995)

### Patents (listed chronologically)

- 1. Extraction process for the selective removal of cobalt (II) from aqueous solutions**  
 Rickelton, William Andrew; Robertson, Allan James, Burley, David Richard European Patent Appl. EP 46933 A2 (1982)
- 2. Extraction process for the selective removal of cobalt (II) from aqueous solutions**  
 Rickelton, William Andrew; Robertson, Allan James; Burley, David Richard European Pat. Appl. EP 46940 A2 (1982)
- 3. Selective removal of cobalt (II) from aqueous solutions with phosphinic extractants**  
 Rickelton, William Andrew; Robertson, Allan J.; Burley, David R. US Patent 4348367 (1982)
- 4. Selective extraction of cobalt (II) from aqueous solutions with phosphinic acid extractants**  
 Rickelton, William A.; Robertson, Allan J.; Burley, David R. US Patent 4353883 (1982)
- 5. Bis-(2,4,4-trimethylpentyl)phosphinic acid**  
 Robertson, Allan J.  
 US Patent 4374780 (1983)
- 6. Use of a synergistic extractant mixture for cobalt-nickel separation**  
 Michels, Bernd Dieter; Mathy, Wolfgang  
 German Patent DE 3411885 A1 (1985)
- 7. Separating rare earths by liquid-liquid extraction**  
 Sabot, Jean Louis; Rollat, Alain  
 European Patent Appl. EP 156735 A1 (1985)
- 8. Recovery of zirconium by solvent extraction**  
 Witte, Margaret Kent; Frey, Carla Corinne  
 European Pat. Appl; EP 154448 a 2 (1985)
- 9. Electroplating zinc utilizing primary and secondary zinc sources**  
 Duyvesteyn, Willem P.C.; Hogsett, Robert F.  
 US Patent 696985 (1985)
- 10. Method of solvent extraction of metal**  
 Babjak, Juraj  
 Belgium Patent 903209 A1 (1985)
- 11. Ion-exchange column**  
 Inco Ltd.  
 Japan Kokai Tokkyo Patent 8673842 A2 (1986)
- 12. Separation extraction process for immiscible liquids**  
 Lowenhaupt, Harris; Hollenbeck, Melinda European Pat. Appl. EP 183501 A1 (1986)

- 13. Purification of a nickel solution by two-stage liquid-liquid extraction**  
Ermirio de Moraes, Luis  
Brazil Patent BR 8404685 A (1986)
- 14. Purification of a nickel solution by liquid-liquid extraction for separation of high-purity electrolytic nickel and cobalt**  
Ermirio de Moraes, Luis  
Brazil Patent BR 8404686 A (1986)
- 15. Recovery of cobalt from ammoniacal solutions containing cobalt and nickel**  
Rickelton, William, A.  
US Patent 4619816 (1986)
- 16. Zirconium isotope separation process comprising photo-assisted solvent extraction**  
Peterson, Steven H; Laboda, Edward J. US Patent 4767513 (1988)
- 17. Recovery of metals from electroplating wastewaters by recycling of metals and of extractants**  
Magdics, Alex; Stain, Donald B. European Patent Appl. EP 332447 A1 (1989)
- 18. Separation of nickel and cobalt from sulfate solutions by solvent extraction**  
Chou, Eddie C.; Beckstead, Leo W. US Patent 4900522 (1990)
- 19. Aqueous-organic softening agents containing soluble salts for detergents for use in hard water**  
Lokkesmoe, Keith D.; Besse, Michael E.; Olsen, Keith E. US Patent 4911856 (1990)
- 20. Polymer beads containing immobilized metal extractant**  
Seidel, D.; Jeffers, T.  
US Patent Appl. 429326 AO (1990)
- 21. Germanium extraction from sulfate solution**  
Vliegen, Jean H.M.; Haesebroek, Guy G.L.B.; De Schepper, Achille J.M. PCT International Patent WO 9013677 (1990)
- 22. Extraction of rare earth metals from sulfurous acid solution using organophosphorus compounds**  
Fulford, George D.; Lever, Gordon; Sato, Taichi Canadian Patent 2,021,415 1991
- 23. Recovery of rare earth elements from red mud**  
Fulford, George Dennison; Lever, Gordon; Sato, Taichi Brazil Pedido; BR 9001453 A (1991)
- 24. Extraction of rare earth metals from sulfurous acid solution using organophosphorus compounds**  
Fulford, George D., et. al. Canadian Patent Application 2,021,415 (1991)
- 25. Cadmium and nickel recovery and recycling from spent batteries**  
Agh, J., et. al.  
Hungary Telges, HU 55451, (1991)
- 26. Solvent extraction of metals and selective redox stripping of cations for separation**  
O'Keefe, Thomas J.  
WO 9,116,465 (1991)
- 27. Manufacture of high purity nickel sulfate**  
Siekierski, Slawomir; et. al.  
Poland; PL 15 8842 B1 (1992)
- 28. Recovery of sulfuric acid from metal sulfate-containing waste sulfuric acid**  
Mikami, Yasuie; Iyatomi, Nabuyoshi  
European Pat. Appl.; EP 541002 A1 (1993)
- 29. Recovery of base metals from geothermal brines**  
Duyvesteyn, Willem P.C.  
United States; US 5229003 A (1993)
- 30. Prevention of formation of jarosite and ammonium and alkali double salts in solution extraction in acid leaching of valuable metals**  
Nyman, Bror Goeran; Hultholm, Stig Erik  
Germany Offen.; DE 4320314 A I (1993)
- 31. Extraction of vanadium using phosphinic acid compounds**  
Inoe, Katsutoshi; Cho, Hen; Tsuyama, Hiromi  
Japan Kokai Tokkyo Koho; JP 94192759 A2;  
JP 06192759 (1994)
- 32. Recovery of vanadium from aluminum-containing solutions**  
Inoe, Katsutochi; Cho, Hen; Tsuyama, Hiromi Japan Kokai Tokkyo Koho: JP 94092760 As: JP 06192760 (1994)
- 33. Recovery of molybdenum**  
Inoe, Katsutoshi; Cho, Hen; Tsuyama, Hiromi  
Japan Kokai Tokkyo Koho; JP 94192761 A2;  
JP 06192761 (1994)
- 34. Recovery of nickel and/or cobalt**  
Tsuyama, H.  
Japan Kokai Tokkyo Koho; JP 94264156 A2 (1994)
- 35. Process for the extraction of strontium from acidic solutions**  
Horwitz, E. Philip and Dietz, Mark L.  
U.S. Patent 5344623 (1994)
- 36. Solvent extraction process for the purification of cobalt sulfate as intermediate solution**  
Fittock, John; et. al.  
European Patent Application; EP 651062 A I (1995)

*As of July 24, 1995*

---

## **Health and Safety**

The oral and dermal toxicity of CYANEX 272 extractant is low. CYANEX 272 extractant produces moderate eye and skin irritation upon contact. CYANEX 272 extractant did not produce an allergic dermal reaction in guinea pigs after repeated dermal exposure. This product did not produce mutations in bacteria. CYANEX 272 extractant is toxic to fish and invertebrates and care should be exercised to avoid environmental exposure.

# **CYANEX®301 Extractant**

## **Solvent Extraction Reagent**

- Extracts zinc, cadmium and many other metals at low pH.
- Selective for heavy metals vs alkaline and alkali earths.

# INTRODUCTION

CYANEX 301 is a dialkyl dithiophosphinic acid extractant. This sulfur-containing compound is a much stronger acid than its analogous oxy-acid, CYANEX 272. As such, it is capable of extracting many metals at lower pH (<2). CYANEX 301 extractant does not discriminate between heavy metals in this pH range, however, a high degree of selectivity of extraction of heavy metals vs the alkaline earths is observed. This reagent was originally developed for the selective extraction of zinc from effluent streams also containing calcium, such as those generated in the manufacture of rayon by the viscose process.

## Chemical Structure

The active component of CYANEX 301 extractant is bis(2,4,4-trimethylpentyl)dithiophosphinic acid.

Molecular Weight = 322

## Typical Properties

Appearance	:	Green mobile liquid
Odor	:	Faintly characteristic of hydrogen sulfide
Assay	:	75-80% Bis(2,4,4-trimethylpentyl) dithiophosphinic acid
Specific Gravity	:	0.95 at 24°C
Viscosity	:	78 centipoise at 24°C
Boiling Point	:	Decomposes at 220°C
Pour Point	:	-34°C
Flash Point (Closed Cup)	:	165°F(74°C)
Solubility in Water	:	7 mg/L*

\*Solubility will be lower in aqueous solutions containing dissolved salts.

# MATERIALS OF COMPATIBILITY

---

## Plastics

Samples of the following plastics and rubbers, in the form of tubing, were immersed for 1000 hours at 50°C in glass vessels containing CYANEX 301. The weights and dimensions of the test samples were determined before and after immersion. The following observations were made.

Material	Remarks
PVC (Solvent Grade)	No change in weight or dimensions. Loss of plasticity. Short-term suitability only.
PVC (Heavy Duty Chemical Grade)	15% loss in weight. Color change from transparent to black. Loss of plasticity. Short term suitability only.
PVC (Laboratory Grade)	20% loss in weight. Loss of plasticity. Short term suitability only.
Polyethylene	Suitable. No change significant changes in weight or dimensions
Polypropylene	Suitable. No change in weight or dimensions.
Teflon	Suitable. No change in weight or dimensions.
Fluorocarbon Film*	Suitable. No change in weight or dimensions.
Latex	Unsuitable. Twofold increase in dimensions.
Viton	15% increase in weight.
Fluoroelastomer*	Some loss of flexibility. Short term suitability only.

## Metals

Samples of stainless steel (316 and 304) and mild steel in the form of coupons (approximate dimensions 50 mm x 20 mm x 3 mm) were immersed for 24 hours at 50°C in glass vessels containing CYANEX 301. No detectable corrosion was observed in this period. However, the shiny surfaces of the test samples became dull and the CYANEX 301 was severely discolored. None of the test metals are recommended for extended service.

\*Product of E.I. du Pont de Nemours & Co.

# HYDROLYTIC STABILITY

Experiments were conducted to investigate the stability of CYANEX 301 extractant in contact with hydrochloric and sulfuric acid.

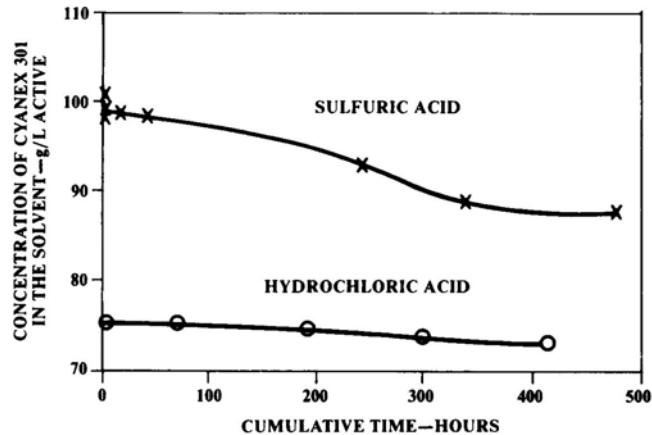

A solvent containing CYANEX 301 extractant was contacted with 75 g/L HCl or 300 g/L H<sub>2</sub>SO<sub>4</sub> in a stirred resin flask at A/O=1 and 50°C for a total of 411 hours (HCl) and 466 hours (H<sub>2</sub>SO<sub>4</sub>).

The flask was equipped with a condenser to minimize diluent evaporation.

Samples of the dispersed phase were removed periodically and the coalesced solvent analyzed by base titration. The results are given in Table 1 and Figure 1.

Although some degradation did occur, the rate appeared to decrease after approximately 300-350 hours in both sulfuric and hydrochloric acids. The observed degradation is approximately equivalent to a plant residence time of 200-250 days.

# PERFORMANCE DATA

## General Extraction Properties

CYANEX 301 extractant is capable of the selective recovery of heavy metals at low pH in the presence of alkaline earths. This is illustrated by the data obtained in some batch, shake-out tests and given in Table 2.

It is also known that this type of compound is capable of extracting cadmium from wet process phosphoric acid<sup>1</sup> and amino acids from fermentation broths.<sup>2</sup>

## Zinc-Calcium Separation

CYANEX 301 extractant was originally developed to recover zinc from the effluent streams of viscose rayon plants.<sup>3</sup> Zinc and calcium are present in this effluent in the form of their sulfate salts at a pH between one and two. The objective was to recover the zinc and recycle it for use in the viscose process acid bath.

It is important to make a highly selective zinc-calcium separation because, if calcium is recycled to the acid bath, gypsum forms and its precipitation has a deleterious effect on the rayon product. One further constraint is that the solvent extraction process must operate at the pH of the effluent. The low dollar value of the zinc and the comparatively low solution tenors, <1 g/L, make it uneconomical to adjust the pH.

Zinc-calcium separation can be effected by such organophosphorus extractants as CYANEX 272 but pH adjustment to approximately 3 is required for complete recovery. In contrast, CYANEX 301 is a stronger acid and complete zinc extraction is possible in the pH range 1-2. Additionally, this reagent exhibits a high selectivity for zinc versus calcium.

This is illustrated by the pH isotherms for CYANEX 301 and CYANEX 272 extractants which are shown in Figure 2. The corresponding data are given in Table 3.

\* A product of Kerr-McGee Corp. U.S.A.

Dithiophosphoric acids are also commercially available. However, acids of this type do not exhibit the high selectivity for zinc versus calcium which is associated with CYANEX 301. This is illustrated by the pH isotherms for di(2-ethylhexyl) dithiophosphoric acid and CYANEX 301 which are plotted in Figure 3. The isotherms were obtained under the same conditions as outlined in Table 3.

## Zinc Extraction and Stripping

A zinc extraction isotherm for a solvent containing 100 g/L CYANEX 301 is plotted in Figure 4 using the data given in Table 4. The isotherm has an almost ideal shape; indicative of low staging requirements. For example, the McCabe-Thiele construction in Figure 4 implies complete recovery from a stream containing 6 g/L Zn in two theoretical stages at A/O=1.

**TABLE 4 - ZINC EXTRACTION ISOTHERM**

Solvent	:	100 g/L CYANEX 301 extractant in Exxsol D-80 diluent
Aqueous	:	9.95 g/L Zn <sup>2+</sup> as the sulfate
Temperature	:	50°C
pH	:	Controlled to 1.50 ± 0.05 with 200 g/L NaOH
Time	:	2 minutes contact after obtaining a stable equilibrium pH

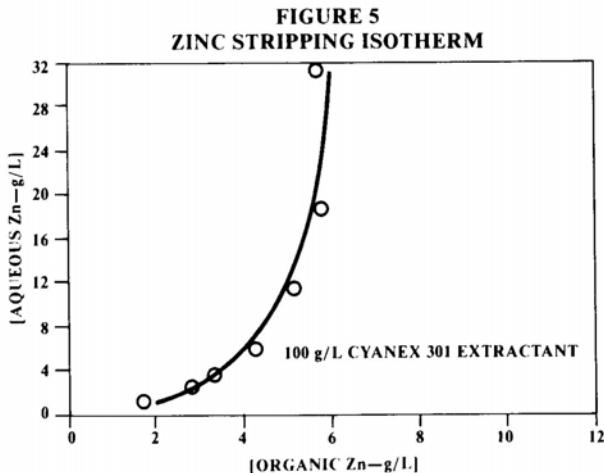

A/O	Equilibrium Zn Concentration (g/L)	
	Organic	Aqueous
0.2	1.99	0
0.5	4.98	0
1	7.58	2.37
2	7.64	6.13

CYANEX 301 is not readily stripped as indicated by the stripping isotherm obtained using 300 g/L H<sub>2</sub>SO<sub>4</sub> as the strip feed (Table 5 and Figure 5). Isotherms of this type are difficult to interpret using standard McCabeThiele constructions. However, a continuous, countercurrent, mini-plant test did reveal that a strip liquor containing in excess of 20 g/L Zn could be produced (Table 6 and Figure 6). A solution of this composition is suitable for recycle in the viscose process.

**TABLE 5 - ZINC STRIPPING ISOTHERM**

Solvent	:	100 g/L CYANEX 301 extractant in Exxsol D-80 diluent loaded to 7.29 g/L Zn by contact with a ZnSO <sub>4</sub> solution

**Figure 6  
Continuous Stripping Test:  
Circuit Profile**

Strip Feed = 300 g/L H<sub>2</sub>SO<sub>4</sub>

Numbers Refer to Zinc Solution Tenors IN g/L

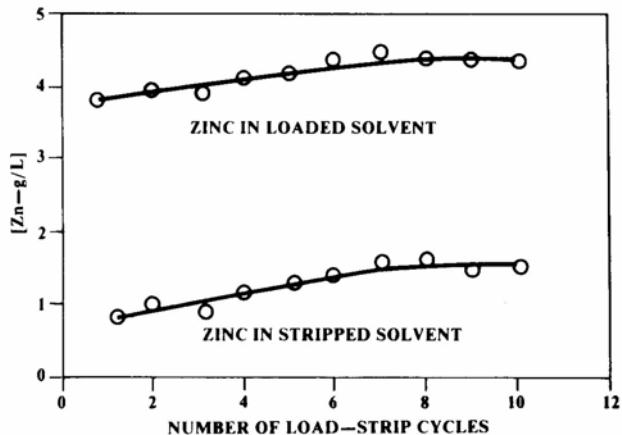

Although zinc is not readily stripped from CYANEX 301, there is no evidence of a zinc accumulation on the solvent which would lead to poisoning. This is illustrated by the results of some cycle tests where zinc was repeatedly loaded and stripped from a solvent containing CYANEX 301. The results are given in Table 7 and plotted in Figure 7.

**TABLE 7 - LOAD-STRIP CYCLE TESTS**

## Recovery of Amino Acids

Dialkylthiophosphinic acids, or their salts, have been shown to be effective in extracting a number of  $\alpha$ -amino acids from fermentation broths. This will be illustrated with particular reference to the recovery of L-phenylalanine using CYANEX 301 extractant.

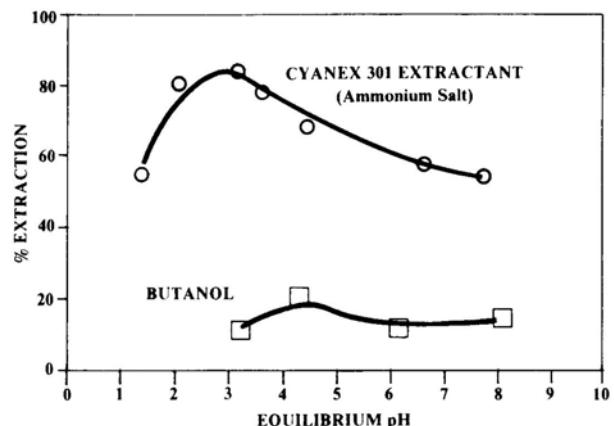

CYANEX 301 is more powerful and less water soluble than other extractants which might be used for the same purpose e.g. butanol. This can be seen by the results of shake-out tests (Table 8 and Figure 8) which show the effect of pH on the extraction of L-phenylalanine with CYANEX 301 and butanol.

**TABLE 8 - EFFECT OF pH ON THE EXTRACTION OF L-PHENYLALANINE**

Solvent	:	(1) 283 g/L CYANEX 301 extractant (ammonium salt) in decanol (2) butanol (undiluted) (3) decanol (undiluted)
Aqueous	:	25.5 g/L L-phenylalanine
Temperature	:	25°C
A/O	:	1
Contact Time	:	5 minutes

	<b>% Extraction</b>	<b>Equilibrium pH</b>
CYANEX 301	55	1.5
	80	2.3
	84	3.1
	80	3.5
	69	4.5
	58	6.5
	54	7.6
Butanol	13	3.4
	20	4.2
	15	6.1
	16	8.1
Decanol	2	3.0
	1	6.7

**FIGURE 8  
EFFECT OF pH ON THE EXTRACTION OF PHENYLALANINE**

Additionally, interpolations from an extraction isotherm obtained with CYANEX 301 (Table 9 and Figure 9) indicate essentially quantitative recovery at A/O=2 in five or six theoretical stages from a fermentation broth containing 20 g/L L-phenylalanine. A polar diluent, such as decanol, is required for good extraction performance. CYANEX 301 was used in its ammonium salt form in the above two series of tests.

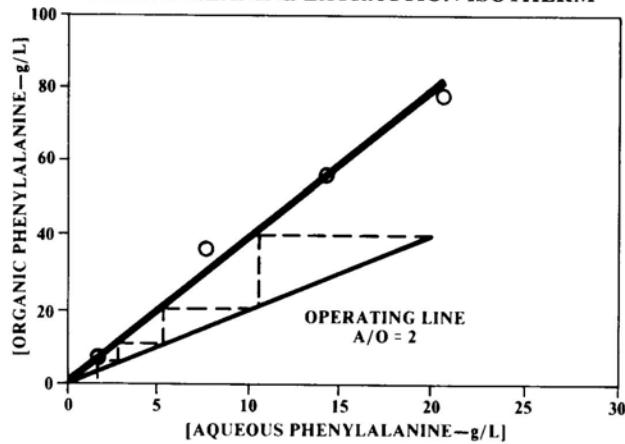

**TABLE 9 -L-PHENYLALANINE EXTRACTION ISOTHERM**

Solvent : 283 g/L CYANEX 301 extractant (ammonium salt) in decanol

Aqueous : 25.5 g/L L-phenylalanine  
Equilibrium pH : 3.0-3.3  
Temperature : 25°C  
Contact Time : 5 minutes

A/O	Equilibrium Concentration (g/L)	
	Organic	Aqueous
0.2	4.8	14.0
2	36.0	79.0
5	56.0	14.4
15	78.0	20.4

**FIGURE 9**  
**PHENYLALANINE EXTRACTION ISOTHERM**

Dialkyl dithiophosphinic acids extract  $\alpha$ -amino acids through a pH dependent mechanism. Extraction is favored at a pH of approximately 3 while stripping is favored at both higher and lower pH (Figure 8). Water, at a pH of approximately 1.3-1.7, has been used successfully to strip L-phenylalanine from reagents similar in composition to CYANEX 301 extractant. A salting-out agent in the strip feed, e.g. 10-20%  $(\text{NH}_4)_2\text{SO}_4$  or  $\text{NH}_4\text{Cl}$ , is required to maintain good phase disengagement characteristics. Data indicate that the amino acid may be selectively separated from the strip liquor by fractional crystallization due to its comparatively low aqueous solubility (approximately 30 g/ L at 25°C).

# ANALYTICAL METHODS

## ANALYSIS IN ORGANIC SOLVENTS

The gas chromatographic procedure described below is suitable for the accurate determination of the concentration of CYANEX 301 in organic solvents, typically containing 5-50 (v/o) CYANEX 301.

The active ingredient present in CYANEX 301 is bis(2,4,4-trimethylpentyl) dithiophosphinic acid. This acid is converted to the corresponding methyl ester for analytical purposes. Trioctylphosphine oxide (TOPO) is employed as an internal standard (ISTD).

### Reagents

1. TOPO (purified-see note 1)
2. Methyl-8® (dimethylformamide dimethylacetal, Pierce Chemical Co.)

### Calibration

The relative response factor of the dithioacid vs. TOPO must be determined. For the analytical conditions below, the RRF was found to have a value of 1.09 (see note 2).

### Procedure

1. Accurately weigh 0.10 g of TOPO and combine with a 1.0 mL aliquot of the organic solution of CYANEX 301 in a Pierce 3 mL Reacti-vial®.
2. Add 0.4 mL of Methyl-80 (see note 3) and maintain the mixture at 65°C, with occasional swirling, for 1 hour.
3. Allow the mixture to cool to ambient temperature, then analyze as described under "Gas Chromatographic Conditions".

### Calculations

$$\text{Concentration of } \text{R}_2\text{PSSCH}_3 = \frac{\text{Area of } \text{R}_2\text{PSSCH}_3 \times 1000 \times 1.09 \times \text{wt. ISTD}}{\text{Area of TOPO}}$$

Where wt. ISTD = wt. TOPO (g)

## Gas Chromatographic Conditions

Instrument	:	Perkin-Elmer Sigma 115 or equivalent
Column	:	Supelco SPB-1 (100% methyl silicone) fused silica capillary column, 30 m x 0.32 mm I.D., 0.25 μ film thickness
Injection Volume	:	0.1 μL
Detector	:	FID
Carrier Gas	:	Helium at 70 psi
Auxiliary Gas	:	Nitrogen at 16 psi
Column Flow	:	1.0 mL/min
Split Ratio	:	60.1
Temperatures	:	°C
Detector	:	290
Injector	:	290
Oven	:	220 (0 min.) programmed to 300 At 10°C/min
Peak Areas	:	Determined by electronic integration

### Notes

1. Pure TOPO can be obtained by recrystallizing commercial grade TOPO from hexane (three recrystallizations are necessary).
2. The RRF value for R<sub>2</sub>PSSH vs. TOPO used here was found to be constant for 5-50 (v/o) solutions of CYANEX 301 in Exxsol D-80.
3. Methyl-8® or equivalent methylation agent is employed to prepare the methyl ester of R<sub>2</sub>PSSH.
4. This method has not been validated.

## ANALYSIS IN AQUEOUS SOLUTION

The procedure is based upon extracting the reagent into methylene chloride and determining the concentration of bis(2,4,4-trimethylpentyl) dithiophosphinic acid by gas chromatography. Trioctylphosphine oxide (TOPO) is used as an internal standard (ISTD).

The solubility of CYANEX 301 extractant in water is 7 mg/L. Soluble losses to a raffinate may be expected to be lower.

### Reagents

1. Methyl-8® Concentrate. Pierce Chemical Co.
2. TOPO (purified-see note 1)

## Calibration

1. Prepare a stock solution of TOPO (ISTD) by accurately weighing ( $\pm 1$  mg) approximately 100 mg of TOPO into a 10 mL volumetric flask. Dilute to 10 mL with methylene chloride and dissolve the TOPO.
2. Determine the relative response factor of the dithiophosphinic acid with respect to the internal standard (TOPO). This is accomplished by accurately weighing these materials, combining with excess Methyl-8® Concentrate, and analyzing as described under "Gas Chromatographic Conditions".

## Procedure

1. A 100 mL aliquot of the aqueous solution is adjusted to pH 1.5 with concentrated HCl and extracted with methylene chloride (3 x 35 mL).
2. The organic extracts are combined and evaporated to 2 mL, transferred to a 3 mL Pierce Reacti-Vial and concentrated with nitrogen to 0.5 mL.
3. Add 70  $\mu$ L of Methyl-8® concentrate, followed by 100  $\mu$ L, of TOPO stock solution (ca. 100  $\mu$ g TOPO).
4. Inject 0.1  $\mu$ L of this solution and analyze as described under "Gas Chromatographic Conditions".

## Calculations

1. Concentration of dithiophosphinic acid in aqueous sample (g/L)

$$= \text{RRF} \times 1.25^* \times \frac{\text{area of methyl dithiophosphinate}}{\text{area of TOPO (ISTD)}} \times \text{wt. ISTD (g)} \times 10$$

\* See note 2

## Gas Chromatographic Conditions

Instrument	:	Perkin-Elmer Sigma 115 or equivalent
Column	:	Supelco SPB-1 (100% methyl Silicone) fused silica capillary Column, 30 m x 0.32 mm I.D., 0.25 $\mu$ film thickness
Detector	:	FID
Carrier Gas	:	Helium at 70 psi, flowrate 1.0 mL/minute
Temperatures	:	$^{\circ}$ C
FID	:	290
Injection Port	:	290
Oven	:	100 to 300 at 15 $^{\circ}$ C/minute, hold Final temp. for 2 minutes
Sample Injection	:	
Volume	:	0.1 $\mu$ L, splitless injection with septum Purge after 30 seconds
Peak Areas	:	Determined by electronic integration

## Notes

1. Pure TOPO can be obtained by recrystallizing commercial grade TOPO from hexane (three recrystallizations are necessary).
2. A factor (1.25) is used to correct for an incomplete extraction of the dithiophosphinic acid from aqueous solutions. If extraction efficiency is 100%, then the factor is unity. It may be determined by spiking the aqueous feed solution with a known quantity of CYANEX 301 and following the steps as described in "Procedure".
3. Retention times for TOPO and methyl dithiophosphinate are approximately 14 and 10 minutes, respectively.
4. The detection limit is approximately 1 mg/L.
5. This method has not been validated.

# INTRODUCTION

CYANEX 302 extractant is a monothiophosphinic acid. Selective metal separations can be performed at a lower pH than is possible with its oxy-acid analogue, CYANEX 272 extractant. This property is particularly useful when metals are present at low concentration and pH adjustment is uneconomical.

## Chemical Structure

The active component of CYANEX 302 extractant is bis(2,4,4-trimethylpentyl)monothiophosphinic acid.

Molecular Weight = 306

## Typical Properties

Appearance	: Pale yellow liquid
Odor	: Faintly characteristic of Hydrogen sulfide
Assay	: 84% Bis(2,4,4-trimethyl-Pentyl)-monothiophosphinic acid
Specific Gravity	: 0.93 at 24°C
Viscosity	: 195 centipoise at 24°C
Pour Point	: -20°C (approximately)
Flash Point (Closed Cup)	: .205°F (>96°C)
Autoignition Temperature	: 739°F (393°C)
Solubility in Water	: 3 mg/L at 50°C

## MATERIALS OF COMPATIBILITY

### Plastics

Samples of the following plastics and rubbers, in the form of tubing, were immersed for 800 hours at 50°C in glass vessels containing CYANEX 302 extractant. The weights and dimensions of the test samples were determined before and after immersion. The following observations were made.

Material	Remarks
PVC (Solvent Grade)	Loss of plasticity. Short term Suitability only.
Polyethylene	Suitable. No significant change in weight or dimensions.
Teflon*	Suitable. No significant change in weight or dimensions.
Fluorocarbon Film	
Latex	Unsuitable. Swelling with loss of mechanical strength.
Red and Black Gum Rubber	Unsuitable. Swelling with loss of mechanical strength.
Neoprene	Suitable. Small increase in weight and dimensions.

### Metals

Samples of the following metals in the form of coupons (approximate dimensions 50 mm x 25 mm x 3 mm) were immersed for 700 hours at 50°C in glass vessels containing CYANEX 302 extractant. The following observations were made.

Metal	Remarks
Stainless Steel (316)	No detectable corrosion.
Stainless Steel (304)	No detectable corrosion.
Mild Steel	Corrosion at approximately 2 mils per year. Although the corrosion rate was low the extractant became discolored and the use of mild steels is not recommended.

\*Product of El DuPont de Nemours & Co.

## HYDROLYTIC STABILITY

A solvent containing CYANEX 302 extractant was contacted for 640 hours in a stirred resin flask with 300 g/L H<sub>2</sub>SO<sub>4</sub> at 50°C and A/O=1. The flask was equipped with a condenser to minimize diluent evaporation.

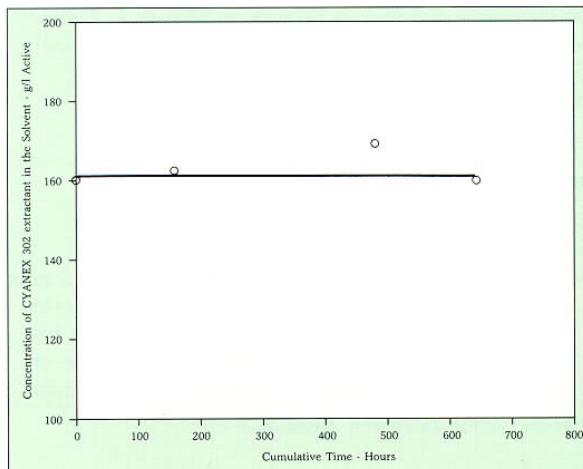

Samples of the dispersed phase were removed periodically and the coalesced solvent analyzed by gas chromatography. The results are given in Table 1 and Figure 1.

**TABLE 1**  
**Stability Testing**

Solvent	:	CYANEX 302 extractant in Exxsol*
		D-80 diluent
Aqueous	:	300 g/L H <sub>2</sub> SO <sub>4</sub>
Phase Contact	:	50°C at A/O=1
<u>Cumulative Time</u> <u>(Hours)</u>		<u>Solvent Analysis</u> <u>(g/L Active)</u>
0		160
160		162
480		169
640		160

\*Product of Exxon Co., U.S.A.

**FIG. 1 — HYDROLYTIC STABILITY**

No significant degradation of the extract was observed. The concentration of tris(2,4,4-trimethylpentyl)phosphine oxide in the solvent (approximately 20 g/L) did not change during the course of the experiment: indicating that diluent losses through evaporation were negligible. The latter compound is an impurity in CYANEX 302 extractant.

## PERFORMANCE DATA

### General Extraction Properties

The fundamental difference between CYANEX 302 extractant and its oxy analogue - CYANEX 272 extractant - is that metal separations can be carried out at lower pH. Displacement of the pH functionality of this extractant toward the acid side is derived from the presence of sulfur in the molecule. This is illustrated by the results of shake-out tests in Table 2 and Figure 2 showing the effect of pH on metal extraction. CYANEX 301 extractant, the dithio analogue, is an even stronger acid than CYANEX 272 or 302 extractants.

**TABLE 2**  
**Extraction From Single Metal Sulfate Solutions**

Solvent	:	0.6 M extractant in Exxsol D-89 diluent
Aqueous	:	0.015 M metal as the sulfate salt
pH Control	:	NH <sub>4</sub> OH or H <sub>2</sub> SO <sub>4</sub> as appropriate
Phase Contact	:	A/O = 1 at 50°C, aqueous continuous

Ca(2+) No extraction detected in the pH range 0.98 to 5.01

Mg(2+) No extraction detected in the pH range 0.65 to 5.30

Cd(2+) quantitatively extracted: pH 0.85 to 4.98

Cu(2+) quantitatively extracted: pH 1.39 to 2.10

**FIG. 2 – EXTRACTION FROM SINGLE METAL SULFATE SOLUTIONS**

Another noteworthy difference between CYANEX 302 and 272 extractants is the ability of CYANEX 302 extractant to separate cobalt (2+) from manganese (2+).

### Zinc-Calcium Selectivity

As a result of its good hydrolytic stability, selectivity and comparatively low pKa, CYANEX 302 extractant is ideally suited to the recovery of metals from effluents or where these metals are present as impurities in process solutions.

This will be illustrated by reference to the selective recovery of zinc from low-pH sulfate solutions also containing calcium. Effluents of this composition are generated in the manufacture of rayon by the viscose process. Zinc can be recycled but must be free from calcium which is deleterious to the process (gypsum precipitates).

A series of shake-out tests was conducted to determine the effect of three process variables, (temperature, pH and diluent aromaticity) on zinc-calcium selectivity. The results are given in Tables 3, 4 and 5.

**TABLE 3  
Effect of Temperature on Zn-Ca Selectivity**

Solvent	:	0.6M extractant on Exxsol D-80 diluent
Aqueous	:	1.04 g/L Zn and 0.090 g/L Ca as sulfates
Phase Contact	:	5 mins at A/O=1
Temperature	:	20, 30, 40, 50 and 60°C
Equilibrium pH	:	1.70±0.01

Temperature °C	% Extraction	
	Zn	Ca
20	99.0	0
30	99.0	0
40	99.0	0
50	99.0	0
60	99.0	0

**TABLE 4  
Effect of pH on Zn-Ca Selectivity**

Solvent	:	0.6M CYANEX 302 extractant in a Mixture of Exxsol D-80 diluent and Toluene (50/50 v/o)
Aqueous	:	1.00 g/L Zn and 0.097 g/L Ca as sulphate
Phase Contact	:	5 mins at A/O = 1 and 24°C
pH	:	Between 1 and 3 (controlled with H <sub>2</sub> SO <sub>4</sub> or NH <sub>4</sub> OH, as appropriate)

Equilibrium pH	% Extraction	
	Zn	Ca
1.00	57.0	0
1.49	93.2	0
2.00	99.2	2.0
2.50	100	2.0
3.03	100	2.0

**TABLE 5  
Effect of Diluent Aromaticity on Zn-Ca Selectivity**

Solvent	:	0.6M extractant in Exxsol D-80 Diluent, toluene and a 50/50 volume Mixture of Exxsol D-80 diluent and Toluene
Aqueous	:	1.02 g/L Zn and 0.10 g/L Ca as sulfates
Phase Contact	:	5 mins at A/O = 1 and 24°C
Equilibrium pH	:	1.70 ± 0.02 (No control necessary)

Diluent Aromaticity (v/o)	% Extraction	
	Zn	Ca
100	96.1	0
50	98.0	0
0	99.0	0

Temperature in the range 20-60°C had no effect. Selectivity increased with increasing pH in the range 1-3. However, in the operating pH range (2.0-0.5), the effect was not significant. The presence of aromatics (toluene) in the diluent depressed zinc extraction without changing calcium extraction. Again, the magnitude of the effect was small.

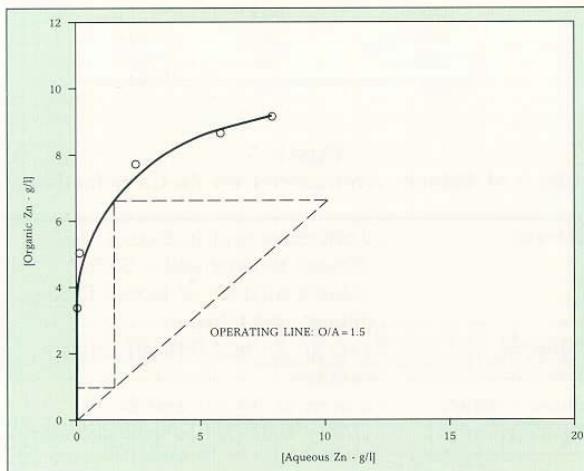

Isotherms indicated low staging requirements in extraction (Table 6, Figure 3) and stripping (Table 7, Figure 4).

# ANALYTICAL METHODS

## ANALYSIS IN ORGANIC SOLVENTS

The gas chromatographic procedure described below is suitable for the accurate determination of the concentration of CYANEX 302 extractant in organic solvents, typically containing 5-50 v/o CYANEX 302 extractant.

The active ingredient present in CYANEX 302 extractant is bis(2,4,4-trimethylpentyl)-monothiophosphinic acid -  $R_2P(S)OH$ . This acid is converted to the corresponding methyl ester for analytical purposes. Trioctylphosphine oxide (TOPO) is employed as an internal standard (ISTD).

### Reagents

1. TOPO (purified -see note 1)
2. Methyl-8 concentrate (dimethylformamide dimethylacetal, Pierce Chemical Co.).

### Calibration

The relative response factor of the monothioacid vs. TOPO must be determined. For the analytical conditions below, the RRF was found to have a value of 1.04.

### Procedure

1. Centrifuge the solvent to be analyzed or filter through PS paper to remove entrained aqueous or suspended solids.
2. Accurately weigh 0.10 g TOPO and combine with a 1.0 mL aliquot of the organic solution of CYANEX 302 extractant in a Pierce 3 ml Reacti-vial glass bottle.
3. Add 0.5 ml of Methyl-8 (see note 3) and maintain the mixture at 65°C, with occasional swirling, for one hour.
4. Allow the mixture to cool to ambient temperature, then analyze as described under "Gas Chromatographic Conditions." Perform the analysis within three hours after addition of the Methyl-8 reagent.

### Calculations

$$\text{Concentration of } R_2P(S)OH \text{ (g/L)} = \frac{\text{Area of } R_2P(S)OCH_3 \times 1000 \times 1.04 \times \text{wt. ISTD}}{\text{Area of TOPO}}$$

### Gas Chromatographic Conditions

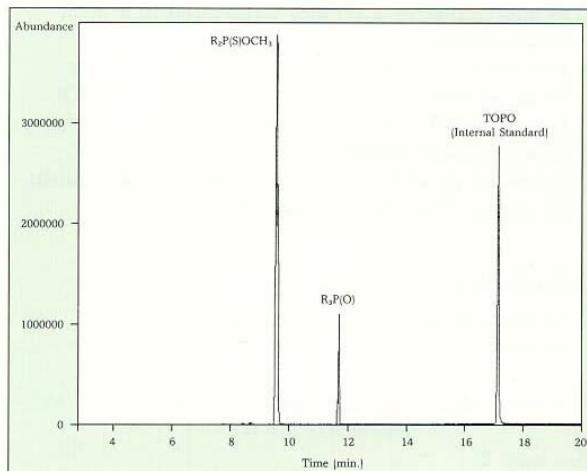

Instrument	:	Perkin Elmer Sigma 115 or equivalent
Column	:	Supelco SPB-5*, fused silica capillary column, 30 m x 0.32 mm x 0.25 $\mu$ film thickness
Injection Volume	:	0.2 $\mu$ L
Detector	:	FID
Carrier Gas	:	He, 70 psi
Auxilliary Gas	:	N <sub>2</sub> , 16 psi
Column Flow	:	1.5 mL/min.
Split Ratio	:	60.1
Temperatures	:	
Detector	:	290°C
Injector	:	290°C
Oven	:	200°C (0 min.) programmed to 300°C at 5°/min.
Peak Areas	:	Determined by electronic integration

\*Product of Supelco Canada, Ltd.

### Notes

1. Pure TOPO may be obtained by recrystallizing commercial grade TOPO from hexane (three recrystallizations are necessary).
2. The RRF value for  $R_2P(S)OH$  vs. TOPO used here was determined for a 10 v/o solution of CYANEX 302 extractant in toluene.
3. Methyl-8 or equivalent methylating agent is employed to prepare the methyl ester of  $R_2P(S)OH$ .
4. This method has not been validated.

FIG. 1A — TYPICAL CHROMATOGRAM OF CYANEX 302 EXTRACTANT

## ANALYSIS IN AQUEOUS SOLUTIONS

The procedure is based upon extracting the reagent into methylene chloride and determining the concentration of bis(2,4,4-trimethylpentyl)monothiophosphinic acid by gas chromatography. Trioctylphosphine oxide (TOPO) is used as an internal standard.

The solubility of CYANEX 302 extractant in water is 3 mg/L. Soluble losses to raffinates may be expected to be lower.

### Reagents

1. Methyl-8 concentrate. (Pierce Chemical Co.)
2. TOPO (purified - see note 1.)

### Calibration

1. Prepare a stock solution of TOPO (ISTD) by accurately weighing ( $\pm 1$  mg) approximately 200 mg of TOPO into a 10 ml volumetric flask. Dilute to the mark with methylene chloride and dissolve the TOPO.
2. Determine the relative response factor of the monothiophosphinic acid with respect to the internal standard (TOPO). This is accomplished by accurately weighing these materials, combining with excess Methyl-8 concentrate, and analyzing as described under "Gas Chromatographic Conditions."

### Procedure

1. Filter the aqueous solution to remove entrained organic.
2. A 100 mL aliquot of the aqueous solution is adjusted to pH 1.0 with concentrated HCl and extracted with methylene chloride (2 x 100 mL).
3. The organic extracts are combined and evaporated to approximately 2 ml and transferred to a 3 ml Pierce Reactivial.
4. Add 50  $\mu$ l of Methyl-8 concentrate, followed by 25  $\mu$ L of TOPO stock solution (ca. 0.5 mg TOPO). Let the solution stand at ambient temperature for approximately 15 minutes.
5. Inject 1.0  $\mu$ L of this solution and analyze as described under "Gas Chromatographic Conditions."

### Calculations

1. Concentration of monothiophosphinic acid in aqueous sample (g/L)

$$= \text{RRF} \times 1.18^* \times \frac{\text{area of } R_2P(S)\text{OCH}_3}{\text{area of TOPO (ISTD)}} \times \text{wt. ISTD (g)} \times 10$$

### Gas Chromatographic Conditions

Instrument	:	Perkin-Elmer Sigma 115 or Equivalent
Column	:	Supelco SPB-1* (100% methyl silicone) fused silica capillary column, 30 m x 0.32 mm ID x 0.25 $\mu$ film thickness
Detector	:	FID
Carrier Gas	:	Helium at 70 psi, flowrate 1.5 mL/min
Temperatures	:	
FID	:	290°C
Injection Port	:	290°C
Oven	:	150°C, programmed to 300°C at 10°/min., hold 5 minutes
Sample	:	
Injection Volume	:	1.0 $\mu$ L, splitless injection with septum purge after 30 seconds
Peak Areas	:	Determined by electronic integration

\*Product of Supelco Canada, Ltd.

### Notes

1. Pure TOPO may be obtained by recrystallizing commercial grade TOPO from hexane (three recrystallizations are necessary).
2. A factor (1.18) is used to correct for an incomplete extraction of the monothiophosphinic acid from aqueous solutions. If extraction efficiency is 100%, then the factor is unity. It may be determined by spiking the aqueous feed solution with a known quantity of CYANEX 302 extractant and following the steps described in "Procedure."
3. The detection limit is approximately 1 mg/L.
4. This method has not been validated.

\* See note 2

## **HEALTH AND SAFETY**

CYANEX 302 extractant has a moderate degree of oral and a low degree of dermal toxicity. Direct contact with this material may cause severe skin and mild eye irritation. CYANEX 302 extractant was determined to be nonmutagenic in the Ames test. For more detailed health hazard information and handling precautions, please consult the Material Safety Data Sheet.

# INTRODUCTION

CYANEX 471X extractant is a new phosphine-based extractant developed by Cyanamid for the hydrometallurgical industry.

This reagent is particularly useful for the selective recovery of silver and in the separation of palladium from platinum.

## Chemical Structure

Triisobutylphosphine Sulfide (TIBPS)

## Typical Properties

Appearance	: Off-white crystalline solid
Specific Gravity at 22°C	: 0.91
Melting Point	: 58-59°C
Solubility in Distilled Water	: 43 µg/mL at 24°C

## Stability

Some hydrolysis of CYANEX 471X extractant (triisobutylphosphine sulfide) to the oxide or other oxygen bearing degradation products might be expected on continuous contact with sulfuric or hydrochloric acid systems. However, as can be seen in Tables 1 and 2, we found that no measurable degradation (detectable by gas chromatography) occurs even at elevated temperatures for 30-40 day exposure periods. Furthermore, gas chromatographic analysis of the aqueous phase at the completion of each test also failed to detect any degradation products.

Solvent : 25.9 g/L CYANEX 471X extractant

## Toxicity

The acute oral (rat) and acute dermal (rabbit) LD<sub>50</sub> values for the active phosphine sulfide contained in CYANEX 471X extractant are 10,000 mg/kg of body weight. No significant skin irritation and only mild eye irritation were produced during primary irritation studies with rabbits. The sulfide was determined to be non-mutagenic in the Ames *Salmonella* Assay.

TABLE 1 – IN CONTACT WITH SULFURIC ACID

# SILVER RECOVERY

## Background

CYANEX 471X extractant is a solvating reagent and will extract silver from sulfate, nitrate and chloride systems. Note that, although silver chloride is essentially insoluble in water, it does exhibit finite solubility in chloride solutions, as follows:

Temperature : 25°C

HCl (g/L)	AgCl(g/L)	Specific Gravity
235	1.12	1.10
372	3.91	1.16
443	4.44	1.19

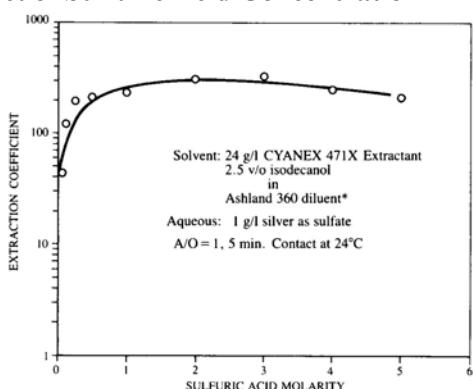

The majority of the world's silver is produced as a by-product from the mining of base metals. Silver may, therefore, form a component of many aqueous streams when the treatment of such ores or secondary sources involves hydrometallurgical processing.

While the source of silver may be a sulfate, chloride or nitrate liquor containing a combination of copper, lead, and other metals, the data cited describes specifically the selective recovery of silver from acid sulfate solutions of zinc or copper.

## Effect of Acidity

Since acidity has a significant impact on the extraction power of solvating reagents in many systems (e.g., TBP-uranyl nitrate), the effect of sulfuric acid concentration on silver extraction with CYANEX 471X extractant was studied. Results and experimental conditions are given in Figure 1.

**FIGURE 1**  
**Effect of Sulfuric Acid Concentration**

As can be seen, silver extraction was essentially quantitative for initial acid concentrations in excess of 0.015M. The small decrease in the extraction coefficient observed with the 4 and 5M acid solutions, may have resulted from a crowding effect due to co-extraction of sulfuric acid.

On the basis of these results the extraction of silver with CYANEX 471X extractant should not be affected by the different sulfuric acid concentrations which might be encountered in commercial practice.

Extraction tests with CYANEX 471X extractant dissolved in Ashland\* 360 diluent produced emulsions even when isodecanol was used as a modifier. For this reason, a number of other diluent-modifier combinations were examined under the following conditions.

Solvent	: 24 g/L CYANEX 471X extractant, 0 and 5 v/o modifier in the diluent
Aqueous	: 1 g/L Ag as $\text{Ag}_2\text{SO}_4$ , 10 g/L $\text{H}_2\text{SO}_4$
A/O	: 1
Contact Time	: 5 minutes
Temperature	: 24°C
Diluents	: Varsol DX-3641**, Kermac 470B***, Aromatic 150**
Modifiers	: Isodecanol, Tributylphosphate, D2EHPA

Silver extraction was essentially quantitative in all of the examined systems. However, only those solvents modified with D2EHPA solubilized the extracted complex. This may be due to the displacement of bonded water from the silver ion by the stronger OH ligand present in D2EHPA. The OH group in water is a stronger ligand than in isodecanol and, conceivably, could account for the failure of the alcohol modifier. In later experiments, p-nonylphenol, which like D2EHPA contains an acidic OH group, also proved to be an effective modifier.

\* A product of Ashland Chemical Co.

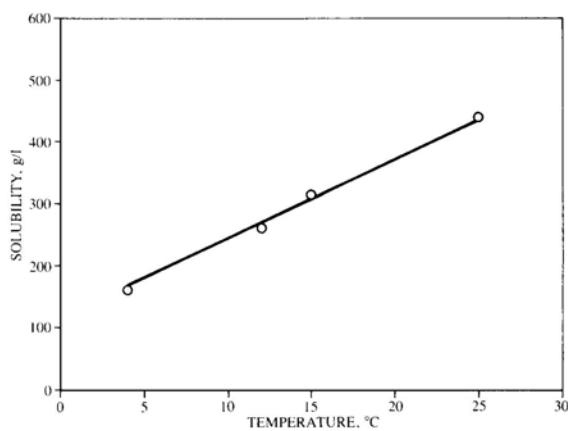

\*\* A product of Exxon Co., USA.

\*\*\* A product of Kerr McGee Refining Corp.

Solvent poisoning may occur in a system where the pH is sufficiently high to allow D2EHPA to extract cations such as  $\text{Fe}^{3+}$ . In this event, p-nonylphenol is the phase modifier of choice.

Based on its performance, availability and the general preference for aliphatic over aromatic diluents, Varsol DX3641 is recommended. The solubility of CYANEX 471X extractant in this diluent is shown as a function of temperature in Figure 2.

**FIGURE 2**  
**Solubility in Varsol DX-3641 Diluent**

### Extraction Isotherms

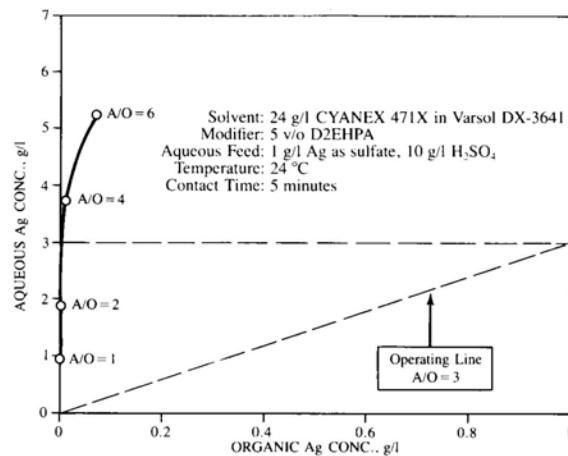

A silver extraction isotherm was generated by contacting an aqueous and solvent feed solution at several A/O ratios. This isotherm along with experimental conditions is shown in Figure 3.

McCabe-Thiele interpolations indicated essentially quantitative silver extraction in one theoretical stage at  $\text{A}/\text{O} = 3$  from an aqueous solution containing 1 g/L silver. The inflection in the isotherm suggested that the loading capacity of the solvent (0.1 M in extractant) was being approached at approximately 5.2 g/L Ag ( $0.024\text{M Ag}_2\text{S}_4$ ).

The solvent loaded to 5.2 g/L Ag darkened after several hours standing; possibly a result of the minimal amount of acid which would be expected to co-extract under these conditions and the consequent hydrolysis of the extracted silver complex.

The solvent loaded to 3.7 g/L Ag at  $\text{A}/\text{O} = 4$  was observed for five days and remained homogeneous.

**FIGURE 3**  
**Silver Extraction Isotherm**

### Stripping Isotherm

Theoretically, stripping may be achieved with any compound which forms a strong ligand with silver. However, reagents proposed in the past for laboratory use have been unsatisfactory for a number of reasons; e.g. cyanide solutions in acid systems are toxic and ammonia tends to form explosively unstable fulminates.

For this reason, it was necessary to find a new stripping system for this class of compounds. The discovery that thiosulfate fixer solutions were effective made possible the commercialization of CYANEX 471X extractant. These reagents are non-toxic and form stable complexes with silver from which silver metal may be recovered by well established processes (see Appendix A). The recovery of metallic silver regenerates the strip liquor which can be recycled. This contributes significantly to lowering process costs.

A silver stripping isotherm was constructed by contacting loaded solvents at various A/O ratios with a stabilized thiosulfate solution of the following composition:

COMPONENT	QUANTITY
Water (at 50°C)	600 mL
Sodium Thiosulfate, $\text{Na}_2\text{S}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$	240 g
Sodium Sulfite $\text{Na}_2\text{SO}_3$	15 g
Acetic Acid (28%)*, $\text{CH}_3\text{COOH}$	48 mL
Boric Acid (Crystal)**, $\text{H}_3\text{BO}_3$	7.5 g
Aluminum Potassium Sulfate, $\text{A1K} (\text{SO}_4)_2 \cdot 12\text{H}_2\text{O}$	15 g
Cold Water to make	1 liter

The following procedure was adopted to prepare the solution from its components.

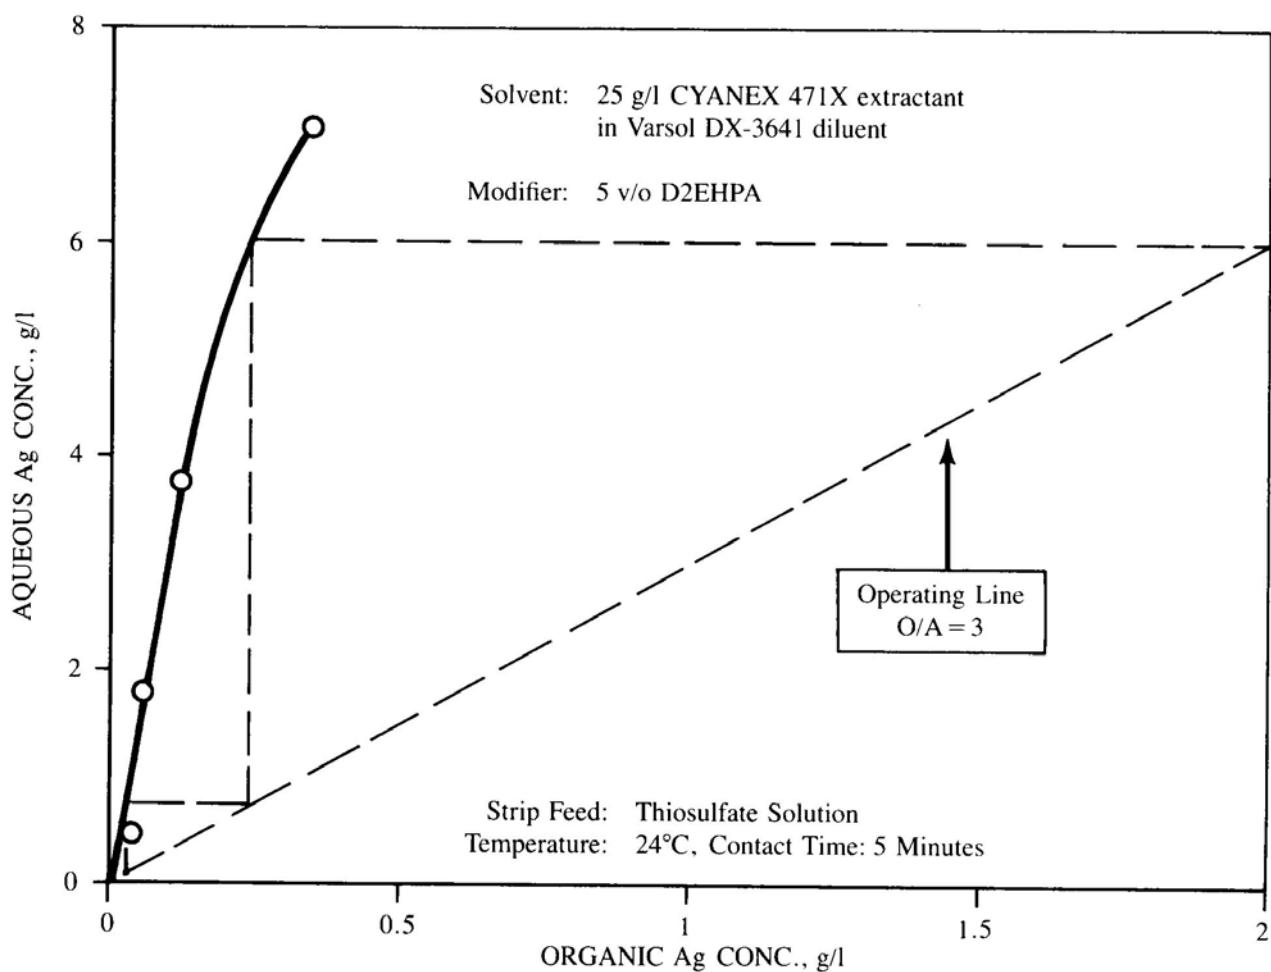

- Sodium thiosulfate was dissolved in the specified volume of warm water.
- The remaining components were added in the given order; ensuring that each was dissolved before adding the next.

The isotherm, plotted in Figure 4, indicates efficient stripping.

\* To make 28% acetic acid, dilute 3 parts of glacial acetic with 8 parts of water.

\* Crystalline boric acid should be used as specified. Powdered boric acid dissolves only with great difficulty and its use should be avoided.

**FIGURE 4**  
**Silver Stripping Isotherm**

## Selectivity in Continuous Testing

The selective extraction of silver from a copper-zinc sulfate solution was investigated in a continuous, counter-current, mini-plant test using a Bell Engineering mixer-settler apparatus. The solvent was recycled through two extraction and two stripping stages. The thiosulfate strip feed was not recycled. Operating conditions and results are given in Table 3.

**TABLE 3 - CONTINUOUS, COUNTER-CURRENT TESTING OPERATING CONDITIONS**

Mixer Volume	:	180 mL
Settler Volume	:	620 mL
Settler Area	:	88.5 cm <sup>2</sup>
Solvent	:	24 g/L CYANEX 471X extractant, 5 v/o D2EHPA in Varsol DX-3641 diluent
Aqueous Feed	:	0.97 g/L Ag <sup>+</sup> , 6.06 g/L Zn <sup>2+</sup> , 10.3 g/L Cu <sup>2+</sup> (as sulfates) 10 g/L H <sub>2</sub> SO <sub>4</sub>
Extraction Stages	:	2
Strip Stages	:	2
Solution Flow- rates (mL/min)		
Aqueous Feed	:	50
Solvent	:	50
Strip Feed	:	50
Continuous Phase	:	Organic (extraction and stripping)
Temperature	:	24°C
Duration of Test	:	4 hours

### Analysis

Raffinate	Ag Recovery	Strip Liquor (g/L)		
		Ag	Zn	Cu
<0.001 g/L Ag	99.9%	0.97	0.012	0.006
Separation Factors:	(Ag/Zn)=0.5 x 106 (Ag/Cu)=1.5x106			

The high separation factors are indicative of the extremely selective separations which can be achieved with CYANEX 471X extractant.

## Aqueous Solubility

Although CYANEX 471X extractant has very little solubility in water, there will be some losses and these will vary from system to system depending upon the composition of the aqueous phase and other operating parameters.

For example, losses to the raffinate and strip liquor described in the continuous test were determined to be 6 µg/mL and <1 µg/mL, respectively. Solubility of the corresponding triisobutyl oxide in water is approximately 40 g/L. If any long-term hydrolysis to the oxide does occur, this compound will be lost to the aqueous phase through preferential solubility.

# SEPARATION OF PALLADIUM FROM PLATINUM

## Background

CYANEX 471X extractant has potential in the separation of palladium from chloride solutions containing platinum (IV) and palladium (II). As with silver, palladium extraction occurs through a solvating mechanism. Similarly, stabilized thiosulfate solutions are an effective strip feed. If present, Ag, Hg (II), Au (III) will be co-extracted with palladium.

The following information on palladium extraction, stripping and palladium/platinum separation will be of use in the design of preliminary batch experiments.

## Extraction Isotherms

The results of two extraction isotherms are shown in Table 4. One was generated with an unmodified solvent and the other using a solvent modified with p-nonylphenol.

In the absence of the modifier, the extracted palladium complex precipitated as a dark brown solid at loadings of 11.2 and 22.4 g/L Pd. The p-nonylphenol solubilized the compound to at least 22.4 g/L Pd in the solvent. This represents an 87% stoichiometric loading; assuming that 2 moles of CYANEX 471X extractant react with 1 mole of palladium.

**TABLE 4 - EFFECT OF p-NONYLPHENOL ON THE LOADING CAPACITY**

Solvent	:	(A) 120 g/L CYANEX 471X extractant in Varsol DX-3641 diluent.
	:	(B) As above, modified with 10 v/o p-nonylphenol.
Aqueous	:	2.24 g/L Pd (as $\text{PdCl}_2$ ) in 2N HCl.
Temperature	:	50°C
Contact Time	:	20 minutes

Solvent	A/O	Organic [Pd] (g/L)	% Pd Extracted

	2	4.48	100
	5	11.20	100
	10	22.40	100

\*Precipitation of the extracted complex occurred.

## Selectivity

Initial batch experiments to investigate Pd/Pt selectivity were made by contacting a solvent containing CYANEX 471X extractant with a Pd/Pt chloride solution. The results were as follows.

Solvent : 300 g/L CYANEX 471X extractant, 10 v/o p-nonylphenol in Varsol DX-3641 diluent.  
Aqueous : 1.23 g/L Pd (II) < 2.54 g/L Pt(IV) as chloride 2N in HCl.  
Contact Time : 10 minutes  
Temperature : 50°C

% Extraction		
A/O	Pd	Pt
1	100	11
2	100	13

Higher selectivities will be obtained by reducing the concentration of CYANEX 471 X extractant in the solvent.

## Kinetics

A study of the rate of Pd and Pt extraction has shown that the selective separation of these two metals is kinetically based; as illustrated in Figure 5. The results were obtained at 50°C and A/O = 2 by contacting an unmodified solvent (30g/L CYANEX 471X extractant in Varsol DX-3641 diluent) with an aqueous chloride

solution containing 1 g/L Pd (II) and 1 g/L Pt (IV) in 2N HCl

## Stripping

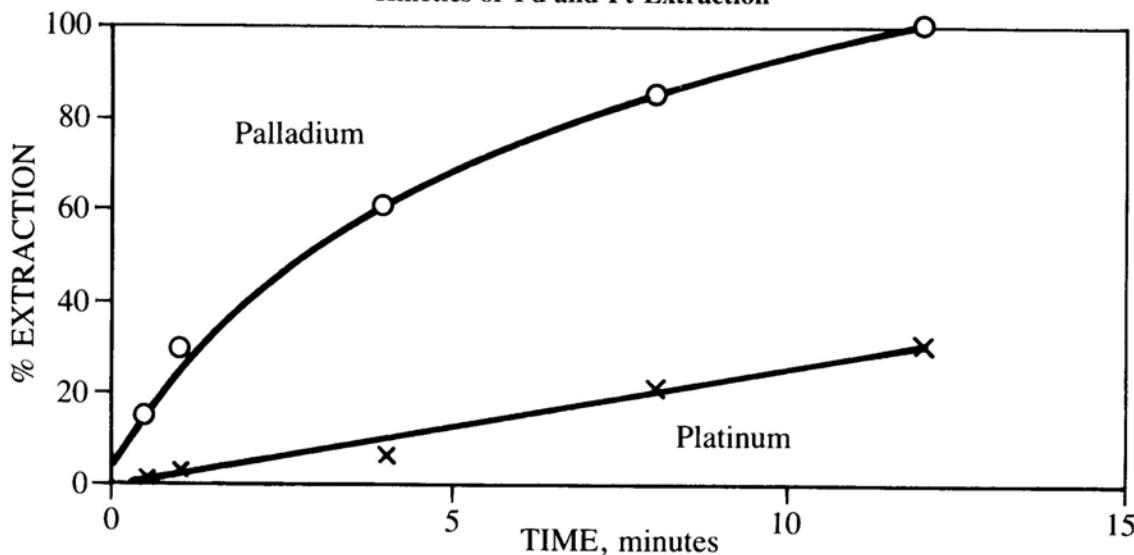

Palladium may be stripped from the loaded solvent using a sodium thiosulfate solution of the same composition as given in the section on silver recovery. The results of preliminary batch tests illustrating the utility of thiosulfates as strip feeds are as follows:

Solvent : 120 g/l CYANEX 471X extractant in Varsol DX-3641 diluent; loaded to 2.21 g/L Pd  
Strip Feed : Stabilized sodium thiosulfate solution  
Temperature : 50°C  
Contact Time : 20 minutes

A/O	% Pd Stripped
1	100
2	100

Ammonia has not been evaluated as a strip feed for palladium in our laboratories. However, its properties are such that it will probably be effective. Palladium-ammonia complexes are stable but care must be exercised to avoid complex formation with other metals which form explosively unstable fulminates; e.g. silver and mercury.

**FIGURE 5**  
**Kinetics of Pd and Pt Extraction**

# ANALYTICAL METHODS

Two gas chromatographic procedures have been developed for the determination of the active ingredient of CYANEX 471X extractant (triisobutylphosphine sulfide, or TIBPS). The first method is designed to analyze the concentration of TIBPS in process solvents and the second, to measure solubility losses in raffinates, strip liquors or other aqueous solutions.

Both procedures require the preparation of standard solutions of TIBPS. Typically, CYANEX 471X extractant will be 95% pure and this should be compensated for when preparing standard solutions from commercial product.

Alternatively and preferably, AR grade CYANEX 471X extractant may be prepared from CYANEX 471X by recrystallization from a 70 v/o solution of 2-propanol in distilled water. The recrystallization procedure is described in Appendix B.

## Analysis In Organic Solvents

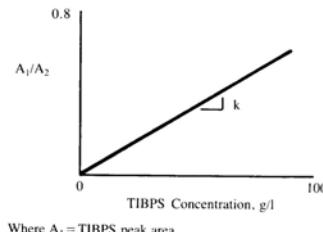

As described, the procedure is suitable for analyzing solvents containing between 20 and 100 g/L TIBPS. Other concentrations may be determined by making appropriate changes to the aliquots and/or dilutions which are cited.

## Reagents

1. 25 v/o solution of hexadecane (internal standard) in toluene.
2. AR grade TIBPS.

## Calibration

1. Make up 20, 40, 60, 80 and 100 g/L standard solutions of TIBPS in the appropriate diluent; e.g. Varsol DX-3641, Escaid 100, etc.
2. Prepare the analyte solutions by pipetting 10 mL of the hexadecane internal standard into a 50-mL volumetric flask and making up to volume with the standard solution. Analyze the solution as described under "Gas Chromatographic Conditions."
3. Plot the calibration curve as follows and determine the slope "k".

Where  $A_1$  = TIBPS peak area  
 $A_2$  = Hexadecane peak area

Hexadecane elutes before TIBPS. The calibration curve should be a straight line passing through the origin.

### Procedure

1. Centrifuge the solvent to be analyzed or filter through PS paper to remove any entrained aqueous or suspended solids.
2. Pipette 10 mL of the hexadecane internal standard into a 50-mL volumetric flask and make up to volume with the process solvent. Determine the hexadecane and TIBPS peak areas as described under "Gas Chromatographic Conditions."

### Calculation

$$\text{Concentration of TIBPS in the solvent (g/L)} = \frac{A_t}{A_h} \times \frac{1}{k}$$

Where  $A_t$  = TIBPS peak area

$A_h$  = Hexadecane peak area

$k$  = Slope of the calibration curve

### Gas Chromatographic Conditions

Instrument	: Perkin Elmer, Sigma 115 or equivalent
Column	: 6' x 1/8" stainless steel, packed with 3% OV 17 on 80/100 Chromasorb W (AW)
Detector	: FIX (Air at 30 psig, H <sub>2</sub> at 20 psig)
Carrier Gas	: Helium (22 mL/min)
Temperatures	: FID = 300°C Injection Port = 310°C
Program	: Column at 175°C for 4 min then raised to 250°C at 30°C/min and held for 5 min.
Sample Injection	
Volume	: 1 μL
Peak Areas	: Determined by electronic integration. hexadecane and TIBPS have approximate retention times of 3.6 and 5.6 min., respectively.

### Notes

1. PS (Phase Separation) paper is available from Whatman, Inc., Clifton, NJ.
2. Escaid 110 diluent is available from Exxon Company, USA.
3. Varsol DX-3641 diluent is available from Exxon Company, USA.
4. Organic compounds generally exhibit high coefficients of volumetric expansion. Care should be taken to maintain all organic solutions at a controlled temperature to avoid errors induced by volume changes.
5. This method has not been validated.

### Analysis in Aqueous Solution

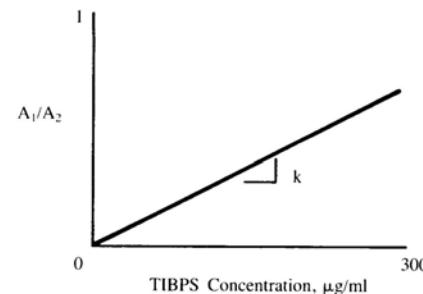

The procedure is designed for the analysis of raffinates or other aqueous solutions containing up to 15 μg/mL of TIBPS. Detection limit is approximately 1 μg/mL.

#### Reagents

1. Cyclohexane
2. 3500 μg/mL solution of hexadecane (internal standard) in cyclohexane.
3. 350 μg/mL solution of hexadecane in cyclohexane.
4. 2000 μg/mL solution of TIBPS in cyclohexane.
5. All reagents are AR grade.

#### Calibration

1. Pipette 1, 5, 10 and 15 mL aliquots of the 2000 μg/mL solution of TIBPS into 100-mL volumetric flasks. Pipette 10 mL aliquots of the 3500 μg/mL hexadecane solution into each of the flasks. Make up to volume with cyclohexane to prepare 20, 100, 200 and 300 μg/mL TIBPS standard solutions each containing 350 μg/ml of the internal standard, hexadecane.
2. Analyze the solutions as described under "Gas Chromatographic Conditions."
3. Plot the calibration curve as follows and determine the slope "k".

Where  $A_1$  = TIBPS peak area

$A_2$  = Hexadecane peak area

The calibration curve is a straight line passing through the origin.

### Procedure

1. Filter the aqueous solution to remove entrained organic.
2. Pipette 100 mL of the aqueous and 5 mL of the 350 μg/mL solution of hexadecane in cyclohexane into a 250 mL separatory funnel (or other suitable vessel) and equilibrate for 10 minutes at room temperature (24°C).
3. Allow 15 minutes to settle and transfer the organic (and any emulsion) to a glass vial and centrifuge for one hour at 1300 g to remove entrained aqueous. If no emulsion is present initially, filtration through PS paper is adequate.
4. Analyze the coalesced organic as described under "Gas Chromatographic Conditions".

## **Calculation**

Concentration of TIBPS in the Aqueous ( $\mu\text{g/mL}$ )

$$= \frac{A_t}{A_h} \times \frac{1}{k} \times \frac{O}{A}$$

Where  $A_t$  = TIBPS peak area

$A_h$  = Hexadecane peak area

$k$  = Slope of the calibration curve

$O/A$  = Organic/aqueous volume phase ratio for extraction (in this case 1/20)

## **Gas Chromatographic Conditions**

Instrument	: Perkin Elmer, Sigma 115 or equivalent
Column	: 6' x 1/8" stainless steel, packed with 3% OV 17 on 80/100 Chromasorb W (AW)
Detector	: FID (Air at 30 psig, $H_2$ at 20 psig)
Carrier Gas	: Helium (10 mL/min)
Temperatures	: FID = 300°C Injection Port = 310°C
Program	: Column at 175°C for 6 minutes then raised to 200°C at 10°C/min and held for 5 minutes
Sample Injection Volume:	0.5 $\mu\text{L}$
Peak Areas	: Determined by electronic integration. Hexadecane and TIBPS have approximate retention times of 6.9 and 10.3 minutes, respectively.

## **NOTES**

1. The solubility of TIBPS in distilled water is approximately 43  $\mu\text{g/mL}$  at 24°C.
2. The solubility in TIBPS in a 10 g/L  $H_2SO_4$  raffinate containing 6 g/L  $Zn^{2+}$  and 10 g/L  $Cu^{2+}$ , is 6  $\mu\text{g/mL}$  at 24°C. The solubility in a thiosulfate stripping solution (ibid) is <1  $\mu\text{g/mL}$  at 24°C. Solubilities will vary depending upon the composition of the solvent, aqueous feed, temperature etc.
3. PS (Phase Separation) paper is available from Whatman, Inc.
4. Organic compounds generally exhibit high coefficients of volumetric expansion. Care should be taken to maintain all organic solutions at a controlled temperature to avoid errors induced by volume changes.
5. This method has not been validated.

## APPENDIX A

### SILVER RECOVERY FROM FIXER SOLUTIONS

Two methods are widely used in the photographic industry to recover silver from fixer solutions used in film and paper processing. These are:

Electrolysis

Cementation

Electrolysis produces high purity silver cathodes. However, it is the more costly of the two alternatives. In cementation the fixer solution is passed through a filter cartridge containing spun steel and silver metal is precipitated according to the reaction:

Both methods can and are operated on a continuous basis. Occasional make-up of the thiosulfate solution is required.

## APPENDIX B

### PURIFICATION OF CYANEX 417X EXTRACTANT

1. At 40°C, dissolve 500 g of CYANEX 471X extractant in 150-200 mL f a 70 v/o solution of 2-propanol in distilled water.
2. Cool to room temperature and vacuum filter to remove undissolved solids.
3. Cool the filtrate to approximately 0°C and maintain at this temperature for 1 hour. Vacuum filter the recrystallized TIBPS and wash the filter cake with 100 mL of the 70 v/o 2-propanol solution (at 0 to 10°C).
4. Repeat the procedure for a total of 3 recrystallizations. Vacuum dry the final TIBPS filter cake at 25-30°C for 24 hours.
5. The final product should be >98% pure by total GC peak integration and have a melting point of 58-59°C.

# INTRODUCTION

CYANEX® 921 extractant, better known as trioctylphosphine oxide (TOPO), was the first member of a family of solvent extraction reagents developed by Cytec. This reagent has been used commercially for many years to recover uranium from wet process phosphoric acid. A more recent industrial application is in the extraction of acetic acid from effluent streams.

## Chemical Structure

The chemical structure of CYANEX 921 extractant is as follows:

## Typical Properties

Trioctylphosphine oxides	:	93%
Appearance	:	Off-white, waxy solid
Specific Gravity at 25°C	:	0.88
Specific Gravity at 61°C	:	0.84
Melting Point °C	:	47-52
Viscosity at 55°C	:	15.0 centipoise (15.0 mPa.s)
Brookfield Viscometer At 100°C	:	5.5 centipoise (5.5 mPa.s) (Viscosity is shown as a function of temperature in Figure 1)

## Compatible Materials

Stainless steel (304 and 316), mild steel and aluminum were found to corrode at <1 mil per year when in contact with a TOPO melt at 60-80°C.

## Stability

Trialkylphosphine oxides, of which CYANEX 921 is one example, are known to be the most stable members of the group of organophosphorus solvating reagents.<sup>(1,2,3,4)</sup>

Losses due to degradation are, therefore, likely to be lower than those associated with extractants such as tributylphosphate and dibutyl butylphosphonate.

## Solubility Losses

Losses of CYANEX 921 extractant by distribution to aqueous solutions of various composition were determined in some batch shake-out tests. The results are given below.<sup>(3)</sup>

Composition of Aqueous Phase	Extractant Solubility mg/L
Water	1.1±0.7
1 M HCl	0.2±0.07
0.5 M SO <sub>4</sub> <sup>2-</sup>	0.2±0.07
0.1 M HNO <sub>3</sub>	
2% Na <sub>2</sub> CO <sub>3</sub>	3.6±0.06
5% Na <sub>2</sub> CO <sub>3</sub>	3.6±1.3

The experimental conditions were as follows:

Solvent : 0.1 M extractant (38.6 g/L) in decane  
Temperature, °C : 25  
Equilibration Time : 10 minutes  
A/O : 1

The soluble losses are generally lower than those of other extractants in commercial use, e.g. losses of amines to acidic sulphate solutions are reported to be in excess of 10 mg/L.<sup>(4,5)</sup>

## Organic Solubility

The solubility of CYANEX 921 extractant in four typical commercial diluents is shown as a function of temperature in Figure 4. Solubility is higher in the aromatic diluents, - Aromatic 100\* and Aromatic 150\* diluents than in the two essentially aliphatic diluents Escaid 110\* diluent and Kermac 470B\*\* diluent.

## Toxicity

The acute oral (rat) and acute dermal (rabbit) LD50 values for CYANEX 921 extractant are >10.0 g/kg and 2.83 g/kg, respectively. Marked skin and eye irritation were produced during primary irritation studies with rabbits. Inhalation of airborne material may be irritating to the respiratory tract. CYANEX 921 was determined to be not mutagenic in the Ames Salmonella Assay.

\*\*Product of Kerr-McGee Refining Corp.

# COMMERCIAL APPLICATIONS

## Uranium Recovery From Wet Process Phosphoric Acid

Original work at the Oak Ridge National Laboratories led to the development of a solvent extraction process to recover the small quantities of uranium (0.1 to 0.2 g/L) present in wet process phosphoric acid.<sup>(6,7,8)</sup> The process, which is based on the extraction of hexavalent uranium using a synergic mixture of CYANEX 921 extractant and D2EHPA, is operating successfully in a number of commercial plants in the U.S., Canada and Belgium.

## Acetic Acid Recovery From Effluent Streams

Processes in petrochemical plants, wood pulp mills and other chemical facilities often generate aqueous effluent streams containing small concentrations of carboxylic acids; particularly acetic acid. Typically, the acids are present in concentrations of 1 to 50 gpl depending upon the source.<sup>(9)</sup>

The use of CYANEX 921 extractant and other reagents to recover acetic acid from these streams has formed the subject of several informative papers in recent years<sup>(10,11,12,13)</sup> and a number of patents have been issued in this area.<sup>(14,15)</sup> Briefly, the described processes consist of extracting the acid into a water-immiscible solvent, recovering or stripping the acid from the loaded solvent by distillation and recycling the solvent. One such plant, which recovers acetic acid and furfural, has been operated successfully by Lenzing AG in Austria since 1983.

The advantages of CYANEX 921 in this application lie in low solubility losses, stability during distillation at elevated temperatures and high extraction coefficients for acetic acid in comparison to other solvating reagents. These properties have the effect of minimizing plant operating and capital costs.

As an illustration of efficient performance characteristics, an acetic acid extraction isotherm obtained with a solvent containing 400 g/L CYANEX 921 extractant is shown in Figure 1. The corresponding experimental results and conditions are given in Table 1.

McCabe-Thiele interpolations from the isotherm indicate essentially quantitative recovery in three theoretical stages at O/A = 1.5; assuming an initial feed containing 10 g/L acetic acid.

Raffinates obtained from the above shake-out tests were analysed and found to contain <2 mg/L of CYANEX 921 extractant (detection limit of the method).

Rapid extraction kinetics play an important role in any solvent extraction process as good kinetic properties allow for the design of compact equipment and, consequently, have a favorable effect on capital expenditures. This property is

particularly important when differential (column) contactors are used because of the comparatively short contact times and low interfacial areas prevalent in this type of equipment.

Data on the rate of extraction of acetic acid with CYANEX 921 are presented in Table 2 and Figure 2 and indicate that extraction is essentially complete in <2 minutes. This rate is sufficiently high so as not to impose any kinetically based limitations on equipment selection for this process.

TABLE 1

# POTENTIAL APPLICATIONS

## METAL EXTRACTION

### Niobium Tantalum Separation

A pilot-plant process using CYANEX 921 extractant to recover and separate niobium and tantalum has been demonstrated recently.<sup>(16,17)</sup> Both metals are extracted from a hydrofluoric-sulphuric acid leach liquor and then selectively stripped from the loaded organic. The advantages of CYANEX 921 extractant in comparison to the commercially used MIBK extractant were shown to be higher stability, lower aqueous solubility, rapid phase disengagement and, particularly, the production of high purity niobium oxide which meets the stringent specifications required for nuclear, optical and electronic applications.

Data comparing the impurities in niobium oxides derived by solvent extraction with MIBK and CYANEX 921 extractant are shown in Table 3 below.<sup>(16)</sup>

TABLE 3  
NIOBIUM OXIDE PURITY

Loss on Ignition	0.1%	0.1%

Table 3 reproduced by the kind permission of VCH Verlagsgesellschaft, Weinheim, Federal Republic of Germany.

### Rhenium Recovery

Rhenium is an essential element in the production of petroleum reforming catalysts. A recent patent granted to American Cyanamid Company<sup>(18)</sup> discloses the use of CYANEX 921 to recover rhenium from these source materials. The process involves leaching the spent catalyst with sulphuric acid, extracting rhenium and then stripping with ammonium sulphate. Excellent selectivity against typical impurity metals such as aluminum, calcium, magnesium and iron is achieved.

### Arsenic Extraction From Copper Electrolytes

The removal of arsenic impurities from copper electrolytes by solvent extraction with CYANEX 921 forms the subject of a recent European Patent issued to Vereinigte Metallwerke Ranshofen-Berndorf AG.<sup>(19)</sup> The process describes the selective extraction of arsenic followed by stripping with an acidic sodium sulphate solution and recovery of arsenic from the strip liquor by precipitation with H<sub>2</sub>S. CYANEX 921 is shown to be a stronger extractant for arsenic than tributylphosphate which is now used in two commercial arsenic solvent extraction plants. This property is claimed to result in lower staging requirements and solvent inventory.

### Lithium Recovery

The commercial significance of lithium has increased in recent years as a result of the development of new uses for this element, e.g. in batteries, and because of increased demand in established applications (ceramics, etc.).

A novel solvent extraction process using CYANEX 921 extractant to recover lithium from one of its sources (neutral brines) has been described<sup>(20)</sup>

### Additional Applications

CYANEX 921 is known to extract approximately 30 metals from aqueous solution as indicated in Table 4.<sup>(21)</sup>

Selective separations can be made depending upon a variety of factors, e.g. the valence state of the metal, the anionic nature of the solution (chloride, sulphate, etc.) and the concentration of the extractant in the solvent.

For example, one separation suggested by these data is the selective recovery of vanadium<sup>(5+)</sup> from chloride solutions containing aluminum, cobalt and nickel (these solutions may be derived from leaching spent catalysts used in the petroleum industry).

The reader is referred to two comprehensive reviews for more detailed information on the performance characteristics of TOPO.<sup>(22,23)</sup>

## ORGANIC EXTRACTION

### Phenol Recovery

Phenol occurs in aqueous effluents from many processes, e.g. in the petroleum, steel and coal gasification industries. CYANEX 921 is a strong extractant for phenol and offers a lower cost alternative to conventional Phenosolvan technology for phenol recovery.

This new process<sup>(24)</sup> involves dissolving CYANEX 921 extractant in a high boiling point diluent, extracting phenol and then stripping the solvent by distillation.

Extraction isotherms given in Table 5 and plotted in Figure 5 show the efficient extraction properties of CYANEX 921.

McCabe-Thiele interpretations from the isotherms indicated the following theoretical staging requirements and A/O ratios for essentially quantitative phenol recovery.

Extractant Conc. (g/L)	Theoretical Stages	A/O Ratio
100	2	2
200	2	3
325	2	5

# ANALYTICAL METHODS

## ANALYSIS IN ORGANIC SOLVENTS

As described, the gas chromatographic procedure is suitable for analyzing solvents containing  $120 \pm g/L$  TOPO. Other concentrations may be determined by making appropriate changes to the tenor of TOPO in the standard solution. (The method is based upon a single point standardization).

### Reagents

1. Didecylphthalate (AR grade-internal standard)
2. TOPO (purified-see note 1).
3. Process diluent (e.g. Escaid 110\* diluent, Aromatic 150\* diluent).

### Calibration

1. Accurately weigh ( $\pm 1$  mg)  $3 \pm 0.1$  g of pure TOPO and  $2 \pm 0.1$  g of didecylphthalate into a 50 mL volumetric flask. Dissolve and make up to volume using the process diluent.
2. Analyze the standard solution as described under "Gas Chromatographic Conditions" to determine the relative response factor of TOPO and didecylphthalate.

### Procedure

1. Centrifuge the solvent to be analyzed or filter through PS paper to remove entrained aqueous or suspended solids.
2. Accurately weigh ( $\pm 1$  mg)  $2 \pm 0.1$  g of didecylphthalate into a 50 mL volumetric flask and pipette 25 mL of the clarified solvent into the same flask. Make up to volume with the process diluent.  
Determine the relative response factor of TOPO and didecylphthalate as described under "Gas Chromatographic Conditions".

### Calculations

$$\text{Trioctylphosphine oxide (g/L)} = \frac{R_1}{R_2} \times 2 \times C_s$$

Where  $R_1$  = Relative response factor in standard solution

$R_2$  = Relative response factor in analyte solution

$C_s$  = TOPO concentration in standard solution (g/L)

### Gas Chromatographic Conditions

- Instrument: Hewlett Packard 5880A or equivalent
- Column: 30 m X 0.32 mm fused silica capillary column coated with  $0.25\mu m$  of SPB-1
- Detector: Thermal Conductivity
- Carrier Gas: Helium
- Temperature, °C
- Detector: 320
- Injector: 290
- Column: 270 (isothermal)

Column Flow:	1 mL/minute
Vent Flow:	60 mL/minute
Sample Injection	
Volume:	0.5 $\mu L$
Peak Areas:	Determined by electronic integration. Retention times for TOPO and didecylphthalate are approximately 6.5 and 10 minutes, respectively.

### Notes

1. Pure TOPO (>99.5%) can be obtained by recrystallizing commercial grade TOPO from hexane. (Three recrystallizations are necessary).
2. PS (Phase Separation) paper is available from Whatman, Inc.
3. Isomers of TOPO will also be detected using the subject method. These compounds may be assigned the same response factors as TOPO and determined accordingly. A typical chromatogram of commercial TOPO is shown in Figure 1A.
4. If the TOPO peak exhibits a leading tail this may effect the accuracy of the electronic integration. The effect can be minimized by increasing the column temperature by 10 to 20°C.
5. Megabore columns can be used as an alternative to capillary columns.

## ANALYSIS IN AQUEOUS SOLUTION

Two methods have been developed which allow trace quantities of TOPO to be determined. The first method is suited to solutions which contain small concentrations of dissolved salts, while the second method is appropriate for high salt concentrations.

Both methods are based upon gas chromatography. In general, the solubility of TOPO in aqueous process solutions will be <5 mg/L.

### Low Dissolved Solids

The concentration of trioctylphosphine oxide (TOPO) is determined by evaporating the aqueous solution to dryness, leaching the residue with chloroform and analyzing the leachate by gas chromatography.

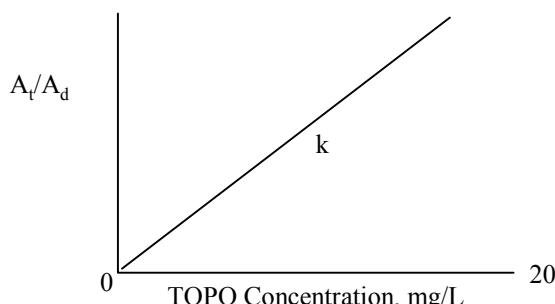

\*Product of Exxon Co., U.S.A.

## Reagents

1. Chloroform
2. Didecylphthalate
3. 25 mg/L solution of didecylphthalate (internal standard) in chloroform
4. TOPO (purified - see Note 1)
5. All reagents are AR grade

## Calibration

1. Prepare standard solutions containing 2, 5, 10 and 20 mg/L TOPO in chloroform. Each solution should also contain 25 mg/L didecylphthalate internal standard.
2. Analyze the solutions as described under "Gas Chromatographic Conditions".
3. Plot the calibration curve as follows and determine the slope "k".

Where  $A_t$  = TOPO peak area

$A_d$  = Didecylphthalate peak area

## Procedure:

1. Filter the aqueous solution to remove entrained organic.
2. Evaporate to dryness exactly 10 mL of the aqueous solution using a nitrogen-swept Pierce Reacti-Therm at 80°C.
3. At room temperature, leach the residue with exactly 1 mL of the chloroform solution containing 25 mg/L didecylphthalate.
4. Analyze the chloroform leachate as described under "Gas Chromatographic Conditions".

## Calculation

$$\text{Concentration of TOPO in the aqueous (mg/L)} = \frac{A_t}{A_d} \times \frac{1}{k} \times \frac{1}{10}$$

Where  $A_t$  = TOPO peak area

$A_d$  = Didecylphthalate peak area  
 $k$  = Slope of the calibration curve

## Gas Chromatographic Conditions

Instrument: Perking Elmer Sigma 115 or equivalent  
Column: 30 x 0.326 mm fused silica capillary column coated with 0.1 µm Durabond 1 (15 or 60 m columns with a film thickness of 0.10 or 0.25 µm may be substituted)

Split Ratio:	10 to 1
Detector:	FID
Carrier Gas:	Helium at 12 psig (30 m column)
Vent Flow:	2.0 mL/minute (23 cm/sec)
Temperatures, °C	
FID:	300
Injection Port:	300
Program, °C	
Isothermal:	270
Sample Injection Volume:	5 µl

## Notes

1. Pure TOPO can be obtained by recrystallizing commercial grade TOPO from hexane. (Three recrystallizations are necessary).
2. TOPO and didecylphthalate will elute at approximately 5.4 and 7.8 minutes respectively.
3. Detection limit approximately 1 mg/L.
4. This method has not been validated.

## High Dissolved Solids

Aqueous solutions containing TOPO are analyzed by direct injection gas chromatography.

## Reagents

1. Tetrahydrofuran (THF). "Baker Analyzed Reagent, 100%"
2. TOPO (purified - see Note 1)

## Calibration

1. Prepare a stock solution by accurately weighing (1±mg) approximately 0.5 g of TOPO into a 50 mL volumetric flask. Dilute to 50 mL with THF and dissolve the TOPO.
2. Dilute aliquots of the stock solution with distilled water to prepare standard solutions containing 2, 5, 10 and 30 mg/L of TOPO.
3. Analyze the solutions as described under "Gas Chromatographic Conditions".

## Procedure

1. Filter the aqueous solution to remove entrained organic.
2. Inject 3 µl of the analyte solution and analyze as described under "Gas Chromatographic Conditions".

## Calculation

\* Response Factor for TOPO (R)  
Conc. of TOPO in Standard (mg/L)

Area of TOPO, Standard Peak

Concentration of TOPO in the aqueous (mg/L) = Area of TOPO peak (Analyte)  $\times R$

\* Response factor for the standard closest in concentration to the sample.

## Gas Chromatographic Conditions

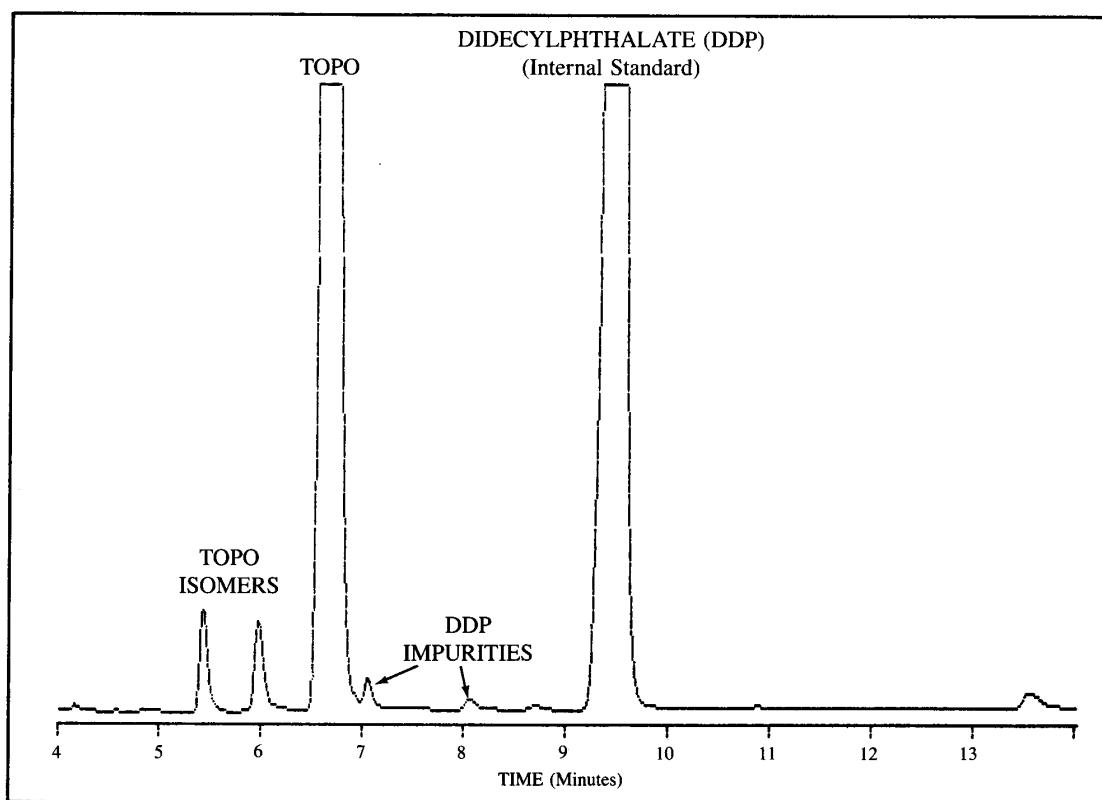

Instrument: Hewlett Packard 5730A or equivalent  
Column: 2 ft. x 1/4 inch OD x 2 mm ID glass  
Column packed with 9% OV-17 and 12% SP2401 on 80/100 mesh Supelcoport

Detector: FID  
Carrier Gas: Helium at 57 psi (flowrate 40 mL/minute)  
Temperatures, °C  
FID: 300  
Injection Port: 250  
Column: 230  
Program, °C  
Isothermal: 230  
Sample Injection Volume: 3  $\mu$ L

## Notes

1. Pure TOPO can be obtained by recrystallizing commercial grade TOPO from hexane. (Three recrystallizations are necessary)
2. Retention time for TOPO is approximately 12 minutes
3. Detection limit approximately 2 mg/L.

# INTRODUCTION

CYANEX® 923 extractant is a liquid phosphine oxide which has potential applications in the solvent extraction recovery of both organic and inorganic solutes from aqueous solution, e.g. carboxylic acids from effluent streams and the removal of arsenic impurities from copper electrolytes.

The major advantage of CYANEX 923 extractant over similar extraction reagents, e.g. TOPO (trioctylphosphine oxide), is that it is completely miscible with all common hydrocarbon diluents even at low ambient temperatures. The major benefit of high solubility lies in the ability to prepare concentrated, stable solvents which can recover solutes (e.g. acetic acid) that are normally only weakly extracted by this type of reagent.

## Composition

CYANEX 923 extractant is a mixture of four trialkyl-phosphine oxides as follows:

Average Molecular Weight = 348 (approximately)

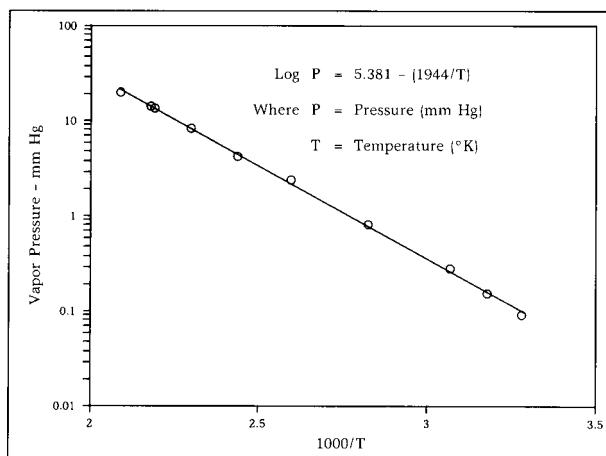

## Typical Properties

Trialkylphosphine oxides	:	93%
Appearance	:	Colorless mobile liquid
Specific Gravity	:	0.88 at 25°C
Freezing Point	:	-5 to 0°C
Viscosity	:	40.0 centipoise at 25°C
	:	13.7 centipoise at 50°C
Flashpoint	:	182°C
(Closed Cup Setaflash)		
Autoignition Temperature	:	281°C
Vapor Pressure*	:	0.09 mm. Hg at 31°C
Boiling Point	:	310°C at 50 mm Hg
Solubility in Water	:	> 10 mg/l
CYANEX 923 extractant	:	8 w/o

Surface Tension	@ 25°C	9.0 dynes/cm
	@ 100°C	7.5 dynes/cm
	@ 150°C	5.2 dynes/cm
Viscosity Kinematic	@ 25°C	51.6 cSt
	@ 50°C	18.9 cSt
	@ 100°C	4.2 cSt
Specific Heat	@ 25°C	0.45 cal/gm/°C
	@ 50°C	0.47 cal/gm/°C
	@ 100°C	0.51 Cal/gm/°C

## **Suitability of Construction Materials**

Samples of the following plastics and rubbers (in the form of tubing) were immersed for 200 hours at 50°C in glass vessels containing CYANEX 923 extractant.

The results are summarized below:

<b>Material</b>	<b>Remarks</b>
Butyl Rubber	Unsuitable. Rapid swelling and softening.
Teflon Fluorocarbon Film*	Suitable. No detectable effect.
Polypropylene	Suitable. No detectable effect.
Natural & Black Latex Rubber	Unsuitable. Complete dissolution in less than 192 hours.
PVC (Laboratory Grade)	Short-term suitability. Loss of plasticity in less than 192 hours.
PVC (Solvent Grade)	Suitable. Only a slight increase in dimension observed.
Red Gum Rubber	Unsuitable: Rapid swelling and softening.
Viton Fluoroelastomer*	Suitable. No detectable effect.
Silicone	Unsuitable. Disintegrated after 56 hours.

Samples of the following metals in the form of coupons (approximate dimensions 50 mm x 20 mm. x 3 mm) were immersed for 1000 hours at 50°C in glass vessels containing CYANEX 923 extractant. The following observations were made.

<b>Metal</b>	<b>Remarks</b>
Mild Steel	No detectable corrosion.
Stainless Steel (316)	No detectable corrosion.
Stainless Steel (304)	No detectable corrosion.
Aluminum	No detectable corrosion.

\*Product of E.L DuPont de Nemours & Co.

# POTENTIAL APPLICATIONS

## ORGANIC SOLUTES

### Carboxylic Acid Recovery

Processes in petrochemical plants, wood pulping mills, and other chemical facilities often generate aqueous effluent streams containing carboxylic acids; particularly acetic acid. Typically, these acids are present in concentrations between 1 and 50 g/l.

A solvent extraction plant to recover acetic acid from an effluent stream has been operated successfully by Lenzing A.G. in Austria since 1983. Briefly, the process involves extracting acetic acid with a solvent containing TOPO and stripping the loaded solvent by distillation.

The advantage of using CYANEX 923 extractant in this application, as opposed to TOPO, lies in the ability to prepare a concentrated, low freezing point solvent.

This leads to lower staging requirements in extraction and virtually eliminates the problem of plant freeze-up during periods when the ambient temperature is low.

The potential for CYANEX 923 extractant in this application is illustrated by the acetic acid extraction isotherms shown in Figure 2. The isotherms were plotted from the data in Table 1.

FIG. 2 — ACETIC ACID EXTRACTION ISOTHERMS

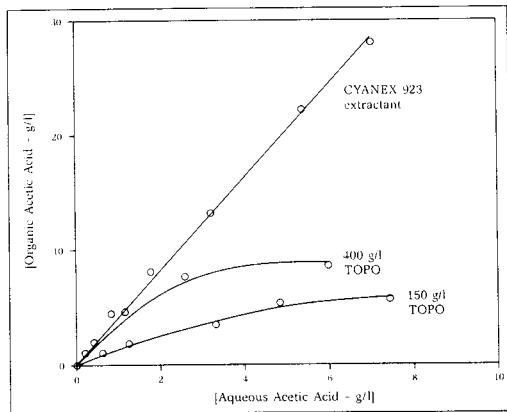

TABLE 1

\* DPA, a high boiling (330-379°C) diphenylalkene diluent, is a product of Conoco Chemicals Co. (a division of Conoco).

### Phenol Recovery

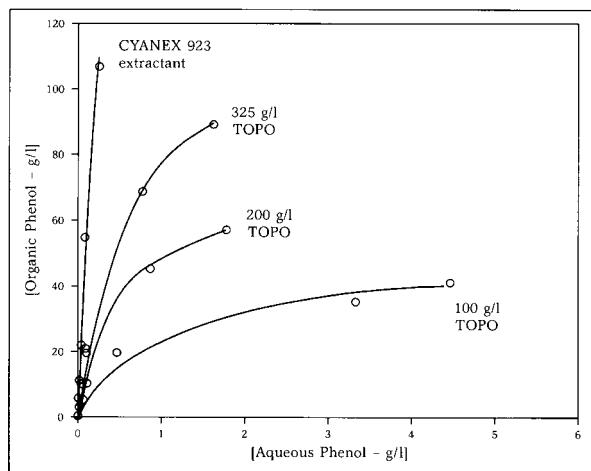

Phenols, like carboxylic acids, are a common component of many aqueous effluents, e.g. waste streams produced during coal liquefaction, coal gasification (steel manufacture), and in the petrochemical industry.

Again, the potential benefit of recovering phenol by solvent extraction with CYANEX 923 extractant is the ability to construct plants with minimal staging requirements. Since phenol is strongly extracted by phosphine oxides, the advantages of CYANEX 923 extractant vs. TOPO are less marked than in the case of the more weakly extracted acetic acid. The major factor in choosing between the two in phenol systems will obviously depend upon the concentration of phenol in the effluent.

Phenol extractions isotherms are shown in Figure 3 and were plotted using the batch, shake-out data given in Table 2. Composition of the aqueous solution was chosen to approximate a real effluent. As with carboxylic acids, stripping is achieved by distillation.

Estimates indicate significant savings in capital and operating costs vs. the conventional Phenosolvan process.

\* Nalkylene 500, a linear alkyl benzene diluent, is a product of Conoco Chemicals Co. (a division of Conoco.)

\*\*Detection limit of the analytical method.

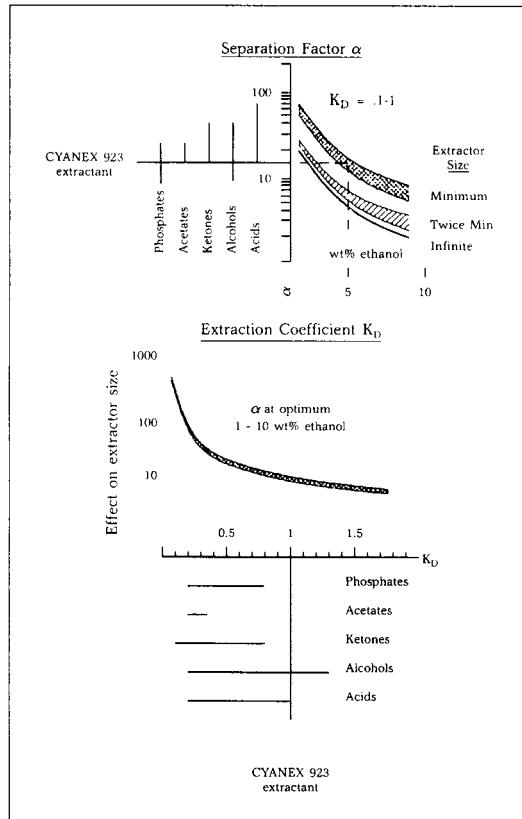

#### Ethanol Extraction

CYANEX 923 extractant exhibits a separation factor in ethanol/water solutions near the maximum useful limit for recovery from continuous fermentation broths, typically containing 5% ethanol. Higher values do not further reduce extractor size or energy required in the downstream distillation. This is illustrated in Figure 4 where separation factors for CYANEX 923 extractant and for other candidate extractants are shown in relation to the upper and lower limits. Extraction coefficients, and their effect on extractor size, are also plotted in Figure 4. The coefficient for

CYANEX 923 extractant is well into the flat part of the curve. This excess capacity can be exchanged for increased separation factor, if needed, by dilution with inert diluents.

The principle advantage of CYANEX 923 extractant lies in its very low solubility in water. This obviates or minimizes extra processing of raffinate that would be required by more soluble extractants. The solubilities in water of CYANEX 923 extractant and of other candidate ethanol extractants are compared in Table 3.

## INORGANIC SOLUTES

### Impurity Removal From Copper Electrolytes

Briefly, the advantages of removing arsenic, antimony and bismuth impurities from copper electrolytes by solvent extraction rather than conventional processes consist of improvements in current efficiency, the quality of electrolytic copper, and in the productivity of the tankhouse. Minimizing the formation of arsine gas is also an important consideration.

Data on the extraction of arsenic, antimony and bismuth from a synthetic, nickeliferous copper electrolyte are given in Table 4. The corresponding arsenic and antimony extraction isotherms are shown in Figure 5. McCabe-Thiele interpolations indicated a reduction in the electrolyte arsenic concentration from 6 g/l to 1 g/l in two theoretical stages at O/A = 4. Under these conditions, the data indicated quantitative extraction of bismuth, 30-40% extraction of the antimony and a solvent loaded to 10-20 g/l H<sub>2</sub>SO<sub>4</sub>. High selectivity against copper and nickel extraction was observed. Copper loading in the solvents varied from 3 to 5 mg/l while no nickel extraction was observed.

Scrubbing sulfuric acid from the loaded solvent was readily achieved with water. The data in Table 5 and Figure 6 implied essentially quantitative removal in 3 theoretical stages at O/A=8 to produce a scrub liquor containing 130 g/l H<sub>2</sub>SO<sub>4</sub> for recycle. The feasibility of a selective metal/acid scrub was also indicated.

Water proved to be an effective strip feed at a lower O/A ratio as shown by the data in Table 6 and the arsenic stripping isotherm plotted in Figure 7

Interpolations from the isotherm showed complete arsenic stripping in 5 stages at O/A = 2. Quantitative antimony stripping was estimated under these conditions while approximately 0.07 g/l bismuth remained loaded on the solvent.

Solubility losses of the extractant in this system varied from 1 mg/l in the electrolyte to 10 mg/l in the strip liquor.

### Uranium Extraction From Wet Process Phosphoric Acid

The conventional process for recovering uranium from wet process phosphoric acid involves extraction with a synergistic mixture of D2EHPA and TOPO. CYANEX 923 extractant is a potential substitute for TOPO in this process and offers a materials handling advantage in that it is a liquid, while TOPO is a solid at normal temperatures (melting point approximately 50°C) and must be melted for ready removal from its container.

The feasibility of using CYANEX 923 extractant in this application is illustrated by the results of shake-out tests which are presented in Table 7 and Figure 8.

TABLE 7  
Uranium Recovery from Wet-Process Phosphoric Acid Using Synergistic Mixtures of Phosphine Oxides and D2EHPA

FIG. 8 – EFFECT OF PHOSPHINE OXIDE MOLARITY ON URANIUM EXTRACTION FROM WPPA

## Niobiurn - Tantalum Separation

Niobium - tantalum separation is normally effected using MIBK. The disadvantage here is the high aqueous solubility of the ketone (approximately 20 g/l) and the consequent need to treat the raffinate for recovery of the extractant. Recent work<sup>1</sup> has shown that TOPO has utility in niobium - tantalum separation and is reported to produce higher purity niobium oxide than MIBK.

The advantage of using CYANEX 923 extractant in place of TOPO is again related to its liquid state and higher organic solubility.

A strong diluent effect was observed in preliminary experiments on niobium extraction. This is illustrated by the results of extraction isotherms given in Table 8 and plotted in Figure 9. Aromatic 150\* proved to be the superior diluent in comparison to both Aromatic 100\* and Exxsol D-80.

The process for niobium - tantalum separation, as with MIBK and TOPO, consists of extracting both metals followed by a selective strip; first of niobium and then of tantalum. This is illustrated in Table 9 and Figure 10 where selective stripping of niobium from a niobium - tantalum loaded solvent was observed using a strip feed containing 0.1 N NH<sub>4</sub>OH and 1 % NH<sub>4</sub>F. Tantalum was subsequently stripped using a more basic strip feed of 0.4 N NH<sub>4</sub>OH and 4% NH<sub>4</sub>F.

\*A product of Exxon Co., U.S.A.

## Cadmium Removal from Phosphoric Acid

Cadmium sometimes occurs as an undesirable impurity in phosphoric and other acids. The data given in Table 11 illustrate the ability of CYANEX 923 to readily reduce the concentration of cadmium from 10 mg/l to below a target of 2 mg/l; the specification in this particular application. McCabe-Thiele interpolations from the isotherm (Figure 12) indicate minimal staging requirements and that cadmium can be reduced from 10 mg/l to < 2 mg/l in two theoretical stages at A/O = 4.

Cadmium, as well as co-extracted acids, are efficiently stripped from the loaded solvent with water as shown by the data in Table 12. The stripping isotherm (Figure 13) again indicates minimal staging requirements.

# ANALYTICAL METHODS

## ANALYSIS IN ORGANIC SOLVENTS

As described, the gas chromatographic procedure is suitable for analyzing solvents containing approximately 120 g/l CYANEX 923 extractant. Other concentrations may be determined by diluting the solvent appropriately or adjusting the composition of the standard solution.

CYANEX 923 extractant is a mixture containing four major components, as follows: Trihexylphosphine oxide (1), dihexylmonoocetyl-phosphine oxide (2), dioctylmonohexyl-phosphine oxide (3) and trioctylphosphine oxide (4).

The method is based upon the fact that, within the limits of experimental error, the response factors for components 1, 2 and 3 are the same as for 4 and that 4 (TOPO) is readily available and may be easily purified to AR grade.

### Reagents

1. Didecylphthalate (AR grade - internal standard)
2. TOPO (purified - see note 1)
3. Process diluent (e.g. Escaid\* 110 diluent)

### Calibration

1. Accurately weigh 1g ( $\pm$  1 mg) of pure TOPO and 2g ( $\pm$  0.1 g) of didecylphthalate into a 50 ml volumetric flask. Dissolve and make up to volume with the process diluent.
2. Analyze the above standard solution as described under "Gas Chromatographic Conditions" to determine the relative response factor of TOPO vs. didecylphthalate.

### Procedure

1. Centrifuge the solvent to be analyzed or filter through PS paper" to remove entrained aqueous or suspended solids.
2. Accurately weigh 2g ( $\pm$  0.1g) of didecylphthalate into a 50 ml volumetric flask and pipette 25 ml of the clarified solvent into the same flask. Make up to volume with the process diluent.
3. Determine the relative response factor of each component of CYANEX 923 extractant vs. that of the internal standard as described under "Gas Chromatographic Conditions".

\* A product of Exxon Co., U.S.A.

\*\* Phase separation paper available from Whatman, Inc., Clifton, NJ

### Calculations

Total Concentration of Trialkylphosphine Oxides (g/1)

$$\sum \left[ \frac{R_{4S}}{R_{na}} \right] \times 2 \times C_{4S}$$

Where  $R_{4S}$  = Relative response factor for TOPO in the standard solution

$R_{na}$  = Relative response factor for the  $n^{\text{th}}$  component in the analyte solution.

$C_{4S}$  = Concentration of TOPO in the standard solution (g/1)

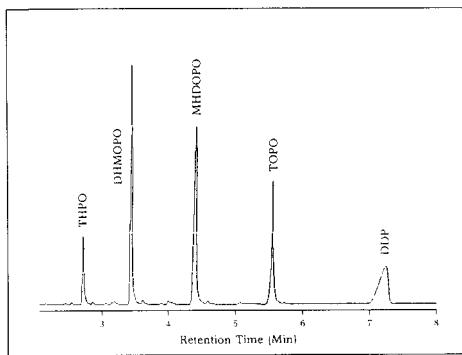

### Gas Chromatographic Conditions

Instrument	:	Perkin Elmer Sigma 115 or equivalent
Column	:	30 in x 0.32 mm fused silica capillary column coated with 0.25 $\mu$ m of DB1
Detector	:	FID
Carrier Gas	:	Helium at 18 psig
Vent Flow	:	100 ml/min
Column Flow	:	4.3 ml/min
Split Ratio	:	23/1
Temperatures °C		
Detector	:	340
Injection Port	:	340
Column	:	220 to 330 at 10°C/min
Sample		
Injection		
Volume	:	0.1 $\mu$ l
Peak Areas	:	Determined by electronic integration

### Notes

1. A chromatogram of commercial CYANEX 923 extractant is shown in Figure 1A.
2. Pure TOPO (>99.5%) can be obtained by recrystallizing commercial grade TOPO from hexane (three recrystallizations are necessary).
3. Megabore columns may be used as an alternative to capillary columns. A thermal conductivity detector may also be used in place of an FID.
4. The method is based upon a single point determination. If required, a calibration curve can be constructed by varying the concentration of TOPO in the standard solution while maintaining a constant concentration of the internal standard.
5. This method has not been validated.

FIG. 2A — CHROMATOGRAM OF CYANEX 923 EXTRACTANT CONTAINING DIDECYLPHTHALATE (DDP) AS AN INTERNAL STANDARD

## ANALYSIS IN AQUEOUS SOLUTION

The aqueous solubility of each component of CYANEX 923 extractant will normally be <2 mg/l. The method is based on analysis of the aqueous sample by gas chromatography. The response factors of the four active components are equal within the limits of experimental error.

### Reagents

1. Tetrahydrofuran (THF). "Baker Analyzed Reagent, 100%."
2. TOPO (purified - see note 1.)

### Calibration

1. Prepare a stock solution by accurately weighing ( $\pm$  1 mg) approximately 0.5 g of TOPO into a 50 ml volumetric flask. Dilute to 50 ml with THF and dissolve the TOPO.
2. Dilute aliquots of the stock solution with distilled water to prepare standard solutions containing 2, 5, 10 and 30 mg/l of TOPO.
3. Analyze the solutions as described under "Gas Chromatographic Conditions."

### Procedure

1. Filter the aqueous solution to remove entrained organic
2. Inject 3 $\mu$ l of the analyte solution and analyze as described under "Gas Chromatographic Conditions."

### Calculation

$$1. \text{ *Response Factor for TOPO (R)} = \frac{\text{Conc. of TOPO in Standard (mg/l)}}{\text{Area of TOPO Standard Peak}}$$

$$2. \text{ Concentration of Component in Aqueous (mg/l)} = \frac{\text{Area of Component Peak (analyte) x R}}{\text{Area of Component Peak (standard)}}$$

\*Response factor for the standard closest in concentration to the sample.

### Gas Chromatographic Conditions

Instrument	:	Hewlett Packard 5730A or equivalent
Column	:	2 ft x 1/4 inch x 2 mm ID glass Column packed with 9% OV-17 and 12% SP2401 on 80/100 mesh Supelcoport
Detector	:	FID
Carrier Gas	:	Helium at 57 psi (Flowrate 40 ml/minute)
Temperatures °C		
FID	:	300
Injection	:	
Port	:	250
Column	:	230 (Isothermal)
Sample		
Injection		
Volume	:	3 $\mu$ l

### Notes

1. Pure TOPO can be obtained by recrystallizing commercial grade TOPO from hexane. (Three recrystallizations are necessary).
2. Retention time for TOPO is approximately 12 minutes.
3. Detection limit approximately 2 mg/l.
4. This method has not been validated.

## **DETERMINATION OF WATER**

The method is based on distilling water from CYANEX 923 extractant in the form of an azeotrope with toluene. On contacting a condenser, the water and toluene separate and fall into a graduated trap. The volume of the distillate is then measured.

### **Apparatus**

1. 500 ml round-bottomed, short-necked glass flask with a 40/50 ground glass fitting.
2. Water-cooled condenser. Cold-finger type.
3. Dean and Stark type trap. 10 ml capacity graduated in 0.1 ml divisions with a 40/50 ground glass fitting.
4. Heating mantle controlled by a rheostat.

### **Reagents**

1. AR grade toluene (water-free)

### **Procedure**

1. Weigh 50 g of the sample ( $\pm 0.5$  g) into the 500 ml flask.
2. Add approximately 200 ml of toluene to the flask and assemble the apparatus.
3. Heat the contents of the flask to boiling and allow to reflux for 30 to 60 minutes or until the volume of water in the trap is constant.
4. Read the volume of water in the trap at room temperature.

### **Calculation**

$$\% \text{ Water} = \frac{\text{Volume of Water in Trap (ml)}}{\text{Sample weight (g)}} \times 100$$

### **Notes**

1. This method has not been validated.
2. Karl-Fisher titration is not recommended.

## **HEALTH AND SAFETY**

The oral and dermal toxicity of CYANEX 923 extractant is low. CYANEX 923 extractant produces mild eye irritation and severe skin irritation upon contact. Repeated dermal exposure for 28 consecutive days produced severe skin irritation, but no systemic toxicity. CYANEX 923 extractant did not produce dermal sensitization in guinea pigs after repeated dermal exposure. This product did not produce mutations in bacteria nor did it produce chromosomal effects in the mouse micronucleus or human lymphocyte aberration assays. CYANEX 923 extractant is highly toxic to fish and invertebrates and great care should be exercised to avoid environmental exposure.

***MINING DILUENTS FOR  
SOLVENT EXTRACTION (SX)***

**ExxonMobil**  
*Chemical*

# Background

---

- 
- ◆ High flash kerosene is commonly used as a diluent in copper recovery operations because it is low cost and available, but in most cases it does not perform well because of their low chemical stability and low purity.
  - ◆ ESCAID® Mining Diluents with their composition and properties perform better than kerosene in copper and other metal SX processes.

# What Determines Whether a Diluent Performs Well?

---

- ◆ Phase Separation
  - Rate at which the organic (diluent, complexing agent and modifiers) and aqueous phases separate.
- ◆ Copper Loading Capacity
  - Loading or uptake refers to the maximum amount of copper that can be taken up by the organic phase. Loading capacity depends on several factors including diluent composition, solubility of the complexing agent and copper complex in the diluent, pH of the aqueous phase and competing ions, especially iron.
- ◆ Transfer Efficiency
  - Transfer efficiency refers to the percent of copper loading transferred between the organic and aqueous phases during the extraction and stripping operations. Most of the copper transfer occurs during mixing.
- ◆ Rate of Mass Transfer
  - Rate of mass transfer is the rate at which copper is transferred from one phase to the other.

# Summary

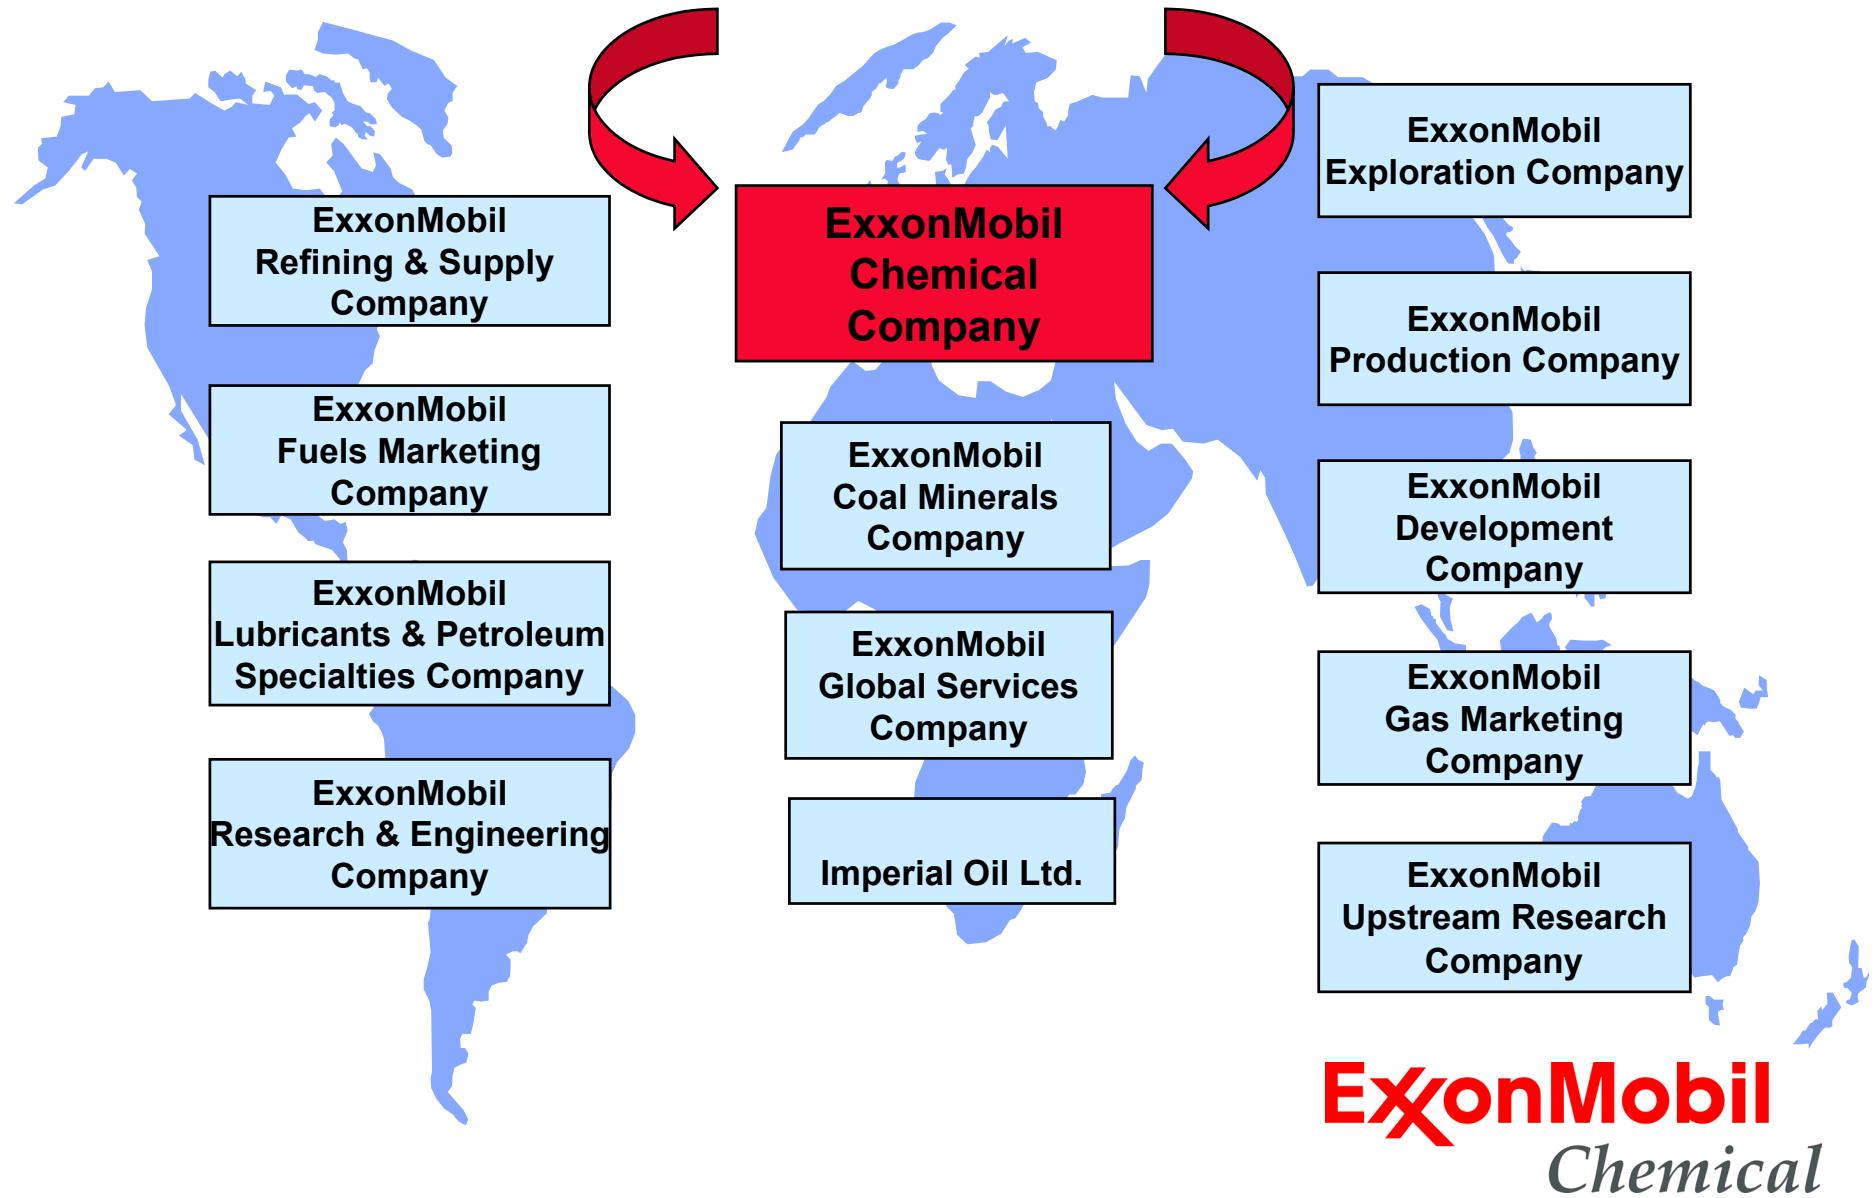

---

- ◆ ExxonMobil Chemical has mining diluents such as ESCAID 100, ESCAID 103, ESCAID 110 and ESCAID 120 that perform better than kerosene in copper recovery processes
- ◆ ESCAID 110 has become the diluent of choice in several mines in Africa and other continents. Close to diluent recommendation in composition and properties, ESCAID 110 offers increased copper loading and high flash point with lower diluent losses

## Our Commitment to Responsible Care®

Responsible Care® is the world-wide chemical industry's commitment to continuous improvement in all aspects of health, safety and environmental performance, and to openness in communication about its activities and achievements.

There are six areas providing clear improvement targets, each aimed at specific public concerns:

1. Community Awareness and Emergency Response
2. Process Safety
3. Distribution
4. Employee Health and Safety
5. Pollution Prevention
6. Product Stewardship

# Introduction to Mintek

*MINTEK, South Africa's national minerals-research organization that was founded in 1934 to assist the mining industry to operate more effectively and profitably, has achieved international recognition for its contributions. Our mining and minerals industry has been extremely innovative, and many notable advances in extraction, refining, and manufacturing technology that originated in South Africa have impacted on the minerals industry world-wide.*

*Aerial view of Mintek*

Mintek works with industry and other R&D organizations to research, develop, and implement new and improved technologies in the minerals and metallurgical sectors. South Africa has become a world leader in this technological niche, with a successful record of technology export, and Mintek itself has become an international player in the field.

## Location

Mintek's research complex is situated in Randburg, about 15 kilometres north of Johannesburg, within easy reach of Johannesburg International Airport.

## Expertise

With a total staff of more than 500, Mintek employs highly qualified and motivated people with a wide range of skills, including metallurgical, chemical, and electronics engineers, chemists, physicists, and

mineralogists. Many of our engineers and scientists are recognized as leaders in their fields of specialization.

## Products and breakthrough technologies

Mintek has been successful in the development of 'breakthrough' technologies that have transformed their industry sectors. Recent successes include the Minataur process for the refining of high-purity gold; gold and copper bioleaching; DC arc furnace technology for the fuming of magnesium, lead, and zinc from ores and wastes, and smelting of chromite, ilmenite, and cobalt-bearing slags; jigging technology for the recovery of ferroalloys from furnace slag; and a range of hardware and software for the stabilization and optimization of metallurgical plants, including submerged-arc furnaces and milling, flotation, and leaching plants. Technologies at an advanced stage of development

include new materials based on the precious metals (gold and platinum), ferronickel production from lateritic ores by pre-heating/reduction and smelting in a DC arc open bath furnace, and hydro-metallurgical techniques for recovering metals from waste streams.

### **Process development and services**

Mintek provides world-class R&D expertise, testwork, and process optimization for the precious and base metals, ferro-alloys, and industrial minerals sectors on an international basis. The activities range from initial investigations to process development, and the design, construction, and commissioning of industrial plants. Working closely with clients, and in conjunction with engineering partners, Mintek supplies a flexible package of technology for process development and optimization.

### **Facilities**

A full range of sophisticated facilities is available for sample preparation and characterization, comminution, flotation, physical separation, smelting, leaching, purification, and metal recovery. Some of these facilities were developed in-house and are unique to Mintek. Processes can be scaled up from initial exploratory batch tests to continuous pilot campaigns operating at feed rates up to 4 tons per hour involving several hundred tons of material, using bulk samples shipped to Mintek. In many cases, work can be carried out at the client's site using modular plant transported in containers. The extensive laboratories and pilot-plants are supported by specialist analytical, mineralogical, and information services, expertise in computer simulation and modelling, and techno-economic studies.

**MINTEK'S Analytical Science Division supports the research activities at Mintek, in particular pilot plant operations. We analyse greatly diverse samples from mining and metallurgical processes, following strict quality procedures and focusing on accuracy and timeous service. Critical operations can be supported by 24-hour standby service.**

The Division has excellent instrumental and laboratory facilities, and highly qualified and experienced staff. The versatility of the laboratory is illustrated by the availability of many different analytical techniques tailored to the needs of specific analyses.

## Equipment and scale of operation

### *Trace ICP section:*

An Elan 6000 ICP-mass spectrometer and an Elan DRC ICP-mass spectrometer are used in measuring a wide range of trace and minor elements in simple and complex sample types. The technique is particularly well suited to precious metals and rare-earth elements. It has great sensitivity, and can readily determine elements in the ppb concentration range. Semi-quantitative analysis of solution samples is generally done by this technique.

An Optima 3300 DV ICP-OES instrument is available for trace analysis of elements not suited to measurement by ICP-MS. A wide range of sample preparation techniques is available.

### *AAS section:*

A number of atomic absorption spectrometers, which work in flame or graphite furnace mode, are available. The technique is useful for the determination of a wide range of elements, and complements the other solution spectroscopic techniques available. Very low levels can be reached by graphite furnace AA. The AA technique is best used where only a few elements have to be determined in a sample.

### *Wet chemistry section:*

Many types of classical analysis are done by volumetric, gravimetric and spectrophotometric determination. These techniques are useful for high-precision work as well as for some difficult analyses.

Total carbon and sulphur determinations at high and low levels, and speciation analyses, are carried out using combustion instruments. A combustion instrument is available for the determination of oxygen and nitrogen in metal samples.

A dedicated water analyser is used for routine water quality analysis, and for the analysis of toxic contaminants in water.

A variety of instruments are available for the

*Emission spectrometer*

*Fire assay*

measurement of pH, TSS, TDS, conductivity and anions. The section also has excellent facilities for TCLP extractions according to US Environmental Protection Agency, Department of Water Affairs and Forestry, and other standards. This technique is used extensively for determining whether solids are acceptable from an environmental point of view. The solutions from TCLP extraction can be accurately analysed by a variety of techniques available in the Division.

### *Chromatography section:*

Ion chromatography, HPLC and FIA are used to determine a wide range of anions and metal complexes. The section has a great deal of experience in dealing with complex sample types. Specialised analysis of cyanide in environmental samples is carried out with a dedicated Skalar segmented flow analyser.

### *XRF section:*

An X-Lab 2000 energy-dispersive XRF instrument is used mainly for the quantitative determination of major and minor elements in geological-type materials and process samples, and for analysis of environmentally important samples such as environmental filter disks. A useful feature of the technique is its ability to provide semi-quantitative information regarding the composition of a wide variety of sample types.

### *ICP-OES section:*

The section uses four Spectroflame ICP-OES instruments, which can determine up to 40 elements simultaneously in the UV and the visible spectrum. The instruments have been set up to be complementary to one another in spectral line combinations. Scanning and background correction facilities are available.

Due to the broad applicability and outstanding analytical capabilities of this technique, a large proportion of the determinations in the Analytical Science Division is done by ICP-OES. A special feature is the capability to carry out accurate analyses at high concentration levels.

### *Fire assay:*

This classical technique is still applied to precious metal analysis, as it allows high-precision analyses for low-level elements in a variety of sample types. This section has excellent facilities for lead collection (mainly for Au, Pt, Pd, and Rh, either as individual elements or as a total figure), and for the nickel sulphide collection technique (Au, Pt, Pd, Rh, Ru, Ir and Os). Generally, a gravimetric finish is used, but individual PGE analysis requires an ICP-OES finish.

Much attention is given to careful control of the tests, so that high-precision results can be obtained. For this reason, electrically heated furnaces are used, lids are used during fusion, and it is preferred to do all samples in duplicate.

### **Quality system**

Mintek's Analytical Science Division has been accredited to ISO Guide 25 since 1995. As Guide 25 has been superseded by ISO 17025, the Division is in the process of converting to the new standard. Accreditation to this internationally accepted quality management system means that stringent standards

have to be followed to ensure reliable results for our clients. Regular internal and external audits, calibration of instruments, and participation in local and international proficiency testing programmes are requirements of the quality management system.

Supporting the quality management system and the operations of the Division is our Laboratory Information Management System (LIMS), which improves the reliable handling of analytical data, reporting of results, maintenance of quality standards, and allows archiving of results.

### **Reference materials**

Mintek has been the only local producer of internationally certified ore and processed material reference materials for over twenty years, and recently also took on the sales and distribution functions for these materials. Mintek has excellent facilities to produce reference materials according to clients' requirements if suitable materials cannot be sourced elsewhere.

### **Staff**

The Division is staffed with experienced and highly qualified personnel. Most members of the analytical and management staff have tertiary qualifications from technikons and universities, and are permanent employees to allow the building of high levels of expertise. Contract staff supplement them when necessary.

All members of staff are thoroughly trained in their fields of expertise, and their competence is tested before they are allowed to report results. The Division stresses all aspects of quality, safety and health and environmental awareness, and is a part of Mintek's QES management systems.

The heads of the various sections have extensive practical experience in the field of analytical chemistry in a mining and metallurgical environment, as well as research experience and proven expertise in their field. They act as consultants and actively participate in national and international conferences.

**Sandra Graham** (Trace ICP and XRF) - 15 years' experience in analytical chemistry, including several analytical techniques.

**Joe Baloyi** (AAS) - 11 years' experience in AA analysis, and 14 years' general analytical experience.

**Joseph Moepane** (ICP-OES) - 12 years' experience in analytical chemistry, specialising in fire assay and ICP-OES.

**Russell Vine** (Fire assay) - 25 years' experience in fire assay at Mintek and in industry.

Highly qualified specialists, supervisors and analysts support the heads of sections.

# Biotechnology

*AS near-surface oxide orebodies become depleted, more mines will have to process deeper, more complex and difficult-to-treat sulphide ores. These will require a modern, simple, environmentally sound technology. In many cases, bacterial oxidation will be the most suitable technique.*

Mintek, together with joint-venture partner BacTech Enviromet Corporation of Canada, offers the full range of services required for the evaluation and commercial implementation of bacterial leaching processes, including proprietary bacterial cultures, testwork and consulting, piloting, flowsheet design, and plant commissioning for gold and base-metal projects. Bioleach pre-oxidation of refractory gold ore concentrates containing sulphide minerals such as pyrite and arsenopyrite (the Bacox™ process) is established commercial technology, and technologies for the bioleaching of copper sulphide concentrates and complex base-metal sulphide concentrates are at the demonstration stage.

The bioleach technologies are supported by comprehensive analytical and mineralogical services, and established capabilities for development, optimization, piloting, and plant design in the areas of ore flotation, solvent extraction, electrowinning, and metal recovery.

## Equipment and scale of operation

- Extensive facilities to handle laboratory bioleach amenability testing.
- Six multi-stage fully instrumented continuous bioleach plants with a capacity of 1 to 5 kg concentrate per day, together with associated solvent extraction and electrowinning facilities.
- Bioleach column rigs for heap-leach simulation studies.

## Recent projects

Mintek and BacTech provided a licence to use the Bacox™ gold bio-oxidation technology for the 25 kt/a concentrate-treatment plant at the Beaconsfield joint venture, Tasmania. A 120 t/d commercial Bacox plant was commissioned at Laizhou Gold Metallurgy Plant in Shandong province, China in 2001. The plant is custom-treating refractory gold concentrates from a number of sources in Shandong, and will also be able to serve as a demonstration facility.

A demonstration pilot plant with integrated SX/EW facilities, with a capacity of 500 kg/d of copper was, commissioned in Mexico in mid-2001 for treating complex sulphide and chalcopyrite-containing concentrates. Together with Industrias Peñoles of

*Continuous bioleaching mini-plant at Mintek*

*Integrated demonstration plant for bioleaching base-metal sulphide, Monterrey, Mexico*

Mexico, Mintek and BacTech are conducting a feasibility study towards a jointly owned 25 kt Cu per annum commercial plant in Mexico.

A major R&D effort, supported by Noranda Inc. of Toronto, Canada, is under way to develop heap bioleaching for the recovery of copper from low-grade chalcopyrite ores. The two-year project aims to optimize the technology and establish its commercial viability.

## **Staff**

The Biotechnology Division includes graduate engineers and scientists qualified in chemical engineering, metallurgical engineering and microbiology, as well as experienced pilot-plant operators.

**Tony Pinches**, Manager: Biotechnology, has over 20 years' experience in biohydrometallurgy and biochemical engineering. He graduated from Cardiff University with a degree in microbiology and went on to obtain a PhD in minerals engineering at the same university, the subject of his thesis being the bioleaching of pyrite and arsenopyrite.

**Petrus van Staden** (Head: Bioprocess Engineering) has over 10 years' experience in hydrometallurgy. He graduated in chemical engineering from the University of Pretoria in 1986, and obtained his MSc (Chemical Engineering) in 1991 from the University of the Witwatersrand. Petrus has extensive experience in gold extraction techniques, and currently specializes in bioleach flowsheet design.

**John Neale** (Specialist: Biotechnology) has over 10 years' experience in chemical engineering and biohydrometallurgy. He joined Mintek in 1985 after obtaining a degree in chemical engineering from the University of Cape Town.

**Vishal Deepaul** (Head: Process Implementation) has 8 years' experience as a production metallurgist (including gold and copper operations) and in R&D. He obtained his BSc in extractive metallurgy and chemistry at Murdoch University in Perth, Western Australia.

**Mariekie Gericke** (Chief Scientist: Bioprocess Support) has 10 years' experience in microbiology. She joined Mintek in 1995. Mariekie graduated from the University of the Free State, and obtained a MSc (Microbiology) from the University of Pretoria.

**Paul Kruger** (Chief Engineer) has approximately ten years' experience in biohydrometallurgy. He joined Mintek in 1992 after obtaining a degree in chemical engineering from the University of Natal (1991).

# Electrowinning

**MINTEK has special expertise in the electrowinning of base metals such as cobalt, chromium, manganese (under exclusive contract), nickel, zinc and gold, and experience in the recovery of platinum-group metals (PGMs) from effluent streams, the production of electrolytic manganese dioxide (EMD), as well as the electrowinning and electrorefining of copper. Testwork is done on laboratory, pilot-plant and industrial scales. Reliable product and electrolyte sample analyses are provided by the Analytical Science Division.**

## Equipment and scale of operation

### Laboratory-scale electrowinning cells

Laboratory cells with a three-electrode configuration have been developed for testwork in electrowinning and electrorefining of most base metals. There are two main categories of cells – divided and undivided. The divided cell is used for metals such as cobalt, nickel, manganese and chromium, where the electrolytes surrounding the anode and cathode are separated by a porous diaphragm. The undivided cell has a common electrolyte, and is used for copper, cobalt, and zinc. The electrode configuration in both types of cell can be changed from a single cathode/two anodes to a single anode/two cathodes system; thus both cathodic and anodic processes can be investigated. There are two different sizes of divided and undivided cells. The smaller cells have a cathode area of approximately  $0.03\text{ m}^2$  and volume of approximately 3.5 - 5.5 l. The larger cells have a typical cathode area of  $0.1\text{ m}^2$  and a slightly larger volume of approximately 6.5 - 8.5 l.

The cells form part of a portable integrated rig that houses the cell and all ancillary equipment required for testwork. Each rig allows for the concurrent operation of two separate electrowinning cells under temperature control, utilising similar or different operating conditions and either synthetic or real plant solution. A total of six rigs have been commissioned for testwork purposes. Previous experience has shown that the performance of the laboratory cells compares favourably with that of well-operated industrial scale cells.

### Electrowinning cells for the production of EMD

Glass electrowinning cells have been developed for the production of electrolytic manganese dioxide (EMD), ranging from 800 g up to 8 kg. This is sufficient to fulfil in-house laboratory requirements and the battery manufacturers' sample requirements for initial testing. A discharge capacity rig has also been developed to quantify the EMD activity, and for comparison against IBA reference samples.

### Pilot-plant-scale electrowinning cells

Minetek has two types of electrowinning cells suitable for pilot-plant testwork on both synthetic and real

*Laboratory-scale electrowinning of EMD*

*Pilot-scale, portable electrowinning rig*

plant solutions - a full depth, full width cell housing up to two cathodes, and a deep (full depth, narrow width) cell, housing a single cathode. The full-scale cell is used to determine the effect of hydrodynamic forces on the deposit morphology, ease of stripping the deposit, impurity deportment, and typical performance data. The cathode area is approximately 1.8 m<sup>2</sup>. The deep electrowinning cell is designed to operate with a full depth, but narrow width, cathode. This allows the factors mentioned above to be examined on a slightly smaller scale, while still retaining the benefits of operating with a full-depth cathode.

Mintek has two deep cells, one with modular electrical, storage and pumping units that fit into a single shipping container. This allows for easy disassembly, transport, and re-assembly of the testing facility at distant locations throughout the world.

#### *Control and test cells in cell-houses*

Once specific recommendations have been made based on laboratory testwork, these can be tested on an industrial scale before implementation throughout the entire cell-house.

Two or three cells in the cell-house are prepared so as to operate with minimal mechanical or electrical faults (i.e. under ideal conditions). One cell (the control cell) is run according to the standard conditions in the cell-house. The other cells are designated as test cells, and are operated under conditions recommended from the laboratory testwork. Once these recommendations have been proved at this scale, they can be implemented successfully throughout the cell-house.

### **Recent projects**

#### *Cobalt*

With an increased international interest in cobalt, testwork has been done on the electrowinning of cobalt in divided and undivided cells has been conducted on laboratory, pilot plant and industrial scales. Clients include:

- Bulong., Australia
- Anglo American Corporation, Zimbabwe
- Kasese Cobalt Company, Uganda.

#### *Nickel*

Testwork on the electrowinning of nickel from standard and dilute solutions, including the effect of certain additives and organics, has been performed at laboratory and pilot scales. Clients include:

- Bulong., Australia
- Billiton Process Research, South Africa, and Queensland Nickel Industries, Australia
- Anglo American Corporation, Zimbabwe
- Anglovaal Mining, South Africa.

#### *Zinc*

Various aspects of zinc electrowinning have been optimised for Zincor Ltd, South Africa's only zinc producer. These include anode preconditioning, manganese removal, suppression of acid mist, the effects of additives, and anode evaluation. This work has been done on a laboratory and industrial scale.

#### *Manganese*

Various aspects of manganese metal production have been investigated on a laboratory scale under an exclusive contract between Mintek and Manganese Metal Company (MMC). Cell-house audits have been completed for both MMC and Zincor Ltd.

#### *Electrolytic manganese dioxide*

The production of EMD has been investigated on a laboratory scale. Clients include:

- Golden Tiger Resources, Australia
- Geometals Ltd., South Africa
- HiTec Energy, Australia (formerly Sovereign Resources)
- SA Mineral Resources Corporation Ltd, South Africa Gold.

Mintek recently provided the conceptual and detailed design for three gold refineries incorporating precious-metal chemical production. Electrochemistry is utilized in the gold refinery, gold potassium cyanide plant, and the silver cyanide production plant.

#### **Staff**

**Isaac Kappers** (Operator) - six years' experience

**Ephraim Mabusela** (Principal Operator) - eight years' experience

**Karen Matchett** (Senior Engineer) - six years' experience

**Ivan Greager** (Senior Engineer) - three years' experience.

**MINTEK'S gold process development programme provides a quick and cost-effective method of ensuring that gold recovery operations perform at their optimum level. Testwork may be carried out at both laboratory and pilot-plant scale, supported by well-proven computer-simulation design packages, so as to arrive at the most appropriate process route.**

The programme offers a complete gold process testing package for

- refereeing routine samples
- preliminary feasibility studies
- elucidation of problems occurring on existing operations
- development and evaluation of process flowsheets for new and existing operations
- evaluation and design of carbon-in-pulp (CIP) and resin-in-pulp (RIP) process flowsheets for gold recovery
- process consulting service.

The expertise base includes the skills of experienced mineralogists, analysts, and engineers with access to comprehensive analytical, laboratory, and pilot-scale facilities.

## Equipment and scale of operation

### Laboratory scale

- Batch cyanidation tests to optimize leaching parameters
- Batch tests to establish amenability of ore to heap leaching
- Batch gravity concentration tests to establish free gold occurrence and composition
- Batch amenability testing for chloride leaching of gold concentrates (Gravitaur process)
- Batch adsorption loading tests to establish the relative merits of activated carbon or ion-exchange resin, and process simulation
- Batch carbon elution testing
- Activated carbon quality assessment
- Quantification diagnostic leaching tests to characterize the mineral phases, establish gold deportment, gold/mineral associations, and thus determine the reasons for gold lock-up
- Cyanide speciation in process streams

### Pilot-plant scale

- Skid-mounted multi-stage contacting systems (5 litre, 150 litre) for continuous leaching and adsorbent-in-pulp process evaluation
- A range of percolation column sizes for heap leaching appraisals
- Minix resin elution and gold electrowinning facility.

*Skid-mounted adsorbent-in-pulp pilot plant at Kloof Gold Mine*

## Projects undertaken

Mintek has undertaken numerous gold processing appraisals on ore sources world-wide. Typical examples include the following:

### Process flowsheet development

Morilla - Mali  
Tirek - Algeria  
Tarkwa- Ghana  
Driefontein - South Africa  
Geita, Tanzania  
Syama - Mali  
Sino Mining - China  
Ararat Gold Recovery Co. - Armenia  
Hindustan Zinc Ltd - India

### Techno-economic evaluation of CIP vs RIP

Vaal Reefs - South Africa  
Hutti - India  
Western Areas - South Africa  
New Consort - South Africa  
CVRD - Brazil  
Millsite - South Africa

## **Staff**

The Gold Technology Group consists of 12 members, six of whom have tertiary qualifications, with the remaining members having extensive experience in metallurgical (and specifically gold) testing.

**Dennis Bosch** - BSc (Chem Eng), MSc (Mineral Process Design) *Head: Gold Technology*

Joined Mintek in 1999 after gaining 30 years' experience in mineral processing in South Africa and Canada, much of this in the gold mining industry. His involvement has been in operations, process development, plant design and consulting.

**Peter Tout** - HND (Extractive Metallurgy) *Principal Scientist*

More than 20 years' experience in gold and uranium processing. Was involved in Minetek's CIP and RIP development programmes, and has extensive experience in gold metallurgy at both laboratory and pilot scales.

**Peter Lotz** - Dipl (Chem) (Swiss) *Principal Scientist*

More than 10 years' experience at Mintek in various fields of process chemistry. Recently specialized in cyanide chemistry and its application to processing and the environment.

# Leaching and precipitation

**LEACHING** is the primary step in most hydrometallurgical processes. The overall recovery of the valuable species is thus directly affected by the efficiency of the leach, and optimization of the leach parameters is therefore of critical importance. Mintek is able to select and optimize leaching conditions for a variety of ores. Mintek's expertise in this field includes an understanding of the basic chemistry involved, mathematical modelling, and process optimization.

Precipitation techniques are often used to purify or concentrate process streams. In these cases, both purity and recovery need to be considered. Mintek's precipitation technology provides a number of techniques that can readily be integrated into new or existing processes. Special expertise is available in base metal precipitation and the removal of iron from process streams.

Mintek has facilities to undertake projects from basic flowsheet design through to laboratory testwork, piloting and full-scale plant commissioning. The services include process design, and optimization of process conditions and economics, based on computer simulation and experimental work.

## Equipment and scale of operation

- Laboratory-scale glass reactors ranging from 250 ml to 5 l for bench-scale batch tests. The vessels can be sealed, and are equipped with mechanical overhead stirrers and gas-dispersing impellers to ensure good agitation and induction of various gaseous reagents.
- A multipurpose six-stage pilot-scale continuous stirred-tank reactor cascade. The reaction vessels are of polypropylene which allows operating temperatures up to 90°C. The vessel sizes range from 10 l to 25 l. This plant is equipped with full PID control circuits for both temperature and pH control.
- A multipurpose five-stage miniplant scale continuous stirred-tank reactor cascade. The reaction vessels are of glass, and range in size from 250 ml to 5 l.
- Multipurpose batch-mode pilot-plant-scale stirred-tank reaction vessels of sizes ranging from 500 l to 2200 l.
- Process variables such as temperature, agitation speed, pH, and redox potential can be controlled.

## Recent Projects

Flowsheet conceptualization, process simulation, laboratory and pilot-scale testwork to develop a process for the production of high-purity electrolytic manganese dioxide from Woodie Woodie ore, Western

*Multipurpose continuous leach and precipitation facility*

Australia. The work was performed for HiTec Energy NL, of Perth. The feasibility study was recently completed, and the project is now at the design stage. Laboratory and pilot-scale testwork for the proposed expansion of Impala Platinum's base-metals refinery. This project implemented recently developed technology for the removal of manganese and iron from nickel and cobalt leach solutions.

Flowsheet conceptualization, process simulation, laboratory and pilot-scale testwork to develop a new process for the treatment of Merensky and UG2 PGM concentrates. This project was for a feasibility study undertaken by Lonmin Platinum to expand their current operations.

Laboratory-scale testwork for upgrading tantalum- and niobium-bearing ferro-alloys for Mamoré Mineração e Metalurgia, Brazil.

Flowsheet conceptualization, process simulation, laboratory and pilot-scale testwork to remove iron from BioNIC® nickel-cobalt bioleach process liquor.

## **Staff**

**George Benetis** (Chief Technician)

Fifteen years' experience in leaching, precipitation, and electrowinning technology. Specializes in intricate laboratory testwork and the management of pilot-plant operations.

**Danie Jacobs** (Chief engineer)

Four years' experience in leaching and precipitation technology. Specializes in the management of large projects and pilot-plant operations.

**Petrus Mafulako** (Senior Operator)

Ten years' experience in laboratory and pilot-plant operations.

**Sydney Mahlatsu** (Technician-in-training)

Three years' experience in leaching and precipitation technology. Specializes in laboratory testwork and the operation of pilot plants

**Michael Ramoipone** (Senior Operator)

Four years' experience in laboratory and pilot-plant operations.

**Patric Tshisikhawe** (Chief Operator)

Fourteen years' experience in laboratory and pilot-plant operations.

**MINTEK'S expertise in solvent extraction (SX) covers testwork requirements from initial laboratory studies through to a complete process design package and full-scale plant commissioning. This range of capabilities includes:**

- **development of solvent systems for individual applications**
- **laboratory shake-out tests and batch countercurrent tests**
- **small- and large-scale piloting**
- **process flowsheet development**
- **process flowsheet simulation modelling**
- **preliminary process design for contracting engineer**
- **auditing of process flowsheets and plant design**
- **commissioning**
- **troubleshooting.**

Mintek has a professional team of process chemists and engineers, supported by a wide range of in-house services such as costing engineers, analysts, mineralogists, and engineering workshops. Ongoing research in solvent extraction of base and precious metals, as well as equipment design, is undertaken to broaden our knowledge and to develop new technologies, as well as improve existing ones. Mintek also has excellent piloting facilities for upstream and downstream unit operations, allowing the continuous testing of solvent-extraction unit operations within integrated process flowsheets.

## Equipment and scale of operation

Mintek has a wide range of modern laboratory equipment for the development, evaluation, and understanding of fundamental SX process chemistry.

Mixer-settler equipment for continuous pilot-plant evaluations is available, with solution throughputs from 60 cm<sup>3</sup>/h up to 3 m<sup>3</sup>/h.

A Bateman pulsed column (BPC) with an internal diameter of 100 mm is also available for treating solution flowrates of 1 to 2 m<sup>3</sup>/day. A 40 mm diameter column will be available soon. Testing and scale-up of the BPC are done in a joint venture with Bateman Projects (South Africa and Israel).

Piloting is undertaken either in Mintek's well-equipped pilot bays or on site at the client's facility. Pilot campaigns have been carried out extensively both in southern Africa and internationally.

Mintek has designed and constructed several small full-scale SX plants.

## Recent projects

Harmony Gold Refinery (Virginia, South Africa). Design, installation, and commissioning of a refinery

*Integrated pilot plant*

to produce 99.99 per cent gold using the Minataur™ process. Similar 2 t/month refineries will be commissioned in Italy, South Africa, and Algeria during 2001. The Minataur (Mintek Alternative Technology for Au Refining) process uses a leach/solvent extraction/precipitation route to produce high-purity gold powder. The process can treat gold-containing materials ranging from jewellery scrap to cathode/anode sludges.

During 1999, Mintek and joint-venture partner Billiton successfully completed integrated pilot-plant campaigns in South Africa and Australia to produce nickel cathode from BioNIC® bioleach process liquor. Treating the sulphate liquor directly, the circuit comprised iron removal by precipitation, cobalt and nickel concentration and recovery by SX, followed by nickel purification by SX, and the electrowinning of LME-grade nickel cathode.

An integrated pilot plant operated in Zimbabwe for several months, treating 15 m<sup>3</sup>/d nickel sulphate electrolyte for the removal of cobalt by SX. The cobalt

stream was purified using ion exchange, followed by electrowinning of 99.9 per cent cobalt metal. LME-grade nickel cathode was produced from the purified nickel electrolyte.

Manganese removal and cobalt recovery from a copper SX raffinate bleed stream was piloted for a North American client as part of an integrated operation involving iron removal, purification by ion exchange, and cobalt electrowinning.

An integrated circuit was operated for the sequential solvent extraction of cobalt and nickel for subsequent electrowinning for a South African producer.

In collaboration with Mintek's bioleaching team, a SX miniplant was operated for recovering copper from chalcopyrite bioleach liquors. This integrated technology is being demonstrated in collaboration with technology partners Bateman (Australia) and Peñoles (Mexico).

An integrated flowsheet for the separation of platinum, palladium, rhodium and iridium from precious-metal alloy scrap has been piloted for a European client. In addition to SX, the flowsheet comprised leaching, precipitation, and effluent treatment.

Mintek has worked with contracting engineers on a number of projects involving the design of solvent-extraction plants to remove cobalt from nickel solutions.

## Specialist staff

**John Preston** (*Specialist Scientist*). More than 20 years' international experience in the development of solvent systems for base-metal, precious-metal, and rare-earth separations, with numerous publications in these areas. Currently process chemistry consultant to Mintek's SX engineers.

**Angus Feather**. Project leader, responsible for process flowsheet development, pilot-plant operations, and commissioning and troubleshooting on full-scale plants. Has spent 15 years in extractive metallurgy R&D, mainly in SX, with particular experience in base metals, gold, and several rare element and inorganic acid systems.

**Marthie Kotze** (*Head: Separation Technology*). Fifteen years' experience in solvent extraction, ion exchange, and resin-in-pulp processes. Currently heads a group of ten professional staff specializing in these areas.

**Rene du Preez**. Fifteen years' experience in developing solvent extraction systems for base metals, platinum-group-metals, and other commodities.

**Sean Scott**. Five years' experience in extractive metallurgy, focusing on SX systems for the recovery and separation of base and precious metals. Project leader, particularly for the BPC pilot-plant evaluation campaigns.

**Wendy Bouwer**. Two years' experience in solvent extraction for base-metals recovery and separation and gold refining.

**ION exchange is a hydrometallurgical technique that can be used to**

- **recover and upgrade valuable species in terms of purity and concentration**
- **remove impurities from a process liquor**
- **remove noxious species from process effluents.**

**Ion exchange can be effective at very low concentrations (ppm levels), and where other separation techniques fail, selective separations may be achieved by the correct choice of ion exchange resin. Ion exchange can potentially treat poorly clarified liquors or even pulps, thus eliminating costly solid/ liquid separations.**

## Applications

The best-known metallurgical application of ion exchange is in the recovery of uranium - a process developed in South Africa in which Mintek, with its patented NIMCIX contactor, played a major role. Other industrial applications include recovery of gold, purification of electrolytes for electrowinning, removal of heavy metals from waste streams, and water purification.

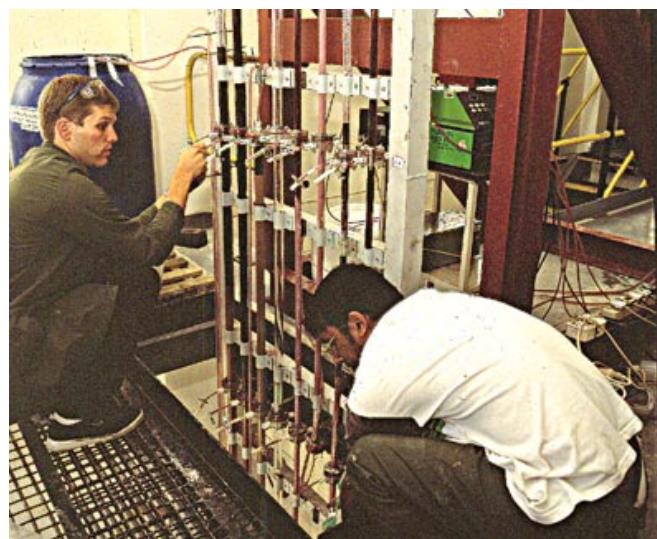

Mintek's biggest effort in ion exchange during the past decade involved the development of a resin-in-pulp (RIP) process for gold. A gold-selective resin (Dowex-Minx) developed at Mintek has been commercialised, and is used for the processing of a preg-robbing ore at the industrial scale. This resin is currently being evaluated by a South American gold producer for the recovery of gold and silver from a heap-leach liquor.

Recent developments in RIP technology have focused on the recovery of base metals from slurries. Evaluations have been carried out on the recovery of nickel, zinc, cobalt and copper at mini-plant scale, and zinc at pilot-plant scale. A final feasibility study using this technology has been completed for a South African client.

During the past 5 years, Mintek has been involved in a number of projects for the design and piloting of fixed-bed ion exchange operations for the removal of impurities such as copper, zinc and nickel from cobalt and copper and zinc from nickel electrolyte streams, as well as the recovery of metals from effluent streams such as solvent extraction raffinates.

## Facilities and scale of operation

Mintek has facilities to undertake projects from basic flowsheet design through to laboratory testwork, piloting, and full-scale plant commissioning. The service includes process design, and optimization of process conditions and economics based on computer simulation and experimental work. Personnel include chemists and engineers who work together in close collaboration throughout a project, and assist the

*Ion-exchange columns being used to remove impurities from a cobalt electrolyte*

*Pump-cell tests on a gold-selective resin*

engineering contractor with the final design and feasibility studies.

Mintek has a range of laboratory and pilot-plant equipment for:

- resin evaluation and comparison
- fixed-bed applications, including countercurrent circuits
- NIMCIX (fluidised-bed) evaluation
- resin-in-pulp evaluation.

All testwork, including piloting, can be carried out either at Mintek or at the client's site.

## Recent Projects

Recent projects in which processes were designed or evaluated for clients include:

- removal of base-metal impurities from cobalt and nickel electrolytes
- primary recovery of nickel from low-grade solutions to produce electrolyte for electrowinning of nickel
- recovery of nickel and cobalt from clear effluent streams such as solvent-extraction raffinates
- recovery of base and precious metals from slurries
- recovery of gold and silver from heap-leach liquor.

Preliminary laboratory testwork for these applications included evaluation of commercially available resins to determine the most suitable resin for a specific application.

## Staff

**Brian Green** (*Specialist Consultant: Hydrometallurgy*)

Twenty-five years' experience in process chemistry, particularly in ion-exchange technology and the development of speciality resins.

**Marthie Kotze** (*Head: Separation Technology and Project Co-ordinator of resin-in-pulp for gold*). Seventeen years' experience in ion-exchange technology.

**Peter Tout** (*Senior Chief Technician*). Twenty-six years' experience in gold metallurgy and the application of resins for gold and silver recovery.

**Jacolien Wyethe** (*Principal Engineer*). Seven years' experience in ion-exchange technology and its application in metallurgy.

**Ivan Greager** (*Senior Engineer*). Five years' experience in ion-exchange technology.

**Johanna van Deventer** (*Senior Technician*). Six years' experience in ion-exchange technology.

## Rhodia - A Leader in Specialty Chemicals

*Rhodia, one of the world leaders in specialty chemicals, contributes to improving the quality of life by developing value-added solutions for the beauty, clothing, foodstuffs and healthcare markets, in addition to transport, industry and the environment.*

*To maintain our commanding market position and reinforce foundations for continued growth, Rhodia is committed to developing innovative new products and services, providing our customers with long-term competitive advantages.*

*Our Phosphorus and Performance Derivatives (PPD) enterprise is dedicated to bringing quality products based on phosphorus technology to our customers. Our extensive product portfolio provides solutions for water management, phosphorus derivatives and flame retardants for the textile and polyurethane markets.*

*The PPD group is a dynamic, technology-driven business that provides innovative solutions to meet customer needs. We work in partnership with our customers to develop new products and technologies, relying on close cooperation and detailed understanding of their processes.*

*We provide a high level of technical and analytical support to help customers overcome challenges and achieve their goals. Products are manufactured at our global production facilities which operate to the highest standards, with ISO 9002 and GMP accreditation.*

## Phosphorus Derivatives

*Rhodia produces a diverse range of organophosphorus compounds within the Phosphorus Derivatives product range, beginning with the basic building blocks of phosphorus trichloride ( $\text{PCl}_3$ ), phosphorus oxychloride ( $\text{POCl}_3$ ) and phosphorus pentoxide ( $\text{P}_2\text{O}_5$ ). Phosphorus Derivatives are a major growth area for Rhodia. Significant investment in research and development, equipment and capacity expansion is key to growing our business. Chemicals produced include organic phosphites, organic phosphates, organic alkylphosphonates, acid phosphates and organic pyrophosphoric acids which are used in a variety of applications. Also included in the range are phosphorous acids which are used in the production of agrochemicals and water treatment products.*

*Rhodia is the world's largest merchant producer of phosphorus trichloride and phosphorus oxychloride. Both products are available in DOT-approved drums or in bulk, utilizing the company's fleet of dedicated tank trailers and rail cars.*

## Primary Derivatives

PRODUCT	DESCRIPTION	APPLICATION
<b>PHOSPHORUS HALIDES</b>		
ALBRITE® $\text{PCl}_3$	Phosphorus trichloride	Basic building block for a range of organic phosphites, phosphates, phosphonates and chlorides, which are used to make a variety of end products, such as antioxidants, stabilizers, peroxides, agricultural chemicals, lubricant additives, water treatment chemicals, pharmaceuticals and flame retardants.
ALBRITE® $\text{POCl}_3$	Phosphorus oxychloride	
<b>PHOSPHORUS PENTOXIDE</b>		
$\text{P}_2\text{O}_5$	Phosphorus pentoxide	Raw material to synthesize acid phosphates which have a variety of end uses both in the acid and neutralized form.
<b>HYPOPHOSPHOROUS ACID</b>		
ALBRITE® 50%	50% aqueous solution	Used as antioxidant, catalyst, color inhibitor, reducing agent and chemicals intermediate.
<b>SODIUM HYPOPHOSPHITE</b>		
$\text{NaH}_2\text{PO}_2 \cdot \text{H}_2\text{O}$	Sodium hypophosphate	Reducing agent in electroless nickel plating, for producing nickel-phosphorus alloy coatings.
<b>PHOSPHOROUS ACID</b>		
ALBRITE® Phosphorous Acid Flake	Solid form of $\text{H}_3\text{PO}_3$ typically 99+ % purity	ALBRITE® phosphorous acids are used to manufacture a variety of inorganic phosphites and organic phosphonates which find use as agrochemicals, chelating agents, scale and corrosion inhibitors.
ALBRITE® 70% Phosphorous Acid	70% aqueous solution of $\text{H}_3\text{PO}_3$ ; contains up to 7% HCl	
ALBRITE® 70% Phosphorous Acid Low Chloride	70% aqueous solution of $\text{H}_3\text{PO}_3$ ; < 35 ppm Cl	

## Secondary Derivatives

PRODUCT	DESCRIPTION	APPLICATION
<b>ACID PHOSPHATES</b>		
ALBRITE® N-Butyl Acid Phosphate		
ALBRITE® N-Octyl Acid Phosphate		
ALBRITE® 2-Ethylhexyl Acid Phosphate		
ALBRITE® Amyl Acid Phosphate		
ALBRITE® N-Hexyl Acid Phosphate	Mixed mono and diesters of phosphoric acid	Organic acid phosphates and their salts are employed in many different applications, such as acid catalysts in coatings, dispersants, lubricants and antistatic agents in textile manufacture.
ALBRITE® Nonyl Acid Phosphate		
ALBRITE® Phenyl (PA-75) Acid Phosphate		
ALBRITE® Cetyl Acid Phosphate		
ALBRITE® Isooctyl Acid Phosphate		
ALBRITE® Octylphenyl Acid Phosphate		
<b>TRIARYL PHOSPHITES</b>		
ALBRITE® Triphenyl Phosphite	A clear, mobile fluid; chemical formula $(C_6H_5O_3P)$	Used as a chemical intermediate for the production of other phosphite esters and phosphonates, as a secondary stabilizer for polyvinyl chloride (PVC) and other polymers such as polypropylene. Also used as a viscosity modifier for epoxide resins, as a flame retardant for polyurethane foams, as an antioxidant for synthetic rubbers and as a lubricant oil additive.
<b>DIALKYL PHOSPHITES</b>		
Diisopropyl		
Dibutyl		
Bis(2-ethylhexyl)	Liquid products conforming to general formula $(RO)_2P(O)H$	Mobile, colorless liquids with mild odors and good thermal stability. Miscible with alcohol, ether and most common organic solvents. Uses include additives for extreme pressure lubricants, adhesives, antioxidants and organic phosphorus intermediates.
Bis(tridecyl)		
Dioleyl		Undergo oxidation, transesterifications and hydrolysis reactions. React with acid halides, acids, esters, amides, aldehydes, ketones, ethers, Grignards and certain unsaturated compounds.

PRODUCT	DESCRIPTION	APPLICATION
<b>TRIALKYL PHOSPHITES</b>		
Tris(2-chloroethyl)		
Triisopropyl		
Tributyl	Liquid products conforming to general formula $(RO)_3P$	Mobile, colorless liquids with characteristic odors. Miscible with alcohol, ether and most common organic solvents. Used as intermediates for insecticides and flame-proofing agents. Additives for lubricants and greases, speciality solvents, stabilizers and color inhibitors for resins.
Tri(2-ethylhexyl)		
Triisoctyl		Highly reactive. Readily oxidized, transesterified or hydrolyzed. Also react with organic acids, halides, ketones, aldehydes, ethers and many other functional groups.
<b>TRIALKYL PHOSPHATES</b>		
Tributyl		
Tributoxyethyl (TBEP)		
Tris(2-ethylhexyl) (TOF)	Liquid products conforming to general formula $(RO)_3P$	Clear mobile liquids with little odor or color. All are miscible in organic solvents. Only triethyl phosphate is soluble in water. Show good thermal and hydrolytic stability. Major uses include plasticizers, dispersants, flame retardants and antifoaming agents.
Triethyl**		
<b>DIALKYL ALKYLPHOSPHONATES</b>		
Dimethyl methyl		
Diethyl ethyl		
Dibutyl butyl	Liquid products conforming to general formula $R-P(O)(OR)_2$	Colorless liquids with mild odors. Stable organophosphorous compounds that are miscible with alcohol, ether and most organic solvents. Uses include heavy metal extraction and solvent separation, pre-ignition additives to gasoline, anti-foam agents in plasticizers and stabilizers, additives in solvents and low temperature hydraulic fluids, flame-proofing agents and to replace organic phosphates for improved stability. Also used as a flame retardant for polyurethane foam, as an antioxidant for synthetic rubbers and as a lubricant oil additive.
Bis(2-ethylhexyl)		
2-ethylhexyl		
Bis(2-chloroethyl)		
2-chloroethyl		

## Metal Extractants

<b>ALBRITE® DBBP</b>	Dibutyl butylphosphonate	Dibutyl butylphosphonate and di(2-ethylhexyl) phosphoric acid are mobile, colorless to light-yellow liquids which are soluble in kerosene-type organic diluents. DBBP exhibits a synergistic effect with di(2-ethylhexyl) phosphoric acid in the extraction of heavy metals.
<b>DEHPA®</b>	Di(2-ethylhexyl) phosphoric acid	Used commercially for the extraction of uranium from wet process phosphoric acid streams, beryllium, rare earths and other metals.
<b>ALBRITE® TBPO<sub>4</sub></b>	Tributyl phosphate	A colorless mobile liquid with low odor. TBPO <sub>4</sub> is an established product for the refining of uranium from yellow cake and is used for solvent extraction of a variety of other metals from aqueous streams.
<b>IONQUEST® 801</b>	2-Ethylhexylphosphonic acid, mono-2-ethylhexyl ester	Used for the extraction and separation of rare earth metals (lanthanides) and the separation of Co from Ni.

\*\* Available only in Europe

## Agricultural Intermediates

PRODUCT	DESCRIPTION	APPLICATION
ALBRITE® TMP	Trimethyl phosphite	Intermediate for monocrotophos, DDVP, NALED phosphamidon, mevinphos and other products.
ALBRITE® TEP	Triethyl phosphite	Intermediate for chlorfenvinphos, fosamine-ammonium, and other products.
ALBRITE® DMHP	Dimethyl hydrogen phosphite	Intermediate for glyphosate, trichlorfon, dimethon-methyl and other products.

## Phosphorus Based Lubricant Additives

DURAPHOS® DMHP	Dimethyl hydrogen phosphite	The dialkyl hydrogen phosphites and acid phosphates are used as intermediates in the formation of extreme pressure (EP) anti-wear (AW) and friction modifier (FM) additives in lubricating oils and greases.
DURAPHOS® DIPH	Disopropyl hydrogen phosphite	
DURAPHOS® DBHP	Diethyl hydrogen phosphite	
DURAPHOS® B(2EH)HP	Bis (2-ethylhexyl) hydrogen phosphite	
DURAPHOS® BTDHP	Bis tridecyl hydrogen phosphite	
DURAPHOS® AP-230	Dilauryl hydrogen phosphite	
DURAPHOS® AP-240	Dioleyl hydrogen phosphite	
DURAPHOS® TLP	Trilauryl phosphite	
DURAPHOS® TPP	Triphenyl phosphite	
DURAPHOS® AAP	Amyl acid phosphate	
DURAPHOS® 610**	C <sub>6</sub> -C <sub>10</sub> alkyl acid phosphate	
DURAPHOS® 2EHAP	2-ethylhexyl acid phosphate	
DURAPHOS® OAP	Octyl acid phosphate	
DURAPHOS® APO 128	Oleyl acid phosphate	
DURAPHOS® 178	Acid phosphonate-based corrosion inhibitor	Approved for use in food grade applications at up to 0.5% by weight. Can also pass EMCOR and ASTM D05969 at higher treat rates in grease formulations.
DURAPHOS® 1700	Low viscosity corrosion inhibitor	Imparts excellent wear protection and corrosion inhibition in grease and oil
DURAPHOS® 444	An effective FG EP for greasers	Anti-wear performance at low levels and good water resistance in both oils and greases.
DURAPHOS® 100**	Neutral phosphonate-based friction modifier	Imparts excellent anti-wear performance

## OTHER

N-Butylchloride*	Intermediate C <sub>4</sub> H <sub>9</sub> Cl	Used in the preparation of a Grignard reagent, in Butyllithium production and in organotin catalyst manufacture.
------------------	---	--

\* Available only in the USA

\*\* Available only in Europe

## Water Management Chemicals

The Water Management Chemicals business specializes in the manufacture and marketing of specialty chemicals designed to control scale, corrosion and microbiological fouling across a wide range of industrial applications. Our extensive product range is targeted at the oil, industrial water, paper, leather and desalination service industries and is supported by worldwide applications expertise.

Products are manufactured to ISO 9002 quality standards from primary locations in the US and UK

TOLCIDE® PS is an innovative product used in oilfield recovery, industrial water treatment and pulp and paper applications. TOLCIDE® PS combines broad spectrum anti-microbial activity with a favorable aquatic toxicity profile and to date has achieved several new registrations including:

- US Environmental Protection Agency registration
- US FDA approval for paper slimicide applications
- German BGW
- Offshore Chemical approvals

Rhodia has also received the US Presidential Green Chemistry Challenge Award in the category of Designing Safer Chemicals.

In addition, BRICORR® 288 is a completely new multi-functional corrosion inhibitor for use in industrial water treatment. BRICORR® 288 combines the benefits of outstanding performance and stability to oxidizing biocides with a favorable environmental profile.

PRODUCT	DESCRIPTION	APPLICATION
<b>BIOCIDES - Key Actives</b>		
TOLCIDE® PS	Series of aqueous solutions of tetrakis(hydroxymethyl) phosphonium sulphate (THPS)	Broad spectrum, fast acting, non-oxidizing biocide for industrial water treatment, oil recovery operations and pulp and paper production. Benefits include excellent performance profile with low environmental impact.
TOLCIDE® MBT	Series of technical active and formulated biocides based on methylene bis(thiocyanate)	Non-oxidizing biocide especially effective as a bactericide and fungicide in paper manufacturing and leather processing.
TOLCIDE® C80* *	Series of products comprising (2-thiocyanomethylthio) benzothiazole (TOMTB), a non-metallic organosulphur compound in liquid form	Used in various stages of leather processing and other preservation applications.
DAZOMET**	Non-metallic organosulphur compound in solid form	Good fungicidal and bactericidal activity effective over a wide pH range.

#### BRIQUEST PHOSPHONATES FOR WATER TREATMENT APPLICATIONS

BRIQUEST® ADPA-60A**	Aqueous solution of 1-hydroxyethane-1,1-diphosphonic acid (HEDP), 60% active acid	Useful in a variety of industrial applications (i.e. cooling water, oilfield, textile) for scale inhibition and metal ion control (sequestration).
BRIQUEST® ADPA-60AW*	Aqueous solution of 1-hydroxyethane 1,1-diphosphonic acid (HEDP), 60% active acid	
BRIQUEST® 301-50A	Aqueous solution of aminotri-(methyleneephosphonic acid), [ATMP], 50% active acid	
BRIQUEST® 301-30SH	Aqueous solution of the pentasodium salt of ATMP, pH10, 30% active acid	
BRIQUEST® 543-45AS	Aqueous solution of diethylenetriaminepentakis (methyleneephosphonic acid), 45% active acid	
BRIQUEST® 462-23K	Aqueous solution of the potassium salt of hexamethylene diaminetrakis (methyleneephosphonic acid), 23% active acid	
BRIQUEST® 5123-45A	Aqueous solution of bis(hexamethylene) triaminepentakis (methyleneephosphonic acid), 45% active acid	
BRIQUEST® 221-50A	Aqueous solution of 2-hydroxyethyliminobis (methyleneephosphonic acid), 50% active acid	
BRIQUEST® 3010-25K	Proprietary, phosphonate formulation as potassium salt solution, 25% active acid	
BRIQUEST® 3010-25KH	Proprietary aqueous phosphonate potassium salt, pH10, 25% active acid	
BRIQUEST® 422-25S	Aqueous solution of the sodium salt of ethylenediaminetetrakis (methyleneephosphonic acid), 25% active acid	
BRIQUEST® 543-25S	Aqueous solution of the sodium salt of diethylenetriamine-pentakis (methyleneephosphonic acid), 25% active acid	

\* Available only in the USA

\*\* Available only in Europe

PRODUCT	DESCRIPTION	APPLICATION
<b>BRIQUEST PHOSPHONATES FOR WATER TREATMENT APPLICATIONS</b>		
BRIQUEST® 281-25S	Neutral, aqueous solution of the sodium salt of 2-ethylhexyliminobis (methylenephosphonic acid), 25% active acid	
BRIQUEST® 2N81-25S	Neutral, aqueous solution of the sodium salt of n-octyliminobis (methylenephosphonic acid), 25% active acid	
BRIQUEST® 8106-25S	Neutral aqueous solution of the sodium salt of pentaethylenhexamineoctakis (methylenephosphonic acid) 25% active acid	Useful in a variety of industrial applications (i.e. cooling water, oilfields, paper manufacture and textiles) for scale inhibition and metal ion control (sequestration).
BRIQUEST® 684-30S	Proprietary phosphonate formulation, supplied as a neutral sodium salt, 30% active acid	
BRIQUEST® Blend B*	Patented synergistic formulation containing phosphonate, 55% active acid	
<b>BRIQUEST PHOSPHONATES FOR DETERGENT APPLICATIONS</b>		
BRIQUEST® 422-25S	Aqueous solution of the sodium salt of ethylenediaminetetrakis (methylenephosphonic acid), 25% active acid	
BRIQUEST® 422-34CS	Calcium/sodium salt of ethylenediaminetetrakis (methylenephosphonic acid), granular, free flowing powder, 34% active acid	
BRIQUEST® 543-25S	Aqueous solution of the sodium salt of diethylenetriaminopentakis (methylenephosphonic acid), 25% active acid	Important properties of sequestration, threshold scale inhibition and dispersion. Used in detergents, textile bleaching and allied applications.
BRIQUEST® ADPA-18SH	Aqueous solution of the tetrasodium salt of 1-hydroxyethane-1, 1-diphosphonic acid, 18% active acid	
BRIQUEST® ADPA-21SH	Aqueous solution of the tetrasodium salt of 1-hydroxyethane-1, 1-diphosphonic acid, 21% active acid	
BRIQUEST® ADPA-60SH	Tetrasodium salt of 1-hydroxyethane-1, 1-diphosphonic acid, free flowing powder, 60% active acid	

\* Available only in the USA

PRODUCT	DESCRIPTION	APPLICATION
<b>POLYMERS</b>		
BRISPERSE® 891*	50% aqueous solution of polymaleic acid	Useful in a variety of anti-scalant and dispersant applications including cooling water, mining, detergents and sugar processing.
<b>CORROSION INHIBITORS</b>		
BRICORR® 288	40% sodium salt solution of a phosphonocarboxylic acid mixture	New generation of environmentally friendly corrosion inhibitor for cooling water systems. Other advantages include stability to oxidizing biocides and scale inhibition properties.
BRICORR® 288B	Ready to use formulation for once through and open recirculating cooling water systems - soft, moderate water conditions	Cooling water treatment - multi functional scale and corrosion inhibitor.
BRICORR® 288C	Ready to use formulation for once through and open - recirculating cooling water systems hard water conditions	Cooling water treatment - high cycled, high hardness conditions.
<b>DESALINATION</b>		
Albrivap & Hagevap	Series of scale inhibitors and antifoams	Desalination chemicals for thermal evaporation processes.
Brinequest 2000*	Scale inhibitor	Desalination applications.

\* Available only in the USA

## Flame Retardants

Rhodia is a leading worldwide manufacturer of phosphorous-based flame retardant chemicals that delay or prevent combustion of materials in textiles, plastics, foams, timber, paper, coatings and adhesives.

The support provided by Rhodia's research and technical teams ensures that the flame retardant range meets both the current and future demands of customers. One of the leading worldwide textile flame retardants is PROBAN®, which is applied to fabrics by textile finishing companies through a license agreement with Rhodia. PROBAN® is used in protective clothing, bedding and furnishings in a wide range of industries.

We also offer the ANTIBLAZE® product line of flame retardants, which includes a series of ammonium polyphosphates, cyclic phosphonate esters and other phosphonates used on a wide range of fabrics and nonwovens containing both natural and synthetic fibers. These products are easily applied to fabric and nonwovens using the most common application methods, including padding, spraying and coating. Properties include binder compatibility, water solubility or insolubility, high efficiency thermal stability, minimal effect on hand and neutral pH. Selected ANTIBLAZE® polyurethane and textile flame retardants also provide innovative solutions to the automotive industry where low fogging performance is required.

The largest range of flame retardants designed for the polyurethane industry for flexible and rigid foam is phosphate esters. Applications in the flexible foam area include soft furnishings and car components. Rigid foams are most commonly used for insulation. A developing range of ANTIBLAZE® products is also available for plastics, coatings and timber.

PRODUCT	DESCRIPTION	APPLICATION
<b>TEXTILE FLAME RETARDANTS</b>		
<b>ANTIBLAZE™ CL</b>	Aqueous solution of ammonium polyphosphate	Non-durable flame retardant for cellulosic fabrics.
<b>ANTIBLAZE™ CU</b>	Cyclic phosphonate ester	
<b>ANTIBLAZE™ CT</b>	Low viscosity modification of <b>ANTIBLAZE™ CU</b>	Durable flame retardant for polyester fabrics. Used in back-coating applications.
<b>ANTIBLAZE™ BQ</b>	Ammonium salts of phosphoric and sulphuric acids	Non-durable flame retardant for cellulosic fabrics. Used in flame retardant paper applications.
<b>ANTIBLAZE™ FSD</b>	Aqueous-based ammonium polyphosphate blend	Non-durable flame retardant for a wide range of fabrics, including blends with high levels of synthetic fibres.
<b>ANTIBLAZE™ LR2</b>	Aqueous solution of polyphosphoric acid salts	Semi-durable flame retardant for cellulosic upholstery fabrics. Meets Furnishing Standard BS EN1021.
<b>ANTIBLAZE™ LR3</b>	Ammonium polyphosphate	
<b>ANTIBLAZE™ LR4</b>	Ammonium polyphosphate of low water solubility	Powder flame retardant used in combination with a binder system. Used in back-coating systems where limited durability is required (e.g. BS EN1021).
<b>ANTIBLAZE™ TR</b>	Aqueous solution of polyphosphoric acid salts	Non-durable flame retardant for cellulosic textiles. Used in flame retardant paper applications.
<b>ANTIBLAZE™ RD1*</b>	Organic phosphonate in aqueous solution	Non-hygroscopic, low-fogging flame retardant for use on a variety of fabrics. Compatible with binders. Non-durable.
<b>ANTIBLAZE® 37*</b>	Organic phosphonate blend	Versatile flame retardant for many fabrics, especially polyester and coatings. Minimal effect on fabric hand. Durable or non-durable, depending on application.
<b>ANTIBLAZE® N*</b>	Cyclic phosphonate ester	Flame retardant for fabrics and latex binder applications. High performance at reduced loadings in many systems.
<b>ANTIBLAZE® NT*</b>	Low viscosity modification of <b>ANTIBLAZE® N</b>	Flame retardant for thermosol application to polyester fabrics.
<b>ANTIBLAZE® NT D-1*</b>	High purity, low color, cyclic, phosphonate ester	Non-durable flame retardant for plastics, synthetics and a wide range of other uses.
<b>ANTIBLAZE® IS*</b>	Chlorinated diphosphate ester	Semi-durable flame retardant for a wide range of fabrics. Can be applied directly or incorporated into binder systems. Low water solubility makes it especially useful for passing leach tests such as BS 5851.
<b>ANTIBLAZE® XL</b>	Organic phosphonate in aqueous solution	Non-hygroscopic, low fogging flame retardant for use on a variety of fabrics. Compatible with binders. Non-durable.
<b>PROBAN® CC</b> <b>PROBAN® ST</b>	Tetrakis(hydroxymethyl) phosphonium chloride based pre-polymer	Cellulosic, cellulosic/polyester blends (durable finish) PROBAN® licensee only.

\* Available only in the USA

PRODUCT	DESCRIPTION	APPLICATION	%P	%Cl
<b>POLYURETHANE FLAME RETARDANTS</b>				
<b>ANTIBLAZE™ DMMP</b>	Dimethyl methylphosphonate	Flame retardant for rigid polyurethane foams.	25.0	0
<b>ANTIBLAZE® N*</b>	Neutral cyclic diphosphonate ester liquid	Flame retardant for all polyether foams where low volatility and high performance is required	21.0	0
<b>ANTIBLAZE™ TDCP</b>	Tris(Dichloropropyl) phosphate	Flame retardant for flexible polyether and polyester foam where hydrolytic stability is critical.	7.2	49.1
<b>ANTIBLAZE™ TDCP LV</b>	Low viscosity version of <b>ANTIBLAZE™ TDCP</b> <b>ANTIBLAZE® 195</b>	Flame redundant for flexible polyurethane foam.	7.4	47.0
<b>ANTIBLAZE™ TMCP</b>	Tris(2-chloropropyl) phosphate liquid	General purpose flame retardant for polyurethane foam including one and two component systems	9.3	33.0
<b>ANTIBLAZE™ 80</b>				
<b>ANTIBLAZE™ V6</b>	Chlorinated diphosphate ester	Flame retardant for polyether, high resilience and moulded foam	10.6	36.0
<b>ANTIBLAZE™ 100</b>				
<b>ANTIBLAZE™ V66</b>	Chlorinated diphosphate ester	Low fogging flame retardant for automotive polyether and moulded polyurethane foams	10.3	32.9
<b>ANTIBLAZE® 78</b>	Chlorinated diphosphonate ester	Flame retardant for rigid polyurethane foam and phenolic based laminates	12.0	34.0
<b>ANTIBLAZE™ V88</b>	Chlorinated diphosphate ester	Flame retardant for polyether, high resilience and moulded foam	10.4	36.1
<b>ANTIBLAZE® 125*</b>	Chlorinated phosphorus ester liquid	Low viscosity flame retardant for bonded flexible urethane foam	11.2	34.0
<b>ANTIBLAZE® 140*</b>	Mixture of chlorinated phosphate & chlorinated phosphonate esters	General purpose flame retardant for all flexible polyether based foams	9.8	39.0
<b>ANTIBLAZE™ 205*</b>	Mixture of alkyl and aryl phosphate esters	Low viscosity, low scorch flame retardant for flexible polyurethane foam	7.6	32.0
<b>ANTIBLAZE® 230*</b>	Mixture of aryl phosphate and phosphonate esters	Low fogging, high efficiency, flame retardant for flexible polyether based foams	13.4	0
<b>ANTIBLAZE™ V280</b>	Chlorinated phosphate ester	Low fogging flame retardant for polyester and polyether foam	7.3	44.2
<b>ANTIBLAZE™ V300</b>	Halogen-phosphate ester mixture	Low viscosity, mixed halogen containing flame redundant for polyether, high resilience rigid and moulded foam	4.7	16.2 (35.4 Br)
<b>ANTIBLAZE™ V490</b>	Organo phosphonate ester	Halogen free system stable flame retardant for rigid polyurethane foams	18.7	0
<b>ANTIBLAZE™ V500</b>	Chlorinated phosphate ester	Low fogging flame retardant for automotive polyether and moulded polyurethane foams	10.4	32.9
<b>ANTIBLAZE™ V610</b>	Mixture of chlorinated diphosphate and chlorinated phosphonate esters	Low viscosity, high efficiency flame retardant for moulded polyurethane foam	11.3	35.0
<b>ANTIBLAZE™ V650</b>	Chlorinated phosphate esters	General purpose flame retardant for polyether high resilience and moulded foams	10.0	34.5
<b>VIRCOL® 82</b>	Neutral phosphorus polyol	Polyol flame retardant for use in rigid polyurethane foam pre-polymers and pre-mixes	11.3	0

\* Available only in the USA

PRODUCT	DESCRIPTION	APPLICATION	%P
<b>PLASTICS ADDITIVES</b>			
<b>ANTIBLAZE™ 1045</b>	Neutral cyclic diphosphate ester	Flame retardant for polyester fibers, extrusions and engineering plastics.	20.8
<b>ANTIBLAZE™ NK</b>	Alkyl amine phosphate salt	Flame retardant chemical filler for polypropylene, other olefins and thermoset applications.	19.6
<b>ANTIBLAZE™ NP</b>	Formulated alkyl amine phosphate salt	Flame retardant chemical filler for polyolefins and EVA co-polymers.	15.7
<b>ANTIBLAZE™ TCP*</b>	Tricresyl phosphate		8.3
<b>ANTIBLAZE® TXP*</b>	Trixylenyl phosphate		7.6
<b>ANTIBLAZE® 519*</b>	Triaryl phosphate ester	Flame retardant fluid/plasticizer used in lubricants, hydraulic fluids, PVC, urea-formaldehyde resins and in elastomers.	8.3
<b>ANTIBLAZE® 521*</b>	Triaryl phosphate ester		8.1
<b>ANTIBLAZE® 524*</b>	Triaryl phosphate ester		7.7
<b>TIMBER</b>			
<b>ANTIBLAZE™ ML</b>	Aqueous solution of ammonium polyphosphate	Integral flame retardant for wood-based panel products.	15.7
<b>ANTIBLAZE™ PI</b>	Ammonium polyphosphate	Powder flame retardant for integral treatment of wood-based panel products.	26.0
<b>COATINGS</b>			
<b>ANTIBLAZE™ MC</b>	Ammonium polyphosphate	For use in intumescent coatings.	30.0

\* Available only in the USA

## Phosphorus Specialties

*The Phosphorus Specialties business works directly with customers on an exclusive basis to develop commercial processes and applications for phosphorus chemicals. Product areas include phosphonate esters (e.g. Horner-Emmons reagents), bisphosphonates, monomeric and polymeric phosphonic acids, phosphorylating agents and derivatives and phosphines and phosphine ligands.*

*We have a fully integrated development program where new processes and products are tested in Rhodia's laboratory, pilot plant and semi-works facilities. We closely manage processes to provide safe operation and timely delivery of products and have a complete hazard evaluation program as an integral part of new product introductions.*

*The business continues to evolve as an increasing number of companies source key intermediates and products from Rhodia. The application areas served by this business include pharmaceutical intermediates and fine chemicals, polymers and plastics, electronics, paints and coatings and other areas related to surface property modification and material science. The product range on the following pages represents a small fraction of more than 50 products in the development pipeline.*

*Our monomer products and their homopolymer and copolymer derivatives continue to attract attention as surface property and performance enhancers.*

PRODUCT	DESCRIPTION	APPLICATION
<b>SURFACE TREATMENT CHEMICALS</b>		
VPA	Vinylphosphonic acid	Surface treatment agent to improve bonding to metals and metal complexing agent.
ALBRITECT® CP30	Copolymeric pretreatment	Surface treatment agent to improve binding to metals.
OPA	Octylphosphonic acid	Metal complexing agent, tin ore flotation aid and surface treatment agent for metals and metal oxides.
ACCOMET® C	Chromium based pretreatment	Dry-in-place metal pretreatment process for coil coating applications.
ALBRITECT® Pre-treatment	Non-chrome pretreatment	Dry-in-place metal pretreatment process for coil coating applications; free from heavy metals.
ALBRITECT® D Series Anti-corrosive Pigments	Non-chrome anticorrosive pigment	Non-toxic anticorrosive pigments effective in general industrial paint systems; lead and chromium free.
ALBRITECT® CC Series	Non-chrome anticorrosive pigment	Anticorrosive pigments. Non-toxic pigments effective in a variety of coil coating primer systems; lead and chromium free.
ALBRITECT® 6835	Ethylene methacrylate phosphate	Adhesion promoter and corrosion inhibitor in coatings and adhesives.
Vicro-Pet® 50	Tan, viscous liquids	Excellent inhibitors for steel, aluminum, mixed alloys, used in wafer-based coatings, antifreeze compounds, cleaners and polishes.

## INTERMEDIATES and REAGENTS

<b>TMP-HP</b>	Trimethyl phosphite (high purity)	Intermediate in manufacturing of phosphonate esters and vinyl phosphates; reagent for dehalogenations, dehydrohalogenations and reductive cyclisations.
<b>TEP-HP</b>	Triethyl phosphite (high purity)	Intermediate in manufacturing of phosphonate esters: reagent for halogenations, dehydrohalogenations and reductive cyclisations.
<b>TIPP-HP</b>	Triisopropyl phosphite (high purity)	Intermediate in manufacturing of phosphonate esters; reagent for dehalogenations, dehydrohalogenations and reductive cyclisation.
<b>TBP-HP</b>	Tributyl phosphite (high purity)	Intermediate in manufacturing of phosphonate esters; reagent for dehalogenations, dehydrohalogenations and reductive cyclisation; scavenging agent for sulphur impurities.
<b>TPP-HP</b>	Triphenyl phosphite (high purity)	Reagent for reductions and peptide coupling. Complexes with halogens and ozone for selective halogenations and oxidations.
<b>DMHP-HP</b>		
<b>DEHP-HP</b>	Diethyl hydrogen phosphite (high purity)	Intermediate in manufacturing of phosphonate esters and chlorophosphates.
<b>DBHP-HP</b>		
<b>DMMP-HP</b>	Dimethyl methylphosphonate (high purity)	Intermediate in manufacturing $\beta$ -Ketophosphonates.
<b>AMPA</b>	Aminomethylphosphonic Acid	Intermediate in manufacturing pharmaceutical intermediates (developmental product).
<b>TMPA</b>	Trimethyl phosphonoacetate	Intermediate in manufacturing of fine chemicals via Horner-Emmons reaction (developmental product).

PRODUCT	DESCRIPTION	APPLICATION
<b>INTERMEDIATES and REAGENTS</b>		
DEMPA	Diethyl methyl phosphonoacetate	Intermediate in manufacturing of fine chemicals via Horner-Emmons reaction (developmental product).
TIPMDP	Tetraisopropyl methylenediphosphonate	Intermediate in manufacturing of bisphosphonate esters, acids and salts; reagent for phosphonate preparation via Horner-Emmons reaction.
TEPA	Triethyl phosphonoacetate	Intermediate in manufacturing of fine chemicals and polyester processing acid.
DECMP	Diethyl cyanomethylphosphonates	Intermediate in manufacturing of substituted nitrile via the Horner-Emmons reaction and their amide and heterocycle derivatives.
TEPF	Triethyl phosphonoformate	Intermediate in manufacturing of phosphonoformic acid and its esters and salts.
PDCP	Phenyl dichlorophosphate	Intermediate in selective manufacturing of phosphoric acid diesters; protective agent for hydroxyl groups.
DPCP	Diphenyl chlorophosphate	Intermediate in selective manufacturing of phosphoric acid monoesters; protective agent for hydroxyl and ketone groups.
<b>PHOSPHINES</b>		
TBPinE	Tributylphosphine	Intermediate for phase transfer catalysts, biocides and Wittig reactions; (phosphine oxide by-product is water soluble).
TPPInE	Triphenylphosphine	Intermediate for phase transfer catalysts and Wittig reactions, ligand for hydroformylation catalysts.
TOTPinE	Tri-o-Tolylphosphine	Phosphine ligand for hydroformylation catalysts, used in Heck and Mitsunobu reactions.
dippe	1,2-Bis (Diphenylphosphino) ethane	Bidentate phosphine ligand used with transition metals to provide catalysts for carbonylations, hydroformylations and organic synthesis.
dppp	1,3-Bis (Diphenylphosphino) propane	
dppb	1,4-Bis (Diphenylphosphino) butane	
dppf	1,1-Bis (Diphenylphosphono) ferrocene

Welcome to Rhodia's Phosphorus and Performance Derivatives Customer Service Page.  
Here you will find contacts designed to help you locate the right resources  
where ever you are in the world.

Rhodia also produces a wide range of solutions for the beauty, clothing,  
foodstuffs and healthcare markets in addition to transport, industry and the environment.  
To learn more about all the products we produce, have a look at the Rhodia website.

# Why buy from Shell Chemicals?

- Multi Site Solvent Manufacture
- Product Quality
- European / Global Specification
- Local Storage
- Security of supply
- Franchised Distributor Network
- R & D facilities : Amsterdam and West Hollow
- On-going Investment
- ISO certification
- Customer Logistics Charter
- Global Website

Shell Chemicals

# Mining Solvents

<u>Application</u>	<u>Shell Solvents</u>
Solvent Extraction	<b>Shellsol 2325</b> <b>Shellsol 2046</b> <b>Shellsol D70</b> <b>Shellsol A150</b> <b>Shellsol D80</b>
Frothing	<b>MIBC</b> <b>HG</b> <b>Shellfroth 10</b> <b>DPM</b> <b>BTTO (bottom from EO glycol ethers)</b> <b>PEG</b> <b>MTTO (bottom PO glycol ether with &gt; MTP)</b>
Coal Flotation	<b>Shellsol 2323</b> <b>Shellsol 2046</b> <b>MTTO (pour point depressant wet coal flow)</b>
Tar Sands Flotation	<b>MIBC</b>
